During the postoperative care of surgical diseases of the kidneys the use of the indwelling ureteral catheter should be a part of the treatment, mainly to prevent fistula or urinary stasis that may lead to infection or to delay the healing of the wound. It also secures perfect drainage by kidney pelvic lavage for the purpose of clearing up infection. Many authors have reported striking results in treating "renal colic" or calculous anuria with a fixed ureteral catheter combined with the use of forced fluids and intravenous in-

they have grown too large to pass through even with the aid of the indwelling ureteral catheter or by cystoscopic manipulations

The etiological study of the formation of urinary calculi is as ancient as the history of medicine and still remains much in the dark notwithstanding the many theories advanced, plus the vast experimental work that has been done recently on animals. But with the new methods of diagnosis at our disposal in modern urology we have come to the conclusion that in the great majority of cases infection plus lack of normal drainage due to pathological conditions of the excretory upper urinary system, has been the chief etiological factor not only of urinary stasis but in many instances of formation of a nucleus for veritable urinary calculi. As a rule outside of the silent stone in the kidney parenchyma infection is always present and plays a definite role. Therefore the securing of drainage will remain as the paramount and most essential of all treatments, as it is to a sound prognosis.

Many of the so called cases of pyelitis and pyelonephritis, with obscure abdominal symptoms and gastro intestinal disturbances characterized perhaps by only microscopic hematuria or a few pus cells in the urine, have proved to be the result of infection in the kidney pelvis, due mainly to retention of urine or faulty elimination, and it has been our experience to see a great number of these cases in our clinic in which the infection, diminution in function, and the positive culture for many micro-organisms have cleared up by means of routine treatment of dilatation of the ureters and kidney pelvic lavage, or the so called indwelling or fixed ureteral catheter, which serves to obtain perfect drainage.

Indeed, the future in urological surgery rests definitely on the correction of infection and the maintenance of function.

In this last decade the continued progress in modern urological diagnosis has secured a new method of examination, which has made it possible to predict the prognosis in certain cases when controlled by pyeloscopy studies. The Necker school has emphasized its value in detecting through the fluoroscopic screen, the physiological contractions and movements in the filling and emptying of the kidney pelvis,

Fig 6. This picture shows the combined use of roentgenography opaque X-ray ureteral catheter and pyelography in relation to diagnosis of anomalies in the upper urinary tract. It illustrates beautifully a fused kidney which lies in the right side of the lower abdomen and which without this method of examination could easily be confused with an abdominal tumor.

obtaining thus a vivid view of the elimination time of the urine from the kidney, as it has been for years known in regard to the fluoroscopic study of the gastro intestinal tract.

The normal kidney pelvis injected through the catheterized ureter with the opaque medium of sodium iodide, empties its contents, physiologically speaking in from 5 to 7 minutes, and whenever its contraction in emptying is slow or retarded, urinary stagnation with tendency to develop infection, or hydro-nephrosis or pyohydronephrosis is consequently in many instances, a common occurrence. Lack of normal drainage or retention in the kidney pelvis may be detected by pyeloscopy, this condition can also be detected by taking a third or fourth plate or roentgenograms in series 10 minutes after the pyelogram and ureterogram are made. This method will serve to reveal much unknown and overlooked kidney pathology and will demonstrate at the same time that the placing

Fig 4 X ray picture showing the value of the indwelling ureteral catheter as a means of diagnosis demonstrating that the two shadows in the ureter correspond with the shadow of the catheter

The catheter should be left in place for one hour or one day, indefinitely but the average time is from 3 to 7 days if required. It is essential that irrigation be done at least three times daily with a mild antiseptic solution in order to prevent the blockage of the catheter with blood or pus to reduce the kidney infection and to maintain a perfect drainage.

Albarran devised a special kind of ureteral catheter, tunnel type in form with an open end to be used as an indwelling catheter, so that later, when it becomes soft and does not serve the purpose of securing drainage, a long thin catheter attached to a bougie (as an urethral filiform is attached to the tip of a sound) could be passed through it and left in its place removing the first one without submitting the patient to further cystoscopy. But, in these days, it is not commonly used due perhaps to the diversified improved cystoscopes which facilitate painless procedure.

The contra indications to an indwelling ureteral catheter are the same as those to cystoscopy. The urethra must be permeable and without actual acute or chronic infection or veritable discharge. The catheter should be removed or replaced in certain instances when

Fig 5 X ray picture of the same case showing beneficial results of the indwelling ureteral catheter which served to dilate the ureter and facilitated the passage of the stone

necessary but it should be definitely taken out when it causes discomfort or pain to the patient and in cases of chill or high temperature.

It is well to remark that there is no definite rule governing the principle of the indwelling ureteral catheter because each case is a law unto itself and clinically or surgically should be treated according to its own requirements. Not long since ureterotomy for stone was a common operation in urinary surgery, but in these days it has become rather rare in view of the fact that 90 per cent of all small and medium sized stones of the ureter and kidney pelvis diagnosed are passed by means of an indwelling ureteral catheter or by dilatation with bougies of ureteral cystoscopic manipulations.

It is wise at this time to emphasize the principles relating to the formation and reformation of stone in the urinary tract because the lastly believed for a time that urinary calculi are dissolved by internal medication and passed out. This theory should by no means be considered because stones in the urinary tract whenever found, are eliminated only by spontaneous passage at micturition when they do not encounter any mechanical obstruction, or by removal at operation when

Fig. 8 This case illustrates the value of the ureterogram for detecting pathological anomalies of the ureter. With the patient in the erect posture the catheter is withdrawn and at the same time the sodium iodide is injected. This case shows a double kidney pelvis and a double ureter with the ureters united before reaching the bladder and therefore showing cystoscopically a normal bladder with normal ureteral orifices. This condition could not be detected without this routine examination.

obtaining satisfactory results in the treatment of such cases when there is an infection and lack of proper drainage.

CASE 2 Use of the indwelling ureteral catheter during nephrectomy for calculous pyohydronephrosis.

Miss L. D., 18 years old, born in Scotland, came to the female clinic of the Urological Department of the New York Hospital on December 23, 1928, complaining of pain in the right kidney region of over 1 year's duration. She suffered from frequency of urination and nocturia four to five times and pyuria and dysuria. Her previous history was irrelevant. Menstruation started at the age of 12 and was always regular. The symptoms and urinary complaint were getting worse and produced fatigue and constant pain in the right lumbar region radiating along the ureter down to the right quadrant. The patient was cystoscoped and the bladder mucosa throughout was found to be slightly congested but otherwise of

Fig. 9 Case 2. Pyelo ureterogram showing a rectangular calculus blocking the injection of the opaque medium at the ureteral pelvic junction. On the left side three distinct extra urinary shadows due to calcified lymph nodes.

normal appearance. On catheterization of the ureters specimens were collected from the left side and none was obtained from the right. The functional tests showed that the left kidney was within normal limits. There was secreted urea 15 grams per liter and the time of appearance of the dye after the phenolsulphonephthalein injection was 3 minutes with 10 per cent concentration. The culture was negative but the culture of the urine from the bladder showed *bacillus coli communis*. The patient returned a week later when another cystoscopy was performed and a specimen was sent to the laboratory for a guinea pig inoculation. Also plain pictures and a right pyelogram were taken revealing a rectangular shadow, apparently in the pelvis of the right kidney at the point of the ureteropelvic junction, therefore blocking the normal drainage of the organ. The left kidney shadow was normal in size and in good position and there could be seen three small round shadows apparently in the contour of the left kidney, but extra urinary and therefore probably calcified lymph nodes. The right pyelogram showed almost a complete blockage of the right pelvis by the stone so that none of the sodium iodide entered the pelvis but ran down the right ureter which is apparently within normal limits. The impression gained was that of a rectangular stone in the right kidney pelvis and it was suggested that the stone be removed under regional anesthesia. The patient entered

Fig 7 Bilateral double kidney and double ureter diagnosed cystoscopically roentgenographically and pyelographically showing kink in the ureter and urinary stasis plus infection which was successfully treated with indwelling ureteral catheter (Kirwin's case)

of the fixed catheter is of great practical value, because it serves to secure drainage from the kidney pelvis of the retained sodium iodide and will prevent the reactions after pyelography such as kidney pain and more or less discomfort until the medium is absorbed or eliminated.

The indwelling catheter after pyelography is therefore highly desirable because it will serve to permit the suction of the opaque medium also lavage of the kidney pelvis thereby relieving pain and maintaining perfect drainage.

I shall describe a few cases which I have had the good fortune to encounter in my own practice and which will serve to illustrate the routine procedure used in the three groups described in the three accompanying tables wherein is briefly explained the incidence of the value and use of the indwelling ureteral catheter.

CASE 1 Value of indwelling ureteral catheter in the diagnosis and treatment of infected horseshoe kidney.

D. S. male 18 years old poorly nourished appeared acutely ill very pale feeble with a blood

pressure of 108-60. He had been sick in bed for the last 2 months before he was brought into The New York Hospital. He consulted me on October 15, 1928 complaining of pain across the lower back with dysuria marked pyuria nausea vomiting headache and high temperature. The family history and the past personal history are irrelevant except that he had an attack of malaria 9 years previously and had been suffering with chronic constipation all his life. He had for many years he had pain in the back particularly radiating to both lumbar regions. Slight frequency of urination both during the day and at night had persisted for many years and was more troublesome whenever he caught cold. On arrival at the hospital cystoscopy was done with a functional renal test and a pyelogram of the right side revealing the presence of a horseshoe kidney with pyelitis and pyelonephritic infection. The ureteral catheters were inserted into the kidney pelvis in order to secure drainage and for the purpose of irrigation. The patient was put on forced fluids having as medication methylene blue and quinine sulphate three times daily internally. Also 1000 cubic centimeters of saline intravenous infusion was administered daily and high colonic irrigation was also instituted. The patient's temperature ran from 101 to 103 degrees for 7 days although his general condition was much improved and he was able to take food and to eliminate large quantities of urine. His blood chemistry was higher than normal and the Wassermann test was negative. On the eighth day another cystoscopy was performed when a pyelogram of the left side was made showing the calyces of the kidney pelvis also pointing inwardly and therefore proving the presence of a fused horseshoe kidney. A slight degree of hydronephrosis with lack of drainage and infection was also detected. The catheters were reinserted and left fixed in place. The sodium iodide was suctioned and the kidney pelvis irrigated with plain distilled water. This was followed with an irrigation of the kidney pelvis with a solution of acriflavine 1 to 1000. The patient gradually improved the temperature came down to normal and he left the hospital on November 1, 1928 with the diagnosis of infected horseshoe kidney for which he was advised to return for further treatment consisting of dilatation of the ureters and kidney pelvic lavage. This treatment has been carried out at intervals of 2 weeks on several occasions and this patient at the present time is free from symptoms and his urine is clear. He is generally improved has gained in weight and has resumed his occupation. However the patient has been advised that if this pathological condition of the kidney persists in troubling him it will be necessary to consider a symphysiotomy operation in order to separate the fusion of the kidney parenchyma from its isthmus.

This case shows the value of an indwelling ureteral catheter both in regard to diagnosis when combined with pyelography and in

Fig 11 Case 3 Bilateral renal lithiasis showing the opaque ureteral catheter in contact with the renal calculi

examination was again made. The specimen obtained from right ureter was clear and showed 10 grams of urea per liter while specimen obtained from the left side was cloudy and showed 4.5 grams of urea per liter. One cubic centimeter of phenolsulphonephthalein injected intravenously appeared on right side in 4 minutes and on left side in 4.5 minutes. The phenolsulphonephthalein test showed secretion on the right side 8 per cent in 10 minutes and 2 per cent on the left side. Microscopical examination of the urine from the left kidney showed it to be loaded with pus cells. However her general condition was much improved the patient had gained 22 pounds in weight and as her kidney function and blood chemistry were better it was suggested that the stone that occupied the complete left pelvis be removed by *nephrotomy*.

The patient was re-admitted to the hospital on March 18, 1929 and under paravertebral anesthesia *nephrotomy* was performed and the large stone from the left kidney was removed successfully. During the operation the kidney was found to be quite large it contained pus but the parenchyma still appeared to be in good condition and therefore sufficient to maintain satisfactory function. The patient had an uneventful recovery and left the hospital 16 days after operation with a small lumbar sinus but in very good condition.

It is of interest to remark in this case how, by simple cystoscopic treatments with cath-

Fig 12 Case 3 Actual size of the two kidney stones removed at operation

terization of the ureters and kidney pelvic lavage, and the method of the indwelling catheter, this patient steadily improved, and notwithstanding the urinary complaints and infection caused by the stones in the kidney pelvis her general health improved with this treatment and thus we could perform successfully the two operations for the removal of the offending stones. The first operation was done by me March 23, 1928, and the second one was done by Dr. Lowsley, one year later in March 1929. The two operations *pyelotomy* and *nephrotomy* were carried out in order to remove the bilateral kidney stone, paravertebral anesthesia being used under which the patient did exceedingly well. She made a complete recovery.

CASE 4 Value of fixed ureteral catheter after *nephrectomy* for renal tuberculosis in an attempt to aid the healing of the lumbar wound

Fig 10 Case 2 Drawing of specimen removed at operation showing the rectangular calculus which had blocked the normal drainage of the kidney and produced the distortion of the whole organ ending in the formation of pyohydronephrosis

the hospital on February 17 1929. In this case the patient was cystoscoped before the operation the right ureter being catheterized with a No 6 French catheter which was left fixed *in situ* during the operation with the purpose of facilitating the surgical procedure and readily exposing the ureter. At the operation when the kidney was exposed it was found to be a shell or a definite pyohydronephrosis with complete distortion of the whole kidney parenchyma and was functionless. Therefore nephrectomy was performed. After a most satisfactory surgical exposure the catheter was pulled out by an assistant and then the ureter was clamped cut and tied in the usual manner. The kidney was removed the pedicle was tied and the wound was closed with small cigarette drainage. Patient made an uneventful recovery and returned home in weeks with the nephrectomized wound closed and practically free from urinary symptoms.

CASE 3 Bilateral renal lithiasis. Right pyelotomy, and one year later nephrotomy for removal of the calculi. Uneventful recovery. The value of the

indwelling catheters in this case is correcting infection and securing drainage.

S A an Italian woman 50 years of age came into the female clinic of the Department of Urology of the New York Hospital March 23 1928 complaining of pain in the right upper quadrant for the past 2 1/2 years with slight frequency of urination and marked nocturia. Urinalysis showed considerable pus. The patient was submitted to complete urological examination. On cystoscopy examination the bladder was found to be very much congested throughout both ureters were catheterized and the functional test was quite diminished on both sides. An X ray picture was taken with the catheters and the instrument fixed in position and showed two enormous shadows in the area of both kidney regions. Therefore a diagnosis of bilateral nephrolithiasis was made. The right kidney having much better function than the left the patient was admitted to the hospital and pyelotomy for removal of the stone on the right side was done. The patient had an uneventful convalescence and the lumbar wound was firmly healed. But on the seventh day of the operation she developed pain on the side of the operation and it was easy to palpate a fairly big distended right kidney. She was running a temperature from normal up to 102 degrees. The patient was then cystoscoped and on catheterization of the right ureter a considerable amount of thick green pus was obtained. The catheter was left in place and the kidney pelvis was irrigated with acidifurine 1:1000 several times. The catheter was removed in 48 hours and the patient was submitted to another cystoscopy 3 days later when much purulent urine was still suctioned from the kidney pelvis. The catheter was left in place for several hours in order to secure drainage and to irrigate the kidney pelvis. The patient's temperature came down to normal and she left the hospital on April 13 1928 when I advised her to return to the clinic where she received weekly cystoscopic treatments with kidney pelvis lavage for several months. The infection subsided and she was sent to the country in order to build up resistance for the second operation. Six months later upon her return her general condition was greatly improved but she was still suffering with a dull pain in both kidney regions and frequency of urination. Cystoscopy and renal tests were made again showing that functional tests in regard to urea secretion and time of appearance of the phenol sulphonephthalein were very much improved. A summary of the past history of the case is of interest and shows that on October 31 1928 the phenol sulphonephthalein test showed secretion 0.05 per cent in 10 minutes on the right side and 3 per cent on the left side. Cultures from right and left ureters showed bacillus coli communis. An X ray of the genito-urinary tract taken on February 13 1929 showed the left kidney shadow to be large in size and in fair position and the entire pelvis was filled with calculi. On March 6 1929 the kidney function was still markedly diminished. A cystoscopic

Fig 15 Case 5 Plain X ray plate showing the value of the ureteral catheter in diagnosis when the shadow of the stone in the ureter corresponds with the shadow of the catheter

Fig 16 Case 5 Picture shows the Kretschmer double exposure to determine that the shadow of the urinary calculus corresponds with the shadow of the catheter

P T an Italian woman aged 55 years married was admitted to the medical ward of the New York Hospital on June 13 1928. The diagnosis was acute pyelitis nephrolithiasis and diabetes mellitus. The patient was submitted to numerous cystoscopic examinations that apparently relieved her condition and she was readmitted to the medical ward a few days later complaining of pain in the right lower quadrant accompanied with chills and bladder symptoms with marked pyuria and frequency of urination. The interesting feature in this case is that while she had the first cystoscopic examination and pyelogram made the diagnosis of stone at the ureteropelvic junction was made and this patient was submitted to further cystoscopic treatments for dilatations of the ureter and kidney pelvis lavage for the purpose of allowing the passage of the stone and to correct infection. In subsequent examinations the shadow of the stone in the X ray plates was found to be at the ureteropelvic junction apparently impacted in that portion of the ureter and being the cause of the retention which produced the presence of acute infection in the right kidney. A plain X ray picture with the catheter in position and with the Kretschmer double exposure showed a definite shadow of urinary calculi in the upper portion of the right ureter just above the transverse process of the

third lumbar vertebra. This point was beautifully corroborated by the filling defect at that point in the pyelogram. As the patient was submitted to numerous cystoscopic treatments and kidney pelvic lavage in the genito urinary clinic of the New York Hospital and did not pass the stone but developed high fever tender kidney and acute renal condition operation for the removal of the stone was advised. The patient entered the hospital and ureterotomy for the removal of an impacted stone of the right ureter was performed on December 14 1928 under paravertebral anesthesia. Before the operation the patient was put in the lithotomy position on the table and cystoscoped without difficulty. A large No 7 ureteral catheter was passed up to the pelvis of the right kidney and allowed to remain. The cystoscope was then withdrawn and the patient was put on the table in the usual position for a kidney operation. It was striking to find during the operation that the catheterized ureter was readily exposed and that there was not any urinary calculus found in this catheterized ureter. Then search for an extra anomalous ureter was made and a super numerary ureter containing an impacted stone was found. This anomalous ureter ran from the upper portion of the pelvis of the kidney down about one half the way to the bladder uniting with the ureter

Fig. 13 Case 4 Right pyelogram of a tuberculous kidney showing a completely distorted and functionless organ

S L History No 157480 an Italian woman 45 years of age, married came to the female clinic of the urological department of the New York Hospital on August 2 1928, complaining of pain in the right lumbar region intermittent hematuria for 1½ years. She suffered from marked pyuria with pain and burning at urination also frequently during the day and at night as often as every half hour during the day and several times at night. Patient was submitted to complete urological examination. On cystoscopy a definite ulcer involving the mouth of the right ureteral orifice was detected. As the patient had a very poor bladder capacity and complained of pain catheterization of the ureters was not made. She was submitted to bladder lavage and methylene blue was given. Two weeks later another cystoscopy was done with catheterization of both ureters. This examination showed that the left kidney had good function and that from the right side no specimen of urine could be obtained. Even after injecting a few cubic centimeters of water no dye was eliminated. Pyelogram of the right side was taken showing a greatly excavated kidney giving the impression of a tuberculous pyonephrosis. The patient was submitted to the hospital for operation September 13 1928 and a right nephrectomy was performed under paravertebral anesthesia. The patient left the hospital October 22 1928 with a small lumbar sinus which discharged purulent urine for which she was treated, in the anti tuberculous clinic with anti

Fig. 14 Case 4 Pyelogram taken of the kidney specimen removed at operation showing complete distortion of the organ with very little parenchyma remaining verifying the diagnosis of kidney tuberculosis

tuberculin and light treatment. She also had a few cystoscopic treatments with irrigations of the stump ureter with a solution of rivanol dextrose 1:1000 and on several occasions the ureteral catheter was left fixed in place to secure drainage and to allow the lumbar wound to heal. Also the ulcer seen at the mouth of the ureteral orifice was fulgurated with an electrode on two different occasions. The patient's wound healed up entirely as well as the tuberculous ulcer of the bladder and she made a complete recovery. Six months after the operation the patient had gained over 60 pounds in weight and her general condition was excellent and she was entirely free from urinary symptoms.

In this case the fixed catheter aided in the healing of the wound securing drainage, relieving infection and hastening the complete closure of the wound thus effecting a permanent cure.

CASE 5 Ureterotomy for impacted stone in an anomalous ureter. Value of the indwelling ureteral catheter during operation to corroborate diagnosis to discover anomalies encountered at operation and to facilitate safe surgical procedure. Case of double ureter containing stone where urography did not reveal the condition found at operation.

results, for instance Watson and Cunningham, in an analysis of 205 cases of calculous anuria, in which a group of 110 such cases were treated expectantly, reported deaths in 80 cases, a mortality of 72.7 per cent, and in an other group of 95 cases, treated operatively, reported deaths in only 44 cases, a mortality rate of 46.3 per cent. Therefore, while many of these cases could have been treated satisfactorily with the method of the indwelling catheter as recently emphasized by Marion and Heitz Boyer, Papin, Beer, Eisendrath, and other writers, at the same time one should not wait too long because if relief from symptoms is not obtained in a reasonable length of time, surgical intervention in the operation of choice. In other words, the indwelling ureteral catheter is not a panacea for all pathological conditions of the upper urinary tract. Nor should operative intervention, when required, be delayed. Moreover, it is obvious that the diagnosis must be accurate and definitely clear, because besides a few contra indications this method should not be used in cases of extrarenal or intrarenal conditions of the kidney when the pathological process has become well advanced or does not communicate with the excretory apparatus of the organ, as in the case of perinephritic abscess, cortical abscess of the kidney, or well advanced renal tuberculosis or hypernephroma of the kidney, when surgical relief must remain as the most imperative hope of cure.

CONCLUSIONS

1 The indwelling ureteral catheter is of value in urinary surgery, not only in regard to diagnosis and treatment but as a convenience during and after operation.

2 The empiric classification of the three groups in the three accompanying tables is made only for the purpose of popularizing a practical procedure, which deserves a wide application.

3 The catheter to be used is preferably a No. 6, No. 7, or No. 8. It should be an X-ray catheter because this type is more durable, more flexible and produces less discomfort.

4 It is essential that the catheter must serve its purpose, that is secure drainage, relieve pain and correct infection.

5 The fixed catheter should be irrigated at least three times daily, with a mild antiseptic solution as boric acid or acriflavine 1:10,000. Also, in certain cases, when possible, two catheters in the same ureter and continuous irrigation may be definitely indicated.

6 The catheter should be left fixed in place for a period of days or even weeks, until symptoms are relieved or as long as necessary.

7 In leaving the indwelling ureteral catheter *in situ*, in certain cases in which there is marked infection of the bladder or in which the bladder does not empty properly, it will be advisable to use a retentive urethral rubber catheter with the double purpose of securing drainage of the infected urine, indefinitely, both from the kidney pelvis and from the bladder. When this double drainage is required, the urethral catheter should be easily passed, it being inserted through the only ureteral catheter.

8 During operation, the fixed ureteral catheter is the best guide to the surgeon. It affords ready exposure of the ureter and facilitates any surgical procedure upon the kidney pedicle.

9 The most striking results are obtained with this method of treatment in "renal colic," ureteral calculi, pyelitis and pyelonephritis, the so called idiopathic hæmaturia, urinary stasis with or without infection, and in calculous anuria. Also in certain instances when elimination of urine is insufficient, forced fluid and daily intravenous infusion are highly desirable.

10 After operation, it will serve to secure drainage and prompt healing of the wound, without leakage of urine or the formation of permanent fistula.

11 Also, after operation, it will serve, too, to divert the urine from the bladder, particularly in operations on vesicovaginal fistulae, thus permitting the bladder to heal without infection from the urine.

12 The technique of the indwelling ureteral catheter is merely that of cystoscopy and catheterization of the ureters and to accomplish it, it does not require more than a working knowledge of these methods by the urologist.

Fig. 17 Case 5. Pyelogram showing a filling defect at the ureteropelvic junction or upper portion of the ureter where the shadow of the calculus was seen in the plain picture. In this case the ureterogram was not taken, thus failing to reveal the anomaly of an extra ureter containing the calculus which was discovered at operation while having the ureteral catheter fixed in place.

which was previously catheterized about the middle of the iliac vessels. The indwelling ureteral catheter during operation proved to be of great assistance in detecting this anomalous condition of the ureter, not revealed by the pyelo ureterogram, and it facilitates the surgical procedure in a most satisfactory manner.

The ureter was incised and the stone was removed in the usual manner, the lumbar wound being closed in layers. The patient had an uneventful recovery. The wound healed by primary intention and the patient left the hospital in 14 days in excellent condition.

SUMMARY

The indwelling ureteral catheter is the most valuable adjunct in urological surgery. Its clinical results obtained in selected cases are most gratifying, but always of paramount importance is correct diagnosis before establishing the proper treatment, because it is obvious that no treatment will ever be adequate if the clinical entity has not been recognized.

In acute clinical conditions, likewise in calculus anuria, if the indwelling ureteral catheter

Fig. 18. Technique of operation in Case 5 showing the value of the indwelling ureteral catheter during operation. The catheterized ureter is readily identified but no stone was found in the ureter and on further dissection an extra ureter was discovered containing the impacted stone which was successfully removed by ureterotomy. The two test ureters united before they reached the bladder and urography did not reveal the condition. This pre-operative procedure of fixing the ureteral catheter *in situ* has proved to be most helpful and satisfactory.

ter fails to relieve the alarming symptoms, surgical intervention should not be delayed (Case 5). The life of our patients could be saved by any operative procedure upon the kidney or ureter in an attempt to remove the obstructing calculus and to secure urinary drainage.

One of the most common incidents in the pathology of nephrolithiasis or ureterolithiasis is the calculus anuria or suppression of urine toward the formation of uronephrosis and fatal uræmia, and the statistics have shown evidence of the gravity of this condition. It has been proved also by many authors that the early operative intervention gives better

CLINICAL SURGERY

FROM THE SURGICAL CLINIC OF ST VINCENT'S HOSPITAL, MELBOURNE

ABDOMINAL TECHNIQUE—A SYSTEM OF OPERATIVE EXPOSURES

H B DEVINE, M.S. (MELB) F.A.C.S. F.C.S. MELBOURNE AUSTRALIA
Stewart Lecturer in Surgery University of Melbourne Hon Surgeon to In patients St Vincent's Hospital

ADEQUATE exposure is the great secret of success in the performance of abdominal operations. It should be such that the surgeon is able to dissect or carry out any manipulations in the particular operation field under perfect sight that he is undisturbed and unhampered by the neighboring viscera, and that the organ or organs on which he is operating are, as far as possible under normal physiological conditions.

It is, of course, a common and traditional practice during the progress of an operation on an organ, to drag it out of the abdominal cavity such a procedure does not constitute a truly scientific exposure. The proper way is to isolate, expose, and operate on the organ while it is *in situ*, that is, while it is in the abdominal cavity where it is naturally kept warm and moist. In these circumstances there is no necessity to handle bowel or to drag on mesenteries both of which are richly supplied with shock susceptible splanchnic nerves. It is perhaps not sufficiently realized what a big factor unnecessary interference with physiological conditions during an operation is in producing shock and inducing inhibition of the movements of the alimentary canal. This has often been signally apparent to us when operating on the abdomen under local anaesthesia. It has been remarkable to see the distinct change in the patient's general condition if much visceral dragging or handling becomes necessary although no pain is produced. On the other hand, while manipulations on a poorly anesthetized abdominal wall give rise to pain they have almost a good effect on the patient's general condition.

Many years ago having these basic considerations in mind we evolved a system of abdominal technique the exordium of which was woven round a rather crude mechanical retractor, designed so that these and other desired principles in abdominal technique might be carried out. It was originally an expedient to render possible certain extremely difficult practically impossible,

secondary gastric and gall bladder operations. This clean, definite, standardized method of operating gradually forced itself by its very potentiality and usefulness into our technique in other abdominal fields. We soon found that it made abdominal operating easier and quicker, so that if it did nothing else it minimized anaesthesia and lessened shock to the patient. Also it saved strain and conserved the energy of the operator.

The keystone of the technique is a gentle, evenly distributed, unvarying protecting instrumental retraction and control of the abdominal wound and wall. Principles concerned in this technique and attained by and embodied in the use of this retractor are:

- 1 Effective wound protection from trauma and infection.
- 2 Control of the anterior abdominal wall, so that it can be lifted away from the viscera, thus creating a space for (a) operative manipulation (b) exploration, (c) the easy replacement of intestines and (d) the toilet of the peritoneum of the anterior abdominal wall.
- 3 Isolation of the organ to be operated on by complete instrumental exclusion of the intestines from the area of operation.
- 4 Systematic 'guy rope' anchoring of hollow viscera to the frame enabling gastric or intestinal suturing to be carried out against constant tension with great precision, exactitude, and neatness.

5 A ratchet "spreader" action enabling the retractor to be used for the surgical approach to the kidney, lung, bladder, etc.

We soon found that an extraordinarily light anaesthesia was possible because the anterior abdominal parietes were not constantly being handled, and because once the retractor and its 'mechanical hands' were "set," great relaxation was not a consideration.

Difficulties in suturing the abdominal wound also disappeared probably because the light but

Fig. 2 Retractor set for a pelvic operation. The incision is in the lower part of the abdominal wall. The edges of the wound are covered with rough glove rubber. Mechanical hands 5 and 6 with a soft scarf acting as a buffer keep the intestines well out of the wound and well up into the abdominal cavity. The pelvis is empty except for the rectum, uterus, and its adnexa. Section of a single hook to show how it jams and fixes the mechanical hands.

inches (Fig. 2) are laid over the wound so that they overlap its edges well. The frame is laid on these and if the wound is in the upper part of the abdominal wall (Fig. 3) the left forefinger is placed on the towels at the lower angle of the incision where they are tucked well under the cut edge of the abdominal wall. Retractor 1 is now substituted for the finger and is held up by the left hand of the assistant so as to elevate the abdominal wall until it is clear of the viscera and thus enable the operator with his left hand at C to tuck the towel at this point well under the peritoneum and unhampered by intestines to insert retractor 2 and lock it on the frame. The assistant using his right hand pulls the frame

toward him and keeps it on tension at the point C so that omentum or intestines cannot get under retractor 2. He still retains the upward tension on retractor 1. This facilitates the insertion and the locking of retractor 3. Retractor 1 is now locked. The assistant with his hands at E and G now lifts the frame enabling the towels to be easily turned under the peritoneum in the upper wound angle and permitting the insertion and locking of retractor 4.

The wound now should be open to its fullest extent under slight tension only and the wound edges, including peritoneum, should be neatly covered so that there should be no fear of disarrangement, damage, or infection (Fig. 3).

Fig. 1. Four bladed abdominal retractor 1 and two slotted L pieces which dovetail into each other 3 sliding bar which moves on 1 and 2 by ratchet action 1 B and 2 double hooks for retractors 1 C H J K and O single hooks for attaching mechanical hands. All these lock the retractors and mechanical hands by a jamming action on the frame because they work on a series of inclined planes.

continuous pressure of the retractor fatigued the abdominal muscles.

The results, both immediate and remote were exceedingly good for this method of operating demanded and developed a special type of desirable operative skill, that is, accurate detailed dry dissections under good vision with long very sharp instruments—really an ideal technique.

That this meticulous and precise method was justified was demonstrated by observations in any secondary operations after this technique. These revealed a remarkable absence of adhesions and some abdomens looked as if they had never been opened before. Since the adoption of this technique, wound infection has been almost unknown to us. Perhaps the most noticeable thing certainly from the patient's point of view is the placid postoperative course, the absence of any definite "after treatment" period. Indeed, the sisters have often volunteered the information that the patients operated on in this way may be distinguished by the remarkably little after treatment they need. We have often demonstrated that, intelligently used, the retractor never in the least degree traumatizes the wound.

In the light of the foregoing it is difficult for us to understand why some surgeons still have a prejudice against the use of proper instrumental retraction, why they prefer to draw the viscera

out of the abdominal cavity where they are kept warm and moist and why they should really make difficulties as for instance, by operating in an area which is inadequately lighted because their own and their assistant's hands are in the light, and because the crowding in of the intestines and of the wound edges prevents the access of natural light to the part.

THE RETRACTOR

The retractor has been redesigned in the light of ten years' experience, and is here illustrated for the first time, Figure 1. It consists of two slotted L pieces 1 and 2 which dovetail into each other a sliding bar, 3 which moves on 1 and 2 by a ratchet action, four retractors (1, 2, 3 and 4 Fig. 2) for clasping the abdominal wound a system of mechanical hands (5, 6, 7, 8, and 9 Figs. 2 and 3 with detachable blades of different shapes and angles Fig. 4).

The instrument is so designed that there are no screws yet the retractors and 'mechanical hands' by a jamming action remain firmly on the frame in whatever position they are placed. This is accomplished by a system of inclined planes incorporated in the frame and in the single hooks (H, K, L, O L) and double hooks (B, Q, V, F) in Figure 2 and in the retractor and handles of the 'mechanical hands'.

When the 'mechanical hands' are inserted it is particularly necessary to note that they are always at first loosely fixed on the single hook at C (Fig. 5) or a point corresponding to it, that is with the handle at right angles and near the center of the bar. A firm lateral movement to L₁ (Fig. 5) will now tighten and jam the 'hand' as the side L₁-L₂ is longer than the side C₁-C₂.

Except for the frame and 'mechanical hands', the retractors used belong as a rule to the armamentarium of any surgeon.

'SETTING THE OPERATION FIELD

The field of operation should be set deliberately as a stage of the operation. It is better to make a somewhat smaller incision than usual in order to get the spring like action of the muscle. It is this that really retains the retractor firmly in position and gives the frame its lifting purchase on the abdominal wall. If this lifting purchase is intelligently cultivated and used it becomes extraordinarily useful in abdominal operating.

If there are no adhesions to the abdominal wall as a first step the retractor should be introduced and fixed as follows:

Two very thick towels or two specially made sheets of rough glove rubber 15 inches by 12

Fig. 2 Retractor set for a pelvic operation. The incision is in the lower part of the abdominal wall. The edges of the wound are covered with rough glove rubber. Mechanical hands 3 and 4 with a soft scarf acting as a buffer keep the intestines well out of the wound and well up into the abdominal cavity. The pelvis is empty except for the rectum, uterus, and its adnexa. Section of a single hook to show how it jams and fixes the mechanical hands.

inches (Fig. 2) are laid over the wound so that they overlap its edges well. The frame is laid on these and if the wound is in the upper part of the abdominal wall (Fig. 3) the left forefinger is placed on the towels at the lower angle of the incision where they are tucked well under the cut edge of the abdominal wall. Retractor 1 is now substituted for the finger and is held up by the left hand of the assistant so as to elevate the abdominal wall until it is clear of the viscera and thus enable the operator with his left hand at C to tuck the towel at this point well under the peritoneum and unhampered by intestines to insert retractor 2 and lock it on the frame. The assistant, using his right hand, pulls the frame

toward him and keeps it on tension at the point C so that omentum or intestines cannot get under retractor 2. He still retains the upward tension on retractor 1. This facilitates the insertion and the locking of retractor 3. Retractor 1 is now locked. The assistant with his hands at E and G now lifts the frame, enabling the towels to be easily turned under the peritoneum in the upper wound angle and permitting the insertion and locking of retractor 4.

The wound now should be open to its fullest extent under slight tension only and the wound edges including peritoneum should be neatly covered so that there should be no fear of disarrangement, damage or infection (Fig. 3).

Fig. 3 Retractor set for an operation upon the gall bladder. The incision is in the upper part of the abdominal wall. The No. 1 broad Iritz retractor is put in the upper angle of the wound. Mechanical hand '9' has the most important function. It draws the duodenum (covered with a scarf) medially and stretches the common duct and draws the gall bladder toward the midline. Mechanical hand '8' keeps the hepatic flexure out of the way and mechanical hand '7' a deep one (1 Fig 4) is used to keep the stomach out of the way.

When the incision is in the lower part of the abdominal wall retractor 1 is inserted first in the upper angle of the wound and the others in order of their numbers (Fig. 2).

When there are adhesions to the anterior abdominal wall, as in secondary abdominal operations, a second step will be necessary. Here it is better at the outset to choose or make on each side of the wound a space clear of adhesions. Into these spaces insert retractors 2 and 3 (Fig. 6), lock them on the frame and with this lift the abdominal wall. The viscera will hang and it is an easy matter to put tension on the now well lighted adhesions thus facilitating what is usually a very difficult task—the neat disconnection of adhesions from the anterior abdominal wall especially those far out from the incision.

When these adhesions have been divided, preferably with a long scissors and the operation field is 'set,' then the abdominal wall is lifted away from the intestines by the gentle elevation of the frame. In this way a space is created through which the operator can explore the abdomen. As a matter of fact, much of the abdominal cavity can in this way even be inspected under good vision certainly it can be explored comfortably because the exploring hand is not hampered and harassed by the intestines and the clinging omentum. It is also wise at this stage to

see to the suturing of any wound made in the peritoneum of the anterior abdominal wall by the severance of adhesions. Lifting the abdominal wall away from the viscera enables this to be done with ease and accuracy, even though the wounds are far out under the wall—an essential precaution to prevent the recurrence of the pernicious parietal peritoneal adhesion.

EXCLUSION OF THE INTESTINES

The next step is to clear away the intestines, stomach, and any other viscera from the operation field and to incarcerate them under the abdominal wall. Here they will be free from injury and will be kept warm. This exclusion of intestines from the operation field by the use of mechanical hands is a very special feature in the technique, and is of great value when the organ is deeply situated and access is difficult, as for instance in the exposure of a contracted and highly situated gall bladder or of the pancreas in a fat person, or of a kidney from the abdominal cavity. This maneuver is carried out by means of large soft veils of a single layer of gauze (a yard by a yard and a half) puckered at one end, and mechanical hands 'with blades set at an acute angle. The method varies according to the particular operation field but follows to a certain extent some general rules.

The veil is laid on the intestines and the frame (not the retractor) is lifted so that the veil tangled up with the intestines is drawn into the abdomen. Add several extra layers of the veil and with the hand draw the intestines far out under the abdominal wall. Substitute a 'mechanical hand' for the hand and fix it to the frame. The crumpled up 'veil' acts as a buffer between the 'mechanical hand' and the intestines. Do this on the sides of the frame where it is necessary until the operation field is quite free from the intestines (Fig. 2, 5 and 6, Fig. 3, 7, 8, and 9). As the acute angled blades of the mechanical hands are so made that they fit well under the abdominal wall there should therefore be no infringement by these on the operation area.

OPERATIVE EXPOSURES

Gall bladder. The precision exactitude, and value of this technique is best seen in a difficult cholecystectomy. Indeed no cholecystectomy can be difficult with it at least that has been our experience. There will be no accidents, such as injury to the common duct.

In the planning of the incision the cystic duct must be regarded as the point of greatest importance—the keystone of the operation and the

Fig 4 Detachable blades for mechanical hands A Long deep blade for special purposes B narrow shallow blade for difficult appendiceal operations and other purposes C blade used for gall bladder pelvic and other work D small blade for use in small wounds such as for acute appendicitis etc and E blade for the urinary bladder

main objective of the operative exposure. For this reason a paramedian incision must be used and made as high as possible. The retractor is now inserted and the wound set in the usual way. The next object is to stretch the gastrohepatic omentum and thus to unravel and straighten out the biliary vessels and ducts. To do this three or four folds of a veil are laid loosely on the second part of the duodenum and by means of a 'mechanical hand' the spine and the surrounding intestines are drawn well over to the left under the abdominal wound. With other mechanical hands and scarves the stomach (use a deep 'hand' for this as in Fig 4 and Fig 3 7) and the colon (Fig 3 8) are drawn out of the way.

If the patient is now put in the reverse Trendelenburg position, the operation area will be flooded with light and dissection of the cystic duct and the gall bladder will be possible under good vision. The exposure¹ is so perfect that it is quite unnecessary to touch or drag on the liver and this means much less postoperative disturbance and nausea.

Common duct. While a good exposure of the common duct is necessary for the removal of gall stones especially in fat people it is of inestimable value in injuries to the common duct which as a rule are due to some accident during a cholecystectomy and occur near the hepatic ducts—a situation very difficult for operative manipulation. The gall bladder and common duct are dissected free from any adhesions and the operation wound

is 'set' as usual. It is wise in exposing the duct to stretch the duodenum downward, not over the spine and to push up the liver. To do this it is necessary to use four 'mechanical hands'. Scarves and 'mechanical hands' should, therefore be used to retract out of the operation area (a) the stomach, (b) the hepatic flexure of the colon, (c) the duodenum and small intestines (d) the liver edge upward. The important retraction is the lifting of the liver, thus stretching, opening up, and exposing the upper part of the common duct for dissection. So as not to injure the liver it is necessary to use a small blade, with extra layers of the soft gauze, and light pressure.

The exposure obtained is surprisingly good the operation area is 'set' and does not require the annoying constant readjustment necessary in the usual methods. Certainly patience and deliberation are required but these are amply repaid by the well lighted operation field and by the precision which is possible in the difficult manipulations of the suturing of the hepatic duct into the duodenum or the suturing of a wound in the upper part of the common duct. Here as in all operations on the gall bladder if a dilated stomach is in the way, it is wise to deflate it with a trocar attached by rubber tubing to a suction pump (Fig 7).

With this exposure it is also quite easy to dislocate the duodenum to probe the common duct and to examine the ampulla of Vater or to carry out any precise dissections or manipulations necessary in this region.

Stomach. The esophageal end of the lesser curvature of the stomach is the point of greatest

¹This technique has been given in much greater detail in Surg. Gynec. & Obst. 19 7 Nov 35-36

Fig. 5. This is to show how the mechanical hand should be inserted and locked. The hand is inserted loosely at right angles to bar of frame on to the single hook at C. A lateral movement in the direction of the arrow to C will now jam the hand without letting the intestine out.

difficulty in gastric operations it is the most inaccessible—it is important from the point of view of lymphatic infection in carcinoma—it is the starting point for the mobilization of the lesser curvature in contracted and cartilaginous old ulcer. Consequently, we think the main object of any exposure must be this point.

When a left paramedian Bevan's incision has been made

1. The retractor should be locked in the way described (Fig. 8).

2. The stomach should be deflated by means of a trocar connected to a suction pump (Fig. 7). In the Australasian Medical Congress of 1920 we first drew attention to the great value of this maneuver in difficult operations on gastric conditions.

3. The left lobe of the liver should be covered with some layers of veil which should be hooked over to the right with a mechanical hand (Fig. 8 10). This exposes the upper part of the lesser curvature.

4. The patient is put in the reverse Trendelenburg position so as to throw light into the depths of the wound.

The importance of adequate exposure of this particular region is also stressed because we think that an operation on a carcinoma of the pyloric end of the stomach should not be started in the usual way that is at the pylorus. In our opinion the stomach should be cut across between Payr clamps proximal to the lesion and the distal segment should be allowed to hang over to the right

Fig. 6. This shows how in operations in secondary abdominal cases a clear space on each side of the incision is made and how into this clear space two retractors are inserted so that the abdominal wall may be lifted to facilitate the disconnection of adhesions from the anterior abdominal wall.

so that very accurate dissection of the subpyloric glands and of the adjacent pancreas may be carried out. Bruising of these glands is liable to occur when the dissection is started from the pyloric end.

Very great expertness and speed in bowel suturing can be attained if the frame is used to suspend the bowel segments in proper position by systematic catgut retraction. Advantage should be taken of this in making the gastro-intestinal anastomosis. The segments of stomach and intestine should be fixed together and to the retractor frame by guy ropes (Fig. 9 1 and B). This gives a definite tension and a fixed resistance against which suturing may be carried out and this makes for great accuracy and neatness.

Once the retractor is fixed in the wound very light anesthesia suffices for an operation on the insensitive stomach.

Posterior wall of the stomach—gastric ulcer penetrating the pancreas. In an operation on the posterior wall of the stomach for a gastric ulcer penetrating the pancreas the following steps are necessary:

1. The wound is set in the way indicated.
2. The stomach is aspirated of air.
3. Large openings are made in the gastro-hepatic and gastrocolic omenta.

Fig 7. This shows a stomach which is dilated and filled with air being punctured by a trocar attached to a suction pump. The inset 1 shows the stomach collapsed. In this latter condition it is much easier to operate upon and it allows better operative access to organs in the vicinity.

4. With a mechanical hand and scarf the transverse colon is held out of the way.

5. The ulcer is exposed and with an aspirating tube a line of cleavage which will be found between the edge of the ulcer and the pancreas is boldly penetrated. The stomach is dried and with the gloved finger the ulcer is shelled off the pancreas. A scarf is drawn through the openings in the gastrohepatic and gastrocolic omenta and drawing on it the posterior wall of the stomach is rotated so that it assumes an anterior position. It is now possible to suture the ulcer in comfort and with precision.

Pancreas. In the ordinary way the exposure of the pancreatic region is most difficult, as the pancreas is so deep down in the abdomen. Manipulations are hampered by the crowding in of the stomach, colon and the small intestines. With ordinary method it is difficult to light the operating area.

1. The retractor is inserted.

A six inch incision is made in the gastrocolic omentum.

3. A crumpled up veil is placed over the transverse colon and another over the stomach (which has been previously deflated) and perhaps another over the duodenum. With as many mechanical hands as necessary these organs are pushed under the abdominal wall out of the operating area.

Fig 8. Exposure of the stomach. Retractor 4 is placed in the upper angle of the wound and the left lobe of the liver protected by many layers of gauze is hooked over out of the way of the lesser curve by mechanical hand 10.

4. The area may now be illuminated either by daylight (reverse Trendelenburg position) or by artificial light.

The surgeon will be surprised to find what an enormous difference this exposure makes in operations on the pancreas. Excision of a very large old suppurating pancreatic cyst wall in the head of the pancreas and incision of the capsule in acute pancreatitis, have been easily and satisfactorily dealt with by this method.

The kidneys from the front. A right upper paramedian incision is made, and the abdominal wound is set in the way that has been indicated (Fig 2). Large folded soft veils are placed over the stomach, ascending colon and the hepatic flexure. With two mechanical hands these structures are drawn toward the midline and the hands are fixed to the median side of the frame. If necessary a low lying liver may be held out of the way with layers of a scarf and a mechanical hand (Fig 10 7). The peritoneum is incised lateral to the hepatic flexure and the upper part of the ascending colon. The mechanical hands are now unlocked on the medial side of the frame and the colon is stripped from the posterior abdominal wall. The mechanical hands reinserted and this loosened segment of the colon incarcerated still farther into the left part of the abdomen. It may be necessary to use a third small mechanical hand on the lower side of the

Fig 9 This gives some idea how segments of stomach and intestine can be fixed to the frame by means of guy rope retraction so that exact suturing and accurate adaptation can be obtained and so that suturing can be carried out against constant tension

frame in order to keep any small intestines out of the operating area. It will now be found that the front of the kidney is well exposed and, if the patient is placed in an exaggerated reverse Trendelenburg position the operation area is flooded with light. It is now a very easy matter to isolate the kidney and display its pedicle which may be delivered more naturally forward than backward. A stab wound in the loin will provide the usual drainage.

This is also the exposure for a chronic subhepatic appendicitis.

Appendiceal region. The average appendectomy gives no trouble, but a good exposure of the appendiceal region is essential and life saving in what one might call the mean appendix that is the acutely inflamed appendix that from a developmental error is anomalously situated as for instance, in the pelvis or in a retrocaecal position the appendix which is intensely inflamed and

gangrenous and undeliverable the appendix that is bound down by the fibrous resulting from inflammation. In all these conditions adequate operative exposure so as to allow dissection under sight will avoid intestinal soiling shock and bleeding and make for a neat, expeditious operation.

The following is the method of exposure of a retrocaecally placed acutely inflamed appendix.

The ordinary muscle splitting incision is made but the incision is continued in the aponeurosis of the internal oblique and transversalis muscles into the sheath of the rectus (after Professor Watson and Davis) (Fig 11). If the appendix is very inaccessible and more room is required the incision is connected with a vertical incision B in the sheath. The edges of the wound are covered with towelling or rough glove rubber sheeting (specially made) or with both. With the retractor the abdominal wound is 'set me

mechanical hands" with small blades being used where necessary (Fig 4, D)

No attempt is made to find the appendix, but by the tracing of the terminal ileum to the cæcum, the ileocæcal junction is located. The base of the appendix nearly always bears a definite relation to this and is isolated and divided by means of a cautery between clamps. The butt is tied and invaginated into the cæcum (Fig 12, A). A crumpled up veil is placed over the cæcum, which, with the hand, is now pushed well under the abdominal wall and so out of the operation area. It is fixed there with a "mechanical hand" (Fig 12, H). Now by the clamping and snipping of what there is of the appendiceal mesentery, G, the appendix itself can gradually be drawn out from under the cæcum without the least tension being put upon it or the slightest force being used. This

lifting out of the appendix is important, because very often it is the surgeon who manually enucleating the appendix, ruptures the inflamed, friable appendiceal tip, and distributes infection through the coils of the very susceptible small intestine. When the appendix lies lateral to the cæcum and ascending colon and is very long extending up toward the liver, it is possible, by means of the lifting action of the retractor, to elevate the abdominal wall away from the intestines and to create a space previously only potential. Then when the patient is placed in the reverse Trendelenburg position and the wound becomes sufficiently well lighted, it is possible to dissect out with long instruments one of these long appendices and to clamp its arterial supply.

Acute pelvic appendicitis. In acute pelvic appendicitis the same wound setting" is used as for the retropertitoneal type of appendix (Fig 12). The base of the appendix is found in the same way (Fig 12 A). Now with "veils" and "mechanical hands" the cæcum is pushed up into the abdomen and the small intestines are cleared from the appendix as it descends into the pelvis (Fig 13, B). If the patient is now placed in the Trendelenburg position, the appendix can be seen the whole way into the pelvis so that unhampered by intestines and under good vision, the appendiceal mesentery (Fig 13 C) can be clamped and snipped with long handled instruments and the appendix itself can be lifted out of the pelvis without the slightest injury. In this way the terminal part of an acutely inflamed pelvic appendix often gangrenous or thin and full of pus, is never ruptured.

It frequently happens that an appendiceal pelvic abscess causes an obstruction of both the small intestine and the sigmoid ileus duplicis (Hand

Fig 10 The exposure of a right kidney by the abdominal route. The ascending colon and hepatic flexure covered with layers of gauze are held in the abdominal cavity by mechanical hands 5 and 6. The liver also well protected with many layers of gauze is held up by the gentle tension of mechanical hand 7.

ley). Here the cæcum and the small intestines adjacent to the appendix will be so much dilated that it would be very difficult to give adequate exposure even to a normally situated appendix and certainly next to impossible to remove the deeply situated acutely inflamed, abscessed pelvic appendix. In such circumstances the operation can be made almost easy by the insertion of a hypodermic needle of a slightly larger caliber than usual, connected to an air pump obliquely through the coats of the cæcum (Fig 14, E) and with this withdrawing intestinal gases. This procedure causes the cæcum and the adjacent foot or so of small intestine to collapse (Fig 14, D). The aspiration through such a fine needle is slow, but the content is mostly gas, and it is remarkable how this maneuver simplifies what appears to be an almost impossible appendicectomy.

In difficult appendicectomy in acute cases, we deprecate the use of the paramedian incision and we claim for our technique, that is, the modified "split muscle" incision combined with the use of this special retractor and its "hands" the following advantages:

1. The incision is made directly over the base of the appendix—the best point of attack.

Fig. 11. A modified McBurney incision. A The sheath of rectus B incision in the conjoint tendon continued into the sheath of the rectus and if necessary vertically down the sheath of the rectus (after Davis and Professor Watson by courtesy *Journal of the College of Surgeons of Australasia*).

2 The small intestine with its larger and more absorbable lymphatics is not disturbed and soiled as it must be in the manipulations through or in suturing of a midline incision.

3 The pelvis and kidney fossa—most important regions—are accessible by an aspirating and drainage tube with the least disturbance of small intestines.

4 Valvular drainage may be established and loose suturing may be adopted. This avoids in future necrosis of muscle and subsequent hernia.

The lower end of the ureter. In operations on the lower end of the ureter in the male when the vas deferens must be conserved a large paramedian incision is not of much advantage. An incision exactly similar to that used for the pelvic appendix may be used except that it should be made an inch above the inguinal canal. The mechanical hands are used in exactly the same way as in the removal of the pelvic appendix except that they are placed outside the peritoneum and the deep mechanical hand (Fig. 4 A) is used in the lower angle. This lower angle of the wound should be at a point an inch above the insertion of the rectus muscle into the pubis. At this point the lower end of the ureter is nearest the surface. The mechanical hands must therefore be utilized to create the biggest cavity in this region.

The ureter is found at the junction of the internal and the external iliac arteries and traced down to the bladder.

The art of the exposure is the creation of a good operating cavity adequately lighted (a good Trendelenburg position will probably do this) right over the lower uterus that is, in the lower angle of the wound.

In a female where the round ligament can be sacrificed without any hurt to the patient a big paramedian incision will give a more comfortable exposure. In the female in order to create an operating cavity it will be necessary to push the peritoneum toward the middle line with veils and two mechanical hands.

The pelvis. This technique is really ideal in operations in the pelvis and makes operations on the rectum and sigmoid very much easier. Retractor J fits neatly over the os pubis (Fig. 1).

The wound is set in the usual way. The upper end of the retractor frame is lifted, the patient is placed in the Trendelenburg position when it will be found that the intestines fall easily out of the pelvis into the main abdominal cavity. Mechanical hands (Fig. 2) are now used to incarcerate them in this situation. The acute angles of the mechanical hands prevent them from encroaching on the operation area. If the rectum or sigmoid is the object of the operation the latter is left lying in the pelvis. If a fibroid is too big to deliver through the retractor it is delivered first and the retractor is inserted afterward.

Urinary bladder. The ratchet action mechanical hands and four blade principles of the retractor can be most successfully applied to operations on the urinary bladder such as those for the prostate papilloma or diverticulum.

Prostate. For operations on the prostate the moveable bar C is adjusted to a position on the frame about the points A and B. Mechanical hands (Fig. 15) with blades E (Fig. 4) are inserted into the opening in the bladder. The bladder wound is now opened with the ratchet which may even tear it a little until there is a sufficiently large opening through which to work. Into the upper angle of the wound is inserted a mechanical hand (Fig. 15) with a very acute angled blade which is made somewhat like a soup spoon. This is used to push the fundus of the bladder up into the abdomen so as to draw up any retroprostatic pouch and flatten the base of the bladder and also to bring it nearer to the surface. It is our experience that in a fat person the weight of the intestines makes the fundus of the bladder bulge downward and renders a satisfactory exposure of the prostate difficult. It may be necessary to use a small blade (Fig. 4 D) in the lower angle of the bladder wound in order to give a bet-

ter view of the anterior margin of the prostatic orifice and to act as counter pressure to the mechanical hand in the fundus.

A small lamp may be screwed into a socket in the middle of the highly silvered spoon mechanical hand (Fig. 15; inset). From the shelter of the fundus this lamp reflects light directly on the prostate and trigone or wherever necessary.

The patient should be placed in the Trendelenburg position.

Papilloma. In operations on papilloma of the bladder the exposure will need to be wider and to be contrived so as to suit the situation of the lesion. It may be necessary to insert the blades in a radiate fashion. At any rate they should be so adjusted that the papilloma area is free to be dissected.

Malignant tumor. In malignant tumor of the bladder where it may be necessary to resect a large portion of the bladder wall a low median incision is made between the recti and pyramidales and the peritoneum is opened. The retractor is inserted in the usual way and with it the abdominal wall is lifted. The intestines are removed from the pelvis and incarcerated in the main abdominal cavity by means of a veil and two mechanical hands (Fig. 2, 3, and 6).

The patient is placed in the Trendelenburg position. With a trocar and pump the bladder is aspirated. The bladder is opened and dried out

carefully with an aspirator tube. The bladder is isolated and the tumor is resected. As the resection of the tumor proceeds, corresponding or particular parts of the bladder wall should be fixed to the frame by catgut "guy ropes" in order to keep the proper relations for reconstitution of the remnants of the bladder. This allows replanning and easy and exact suture of the much mutilated bladder.

Diverticulum of the bladder. "Guy rope" catgut retraction is particularly valuable in the removal of a very large and adherent diverticulum through the bladder.

The edges of the diverticular opening are freely incised and the neck of the diverticulum separated from the bladder wall. The diverticulum is now freely exposed by the drawing of the bladder wall away from it by a number of guy rope catgut retractions placed symmetrically round the frame. It may even be possible to expose the diverticulum further by the insertion of a couple of narrow deep mechanical hands. By these means the opening in the base of the bladder is set widely open and brought nearer the surface. This

Fig 14 Exposure of pelvic appendicitis with ileus duplexis. *A* Infected appendix (dotted in) *B* abscess (shadowed in) *C* paralyzed segment of small intestine *D* obstructed small intestine *E* dilated cecum and *F* hypodermic needles attached to air pump deflating cecum

renders it possible, with long scissors and forceps, to dissect out the diverticulum under good vision so that it keeps on coming up to the operator as he snips around the walls.

This system of retraction is also most useful in the extraperitoneal removal of a diverticulum.

SUMMARY

We have found that this technique has great potentiality in enabling the surgeon to get out of serious operative difficulties. To every surgeon there must come a time when unexpectedly an almost insurmountable operative problem occurs at an operation or the unexpected happens. For instance, a patient has been operated on for gall stones. No disease of the gall bladder has been found, but examination reveals that the kidney has a dilated pelvis. It is a matter of a few minutes to rearrange the retractors, deliver the kidney into the wound, and explore or deal with the kidney condition without making a fresh incision. Or if a gastric lesion is found, the incision can be

Fig 15 Retractor set in the bladder for exposure of the prostate. Mechanical hands 1 and 2 are used to retract opening in bladder (see Fig 4 *e*). Retractor 4 is seen in Figure 4 *d* and retractor 3 is a spoon shaped mechanical hand with a light in the middle of the highly silvered spoon.

made to expose the whole of the stomach by just rearranging the retractor so that the incision is made wider at the expense of its length. The reverse happens. During an operation for a gastric lesion a pathological condition of the gall bladder is found, the gall bladder can be removed without enlarging the incision.

Let us suppose that in operating from the abdomen a hydatid cyst or an abscess of the upper surface of the liver is found, then it is possible to elevate the costal arch to press the liver down, and to create a space that enables the surgeon to attack the upper surface of the liver. It is quite unnecessary to go through the pleura. Once the abscess is opened counter drainage at its lowest point can be easily established. In a similar way, access can be obtained to the left side of the diaphragm so that adhesions from a spleen can be severed with a scissors rather than be torn by the hand.

The patient has disease of the gall bladder but needs the removal of the appendix as well. An incision is made as high as possible in the abdomen just sufficiently big to enable the gall bladder to be removed. The abdominal wall is elevated a swab on a holder is pushed against the anterior abdominal wall at McBurney's point from inside

the abdomen. A stab incision is made on to this. With the left hand in the abdomen the appendix is delivered through this stab incision and removed. One stitch closes it. This means that there is an incision very high up in the abdomen and a tiny incision in the lower part of the abdomen—a much better arrangement from the patient's standpoint so far as the strength of his abdominal wall is concerned than the necessarily big incision in the middle of the rectus, made to give access to a high gall bladder and a low appendix, at a point where there is the greatest postural tone.

An appendix is being removed it is found that the patient has a uterine fibroid. It is an easy matter by the incision of the sheath of the rectus and the re-arrangement of the retractor to elon-

gate the incision so that the fibroid tumor can be removed without a fresh incision being made. A hernia is found it is possible to close the opening from the inside. Indeed, additional uses are constantly being found in which this method of operating is a distinct advantage.

This technique has to be seen in order that its potentiality and its rationality may be appreciated but even we who have employed it for years, could not adequately tell our readers what it has meant to the great number of patients on whom we have operated, to the surgeons whom we have initiated into its many uses and to the assistants and nursing sisters. Any surgeon who would assimilate this method, must cultivate it before he can regard it as part and parcel of his general technique.

FROM THE DEPARTMENT OF SURGERY OF WASHINGTON UNIVERSITY

ARTHRORHISIS OF THE SHOULDER BY MEANS OF OSTEOPLASTIC GRAFTS

J. MURPHY, M.D., ST. LOUIS, MISSOURI

Director of Shriner Hospital for Crippled Children

ARTHRORHISIS of the shoulder is an operation which is definitely indicated in certain conditions and one which may effect the cure of disease and result in an upper extremity which is very useful as well as free from pain and obvious deformity. However a firm bony ankylosis of the shoulder is difficult to obtain because when the shallow glenoid is denuded the area of raw bone obtained is disproportionately small in comparison to the head of the humerus to which it must be opposed. A further difficulty is that the scapula is movable on the thorax and cannot be completely immobilized by any form of apparatus. Consequently the usual type of arthrodesis operation often results in a complete failure or only a fibrous ankylosis of the shoulder is obtained. The difficulty is partly overcome by collapsing the denuded or split acromion on the upper end of the humerus but even this type of operation is often unsuccessful.

In this paper an operation is described which offers a better chance of success than any other with which I am familiar. It is similar to a procedure which I described in 1916 for the treatment of tuberculosis of the hip.¹ The advantages of the operation are that it gives a complete exposure of the shoulder joint thus enabling the surgeon to perform a thorough operation and it supplies extra bone at the points where needed.

INDICATIONS FOR THE OPERATION

The chief indications for arthrodesis are tuberculosis of the shoulder joint, complete and permanent paralysis of the deltoid and certain chronic painful conditions of the shoulder which cannot be relieved by less radical methods. A brief explanation of these indications follows.

Many competent orthopedic surgeons believe that tuberculosis of large joints is most satisfactorily treated by conservative methods especially heliotherapy. These men will, of course, not consider this or any other extensive operation in tuberculosis of the shoulder. Personally I have never seen a case of proved tuberculosis of a large joint in an adolescent or adult cured with a useful

range of motion in the joint. Consequently, I recommend arthrodesis as soon as the diagnosis is definite and patient is ready for operation.

The paralyses of the deltoid are usually the result of poliomyelitis and in these cases there is often extensive paralysis of the entire upper extremity. It is almost useless to operate on cases in which immobilization of the shoulder in a good functional position will not materially benefit the patient. For this reason one should operate only upon the patient who has sufficient muscle power in the arm and the forearm to give him a hand which would be useful if it could be properly controlled. It is also necessary that the patient have sufficient power in the shoulder girdle muscles especially the trapezius and serratus magnus to control the movements of the scapula.

The painful arthritic conditions of the shoulder which warrant such a serious procedure as arthrodesis are usually the result of an old fracture involving either the head of the humerus or the glenoid in which the fragments are healed in malposition and the mechanics of the joint are disorganized. In these cases the operator can feel that he is not liable to do any harm as there is rarely enough motion left in the joint to be of use to the patient but just enough to cause frequent attacks of pain which may or may not radiate down the extremity. Before resorting to arthrodesis in these cases of so-called traumatic arthritis the surgeon should endeavor to relieve the patient by immobilization in a good functional position and by physiotherapy (local heat and also massage). As a rule conservative treatment should be continued from 6 months to 1 year before an arthrodesis is performed in a case of traumatic arthritis of the shoulder.

The object of the operation is to fix the humerus to the scapula in such a position that the arm can be elevated to the level of the shoulder or be proximated to the side. This amount of motion is accomplished by the movements of the scapula on the trunk. There is also a certain amount of rotation of the arm and backward and forward motion which is obtained in the same manner. In the case of infantile paralysis with total paralysis of the deltoid the abduction and elevation of

¹ J. J. A. Treatment of tuberculosis of the hip. J. Missouri Ch. & A. Soc. 1920, November, 3rd 397.

Fig. 1 Split plaster jacket with spica trough for arm prepared before the operation

the arm obtained by the patient are practically all due to the operation

PREPARATION FOR THE OPERATION

If the shoulder is movable and can be abducted to the desired functional position it is wise to apply before the operation a plaster spica jacket which fits well around the iliac crest and includes the shoulder and arm down to the elbow. This will shorten the length of time which the patient must spend under the anæsthetic and the jacket can be applied while he is able to sit or stand. It is applied with the arm abducted 70 to 90 degrees and brought forward about 30 degrees from the frontal plane so that the hand can reach the face. The top of the plaster covering the arm and shoulder is then removed and the plaster jacket is split on the opposite side and removed. The top is discarded but the plaster jacket with the trough for the arm is saved in order that it may be applied after the operation (Fig. 1). It is useless to include the elbow and forearm in the preliminary plaster because the operation shortens the upper arm slightly and the flexed elbow and forearm will therefore not fit in the trough which has been prepared for them.

After the cast is made the operative fields are given a 48 hour preparation. On the first day the entire arm and shoulder region including the axilla is shaved and scrubbed with soap and water then it is washed with alcohol and ether and a sterile dressing is applied. As it is convenient to procure the bone grafts from the tibia of the leg on the opposite side this leg is then prepared in a similar manner. The scrubbing with soap and water followed by alcohol and ether and the application of a sterile dressing are repeated on the second day.

Fig. 2 Position of patient on the table with shoulder elevated. The black line shows the site of the skin incision

TECHNIQUE OF THE OPERATION

The patient is placed on the table, anesthetized with ether and turned on the opposite side with the shoulder facing directly upward, large sand bags are placed next to the back and chest to maintain the position (Fig. 2). The arm is draped in such a manner that it may be moved freely. Sterile stockinette has been found convenient for this purpose. The leg and foot also may be covered with stockinette. Since the operation may be rather long and difficult and since it is always well to be ready to proceed to the conclusion of a major surgical procedure should the patient show symptoms of shock it is preferable to remove the grafts from the tibia before the operation on the shoulder is started.

A long straight incision is made over the middle of the subcutaneous surface of the tibia extending

Fig. 3 Outline of skin incision. The black dot is placed over the tip of the acromion

Fig 4 Exposure by Codman's incision. 1 Methods of removing grafts from the tibia. 2 The glenoid prepared for the reception of the head of the humerus. 3 acromion of clavicle. 4 base of acromion cut by saw and 5 detached acromion. 6 Relation of grafts to humerus.

from the level of the tubercle down to the lower fourth of the leg. This is carried down to the periosteum and the skin and subcutaneous tissue are dissected back on either side. Then with a knife four parallel incisions are made in the periosteum. These are about $\frac{1}{2}$ inch apart and include practically all of the subcutaneous surface of the bone. Transverse incisions in the periosteum are made at either end of the vertical incisions. With a small curved chisel, the osteoperiosteal grafts are then removed in such a manner that a thin layer of cortical bone is raised with the strip of periosteum. Three such strips are cut and placed in a bowl which is covered and kept sterile. (I do not wrap these grafts in sponges saturated with salt solution as I believe that this may injure the cells, but simply use a gauze soaked with blood from the wound and since the bowl is covered, the grafts are thus in a moist chamber.) An assistant closes the wound in the leg while the operator devotes his attention to the shoulder.

In order that the operation may be performed thoroughly, it is necessary that an adequate exposure of the shoulder joint be obtained. For this purpose I prefer the saber cut, devised by Codman¹ originally for suture of the supraspinatus tendon but ideal for arthrodesis of the shoulder as it gives a complete exposure of the joint. The saber cut incision for arthrodesis provides an incision a little more extensive than that described by Codman but the lines and principles are identical.

The skin incision begins in front opposite the lower border of the glenoid and extends straight across the shoulder from before backward directly over the acromioclavicular joint to a similar level behind (Figs 2 and 3). The incision is carried down to the bone and muscle, and after the superficial bleeding points have been clamped skin towels are applied. The anterior and posterior portions of the deltoid are split rather than detached from the clavicle and spine of the scapula. The acromion is separated from the clavicle at the acromioclavicular joint by dividing the capsule of that joint and is then sawed through at its base in the line of the incision, thus detaching the acromion with the flap or epaulet consisting of the lateral portions of the deltoid, together with the skin and subcutaneous tissues. This is retracted outward to expose the subacromial bursa and the superior portion of the capsule of the shoulder joint. The upper portion of the capsule and the loose subacromial tissue are excised in mass, thus exposing the joint. The tendons of the supraspinatus and the infraspinatus are retracted backward while that of the long head of the biceps is detached from the upper border of the glenoid and sutured to its sheath in the depth of the wound. The synovial lining of the joint is then excised by sharp dissection.

After the synovial membrane and diseased tissues have been removed the head of the humerus and the glenoid are completely denuded of cartilage and diseased bone with a curved chisel or gouge, and the periosteum is raised from the upper end of the shaft of the humerus and from the scapula around the margins of the glenoid. If the glenoid is much eroded the base of the acromion is also denuded and the nerve to the infraspinatus is ruthlessly disregarded as the muscle will be useless anyway if the operation is successful. The same is true of the tendon of the supraspinatus if it interferes with bone-to-bone opposition between the upper end of the humerus and the lower surface of the acromion. As a rule it is loosened from its insertion and pushed back.

Codman E. Obscure lesion of the shoulder joint. The supraspinatus tendon. Boston M & S J. 9: 7, 1897.

Fig 5 Postoperative plaster jacket showing position of arm and shoulder

ward. Hemostats which were placed on bleeding points during the operation are now removed, and usually it will not be necessary to tie any vessels. The periosteum is now removed from the deep surface of the detached tip of the acromion in order that it may be approximated to the denuded upper surface of the humerus. With a small drill a hole is made through this fragment and through the base of the acromion at a point opposite for the placing of the suture to hold the fragment in place.

The osteoperiosteal grafts, cut in lengths of about 2 inches are now inserted as thickly as possible around the borders of the glenoid beneath the elevated periosteum of the scapula with their free ends sticking out like the fingers of a half closed hand to receive the denuded head of the humerus (Fig 4). The deep or bone surface of the grafts faces inward to make contact with the denuded upper end of the humerus. All of the grafts available are used and several more than are shown in the drawing are placed around the glenoid spanning the space between its margins and the head of the humerus.

The humerus is then placed against the glenoid and in tuberculous patients a small stab incision is made in the skin of the outer surface of the upper arm at a point about 3 inches below the upper end of the humerus. With the humerus held against the denuded glenoid and in the desired functional position, a large nail is introduced through the stab incision and driven through the

upper end of the humerus in such a manner that its point enters the glenoid as near its center as possible. The arm meanwhile is held in a position of abduction of about 90 degrees and anterior flexion of about 25 degrees. In non tuberculous patients the nail will not be necessary, and in tuberculous patients in whom the entire head of the bone is destroyed it will not be practical, as it cannot be driven through thick cortical bone.

It is important from this time on to move the arm as little as possible. The acromion is now sutured to the clavicle by means of chromic catgut, and another piece of chromic catgut is passed through the holes in its tip and in the base of the

Fig 6 Postoperative arthrodesis of shoulder in a case of infantile paralysis showing a bony ankylosis of the humerus to both the acromion and the glenoid

acromion and tied tightly thus permitting the acromion to collapse upon the denuded lateral surface of the upper end of the humerus. Interrupted subcutaneous sutures of plain catgut are used to close the wound and continuous silk suture to close the skin. No drainage is used.

A snugly fitting dry dressing is applied. One or two 5 yard gauze rolls are used to make a firm figure-of-eight bandage to compress the tissues around the shoulder. This lessens postoperative oozing and hastens healing in addition to securing more adequate immobilization in the plaster. The split plaster jacket is now slipped upon the patient care being taken not to disturb the position of the shoulder any more than necessary and the arm is placed in the plaster trough. The forearm and hand are covered with sheet cotton and plaster bandages are placed around the trough and over the arm and shoulder in order to immobilize the part. The elbow is flexed to 90 degrees the forearm is supinated and the plaster is extended to the base of the fingers (Fig 5). Plaster bandages are placed around the jacket to strengthen it. The head of the nail is left protruding through the skin and through the plaster. If the plaster jacket with the shell for the arm has not been prepared beforehand it is of course necessary to apply the entire plaster while the patient is under the anæsthetic. If this is to be done on the ordinary Hawley table the operation should be performed with the patient reversed on the table that is with the patient's head at the foot of the table so that when the

operation is finished, the sand bags can be removed and the patient turned on his back with the pelvic rest between the shoulders. It is of course necessary for someone to support his head when the table is lowered and jacket is being applied.

The position of optimum function for ankylosis of the shoulder is usually given as 75 degrees of abduction for children and 50 degrees for adults with the arm slightly forward from the frontal plane. I use the 90-degree abduction for the first plaster because it enables one to push the humerus firmly against the glenoid while the plaster is being applied and because some abduction is always lost during the period of consolidation.

AFTER TREATMENT

The patient may be permitted to sit up in bed on the day after the operation and may be ambulant as soon as his strength permits. At the end of 12 or 14 days the plaster jacket is removed and the wound is dressed. The stitches are removed and a new plaster jacket is applied. The nail is removed about a week later and the second plaster is left on about 3 months. At the end of this time it is removed and an X ray picture is taken. If there seems to be firm bony union (Fig 6) an abduction splint or removable plaster is fitted and the patient is permitted to exercise the arm. In the case of a tuberculous joint it is better to continue the solid plaster for at least 6 months after the operation before attempting motion. The movable support should be worn for at least 3 months after removal of the plaster.

HEMINEPHRECTOMY OR RESECTION OF A PART OF THE KIDNEY

REPORT OF FOUR CASES¹WALTMAN WALTERS M.D. F.A.C.S. ROCHESTER MINNESOTA
Division of Surgery The Mayo Clinic

IDFAL cases for heminephrectomy would seem to be those in which there is complete duplication of the renal pelvis and ureter and in which it is necessary to remove only the portion of the kidney involved by the lesion. Large solitary cysts of the kidney form a second group of cases in which the portion of the kidney containing the cyst should be resected whenever possible, instead of the entire kidney being removed. McCham and Smith reported from the literature 34 resections of the kidney for solitary cyst with recovery in 31 cases. This should indicate without further emphasis the value of conservative operation whenever possible in such cases.

I shall report 3 cases in which successful resection of the diseased portion of a duplicated kidney was carried out, and also 1 resection of the lower pole of a kidney containing a large solitary cyst. The technique used in the resections will be described. Success depends on the avoidance of opening into the adjacent calyx of the remaining portion of the kidney, and on the assurance of complete hemostasis at the site of the resection. To avoid the former, I have found it an advantage after beginning the resection, to place a finger in the dilated calyx and pelvis of the portion to be resected so as to assist in determining its outer limits. It has not seemed necessary during the resection even temporarily to interfere with the blood supply to the remaining portion of the kidney. Immediate bleeding from the cut renal parenchyma ceases quickly with the placing and tying of mattress sutures over small bits of muscle tissue and approximation of the cut edges of the kidney. One may be assisted in this maneuver by making a V shaped resection if possible. Pieces of muscle are used to prevent the mattress suture from tearing through the parenchyma; it is surprising how much pressure can be used in bringing the edges of the kidney together (Fig. 1, c). In 3 of the cases such excellent approximation was obtained that after the mattress sutures were placed I was able to approximate the edges of the fibrous capsule with a running suture (Fig. 1, d). In one instance in which this was not possible the denuded area of the kidney was covered with a portion of the perirenal fat in the form of a patch (Fig. 1, e).

Studies were made pre-operatively and post-operatively of the function of each kidney separately and pyelograms were made of the duplicated kidney. Since details of such procedures have been reported elsewhere, I shall merely say that resection of the diseased portion of the kidney did not interfere with the function of the remaining portion and that resection has been followed in each instance by excellent results (Fig. 2, Case 2).

CASE 1. A woman aged 18 years had had attacks of pain in the right side of the abdomen with chills and fever and pyuria since August 1918. When she was examined November 19 1928 marked secondary anemia was found and the urine contained pus graded 3. Cystoscopic and pyelographic examination on November 22 revealed complete duplication of the left renal pelvis and ureter. Dilatation of the lower pelvis was graded 3; it contained infected urine graded 4. The upper pelvis apparently was normal; the return of indigo-carmin was graded 3. There was no return from the lower pelvis. Excretion of indigo-carmin from the right kidney was graded 4.

On December 28 1928 the lower infected hydronephrotic segment of the left kidney and its pelvis were removed. Nephropexy of the remaining segment was done. The postoperative course was uneventful. Cystoscopic examination January 15 1929 showed a return of indigo-carmin from the right kidney graded 4 and from the remaining portion of the left kidney graded 3. A pyelogram of the remaining segment of the left kidney was similar to that before operation; it was not grossly abnormal. At examination on May 3 the patient was found to be in excellent condition; she was gaining in weight and felt well. Urine from the bladder contained pus graded 1. On July 22 1929 the hemoglobin had increased from 60 to 75 per cent (Dare) and the erythrocytes had risen to 4,150,000. She had been free of pain had gained in weight and was in excellent condition.

CASE 2. A man aged 43 years complained of periodic dysuria with gross pyuria and hematuria that had been present since childhood. The urine contained pus graded 4 and the phenolsulphonphthalein return was 70 per cent in 2 hours. The blood urea was estimated as 30 milligrams for each 100 cubic centimeters. Cystoscopic and pyelographic examination on January 2 1929 revealed complete duplication of the right renal pelvis and ureter. The lower pelvis and its calyces were dilated graded 3; the upper pelvis was normal (Fig. 1, a). Urine from the upper pelvis contained pus graded 1; from the lower pelvis it was graded 3. The left kidney contained pus graded 2.

The lower pelvis of the duplicated right kidney was resected on January 22. The pelvis was sacculated and when not distended measured 5 centimeters in diameter (Fig. 1, b). Its ureter was three times normal size. Ureteropelvic obstruction was not demonstrable. Postoperative course was uneventful. On February 12 urine from remaining portion of right kidney contained pus graded 1; incision had healed and patient's condition was excellent.

Fig 1. *a* and *b* Heminephrectomy or resection of the lower infected hydronephrotic portion of the right kidney. *c* approximation of cut edge of remaining kidney by mattress sutures tied over bundles of muscle. *d* closure of renal capsule by suture and *e* the use of a patch of perirenal fat when the cut end of kidney can be closed as in *d*.

CASE 3. A woman aged 29 years had complained of abdominal distress for a number of years. I urina had been discovered on examination. Cystoscopic and pyelographic examination on April 15, 1919, revealed complete duplication of the right renal pelvis and ureter; the lower of the two portions appeared normal. Dilatation of the upper portion was graded 2 and the calyces were obliterated. Dilatation of the corresponding ureter was graded 3 to 4 throughout its course. Moderate infection was present. Indigocarmine was not excreted from the upper pelvis of the right kidney but from the lower pelvis excretion was graded 4. Excretion from the left kidney was also graded 4.

On April 25 the atrophic infected upper portion of the right kidney and part of the ureter were removed (Fig. 3).

An anomalous renal artery and vein crossed both ureters. They were not divided because they appeared to constitute the entire blood supply of the lower portion of the kidney which seemed normal and was preserved (Fig. 4). Post-operative convalescence was normal. Cystoscopic and pyelographic examination about 6 weeks later showed the outline of the remaining segment of the right kidney to be the same as before operation with slight clubbing of the calyces. The function of the remaining segment of the right kidney was reported to be normal excretion of indigocarmine was graded 4. Urinary infection was not present.

CASE 4. This case is included in the series since the type of resection performed was similar to that used in

Fig 2 Case 2 Temperature chart

heminephrectomy and because pre-operative (Fig 5) and postoperative (Fig 6) pyelograms with a lapse of 8 months between have been made.

In October 1926 a woman aged 50 years noticed a lump in the left side of the abdomen which was more painful when she moved. The mass had increased in size steadily. In April 1928 the feet and ankles had begun to swell. In the last 3 or 4 months before examination at the clinic the abdomen had increased in size and she had been told by her physician that this was due to ascites.

In the left side of the abdomen a mass was palpated which extended for 5 centimeters below the level of the umbilicus. It was freely movable and approximately 10 centimeters in diameter. The urine contained pus, graded 1. The blood count was normal. The Wassermann reaction of the blood

Fig 3 Case 3 Removal of the upper infected hydronephrotic portion of the duplicated kidney on the right side

Fig 4 Case 3 Anomalous artery and vein the only blood supply to the normal lower segment of the duplicated right kidney

Fig 5 Case 4 Pyelogram before resection of a large solitary cyst in the lower pole of the left kidney

was negative. Roentgenograms of the kidneys, ureters and bladder showed a circumscribed shadow in the region of the lower pole of the left kidney opposite the second and third lumbar vertebrae. Cystoscopic examination was performed

Fig 7 Kidney removed on eighth day because of hemorrhage. Resection of the lower pole had been done and a solitary cyst removed. Attention is called to the healed cortex of the lower pole of the kidney at the site of the resection and the sclerotic open mouthed blood vessels in the calyces

Fig 6 Pyelogram 8 months after resection of the cyst and the lower pole of the kidney

on October 12. The pyelogram of the left kidney was normal save for the lower calyx which was elongated and flattened on a spherical shadow of the mass. The function of both kidneys was normal. The left kidney was not infected.

On October 16 operation was performed through a left lumbar incision with resection of the lower pole of the left kidney and removal of a solitary serous cyst which was distended to 15 centimeters in diameter and contained approximately 500 cubic centimeters of straw colored fluid. The remainder of the kidney was normal in size and consistency. It seemed advisable to remove only the lower portion containing the cyst which was done with reconstruction of the lower pole by mattress sutures tied over small bundles of muscle. The cut edges were brought together completely and the capsule was sutured. The postoperative convalescence was uneventful. The patient was dismissed from the hospital October 9, 13 days after operation.

On June 6, 1919 the patient returned for examination. The urine was normal. Roentgenograms of the kidneys, ureters and bladder were negative. Cystoscopic examination showed a bidd type of pelvis with ptosis graded 1; the pelvis was otherwise normal. The ureter was normal. The patient's general condition was excellent.

Since this article was handed in for publication two additional resections of the kidney have been performed in one case of hydronephrosis of the lower segment of a duplicated kidney and in one of solitary cyst of the kidney.

The patient with hydronephrosis was a woman aged 39 years. The infected hydronephrotic segment (lower) of the left kidney was removed.

In the second case the patient was a woman aged 64 years. A large solitary cyst of the lower pole of the left kidney was resected. Eight days after ward nephrectomy was performed because of continuous hæmaturia. Examination of the removed kidney showed that the bleeding was due to sclerotic open mouthed branches of the renal artery (Fig 7). The patient recovered, but the corollary seems to be that plastic procedures on the kidneys of elderly patients with arteriosclerosis may be a radical rather than a conservative procedure.

Successful heminephrectomy or resection of a part of a kidney has been reported by Albarran, W J Mayo Young and Davis, and Rumpel. Albarran's patient was operated on in 1905. Gayet, in 1912, reported heminephrectomy in a case of duplicated kidney from which the patient recovered in 3 months. At that time, 17 cases had been reported in the literature. According to Young and Davis the 3 resections of the kidney, performed by W J Mayo and reported by Braasch in 1912, were probably the first successful operations of the kind reported in this country. Young and Davis reported successful heminephrectomy (removal of the portion of a duplicated kidney containing a calculus) in 1917. At that

time, they were able to find only 26 cases in the literature in which operation had been done for complete duplication of the renal pelvis and for different grades of ureteral duplication. In 20 of these nephrectomy had been performed. They stated that in 16 of these double kidneys, half of the kidney was normal and that partial nephrectomy could have been performed. They gave a detailed description of the embryological development of this abnormality.

USE OF ULTRAVIOLET LIGHT IN THE PREPARATION OF INFECTED GRANULATION TISSUE FOR SKIN GRAFTING, THE VALUE OF VERY THICK THIERSCH GRAFTS

W. D. CATCH, M.D., F.A.C.S. AND H. M. TRUSLER, M.D., INDIANAPOLIS, INDIANA

From the Department of Surgery, Indiana University School of Medicine

THE grafting of skin on infected granulation tissue has always been attended by a great number of failures. When the areas involved are large it has often required many months to cover them. Following repeated failures, the persistent infection and increasing cicatrization of the wound render the surface progressively less favorable for the growth of epithelium. We believe that the method of skin grafting we are about to describe is a distinct improvement over those commonly in use. In our hands it has been almost uniformly successful and has brought about a great improvement in our results.

Granulating surfaces resulting from third degree burns or injuries which destroy large areas of skin are always infected. If healing has been delayed by the great size of the wound or by excessive sloughing the granulations are œdematous and poorly supplied with blood. In cases of very long standing, the wound presents the appearance of a callous ulcer with a thick base of poorly vascularized scar tissue underlying cyanotic indolent granulations over which epithelium grows poorly, or not at all. It is evident that under these conditions skin grafts will not grow. The blood supply must be revived and the infection must be overcome.

PREPARATION OF GRANULATION TISSUE

The steps in preparation of the surface to be grafted will vary according to existing conditions. If the patient is anæmic or debilitated blood transfusion may be necessary to raise his general resistance. For an infected or sloughing wound we first employ intermittent soaking in normal or hypertonic salt solution with continuous wet dressings of 1½ per cent chlorazene solution. The dressings are changed daily. If during the stage of sloughing the granulations become œdematous and indolent they may be scraped away and given a fresh start. Often, however, we have found that such granulations may be rendered firm and vascular by means of a pressure dressing of dry gauze compressed against the wound with elastic bandage or adhesive tape.

When the wound is of too long standing with a resulting thick fibrous base, it is necessary to

excise this tissue completely and allow a thin layer of granulations to develop on healthy tissue. The same procedures are essential in the correction of extensive scar contractures where wide excisions are necessary to relieve deformity.

When in any case these measures have insured an adequate blood supply to the granulations, the problem of infection is still to be dealt with. In the presence of purulent exudates, the grafts are floated loose and destroyed by proteolytic ferments. Even with lesser degrees of infection such that the granulations are covered by a thin whitish scum of coagulum grafting is liable to fail. The tissue must be firm, beefy, red and clean.

THE USE OF ULTRAVIOLET LIGHT

It occurred to us 3 years ago that superficial infection in granulation tissue might be effectively reduced by exposure to ultraviolet light. This idea was suggested by the use of ultraviolet light to sterilize water. Our observations lead us to believe that granulation tissue should not be subjected to heavy exposure. Accurate judgment as to the duration and number of treatments is acquired only by experience. Each case is an individual problem and treatment will vary accordingly. We have used air cooled lamps of standard make, average voltage 70 at close range (10 inch distance). The time of any one exposure may be as great as 5 minutes where the granulations are in a bad state. Treatments are given daily and the time is reduced to 1 or 2 minutes as the surface improves. It may also be desirable to secure a milder action by removing the lamp to a greater distance. The normal reaction is one which renders the granulations red, vascular and surprisingly free from exudates.

ADVANTAGES OF THE THIERSCH GRAFT

When by the procedures just described, a thin but firm bed of beefy red non infected granulation tissue has been built up and when a thin blue line of growing epithelium can be seen at the edges of the raw area conditions are right for skin grafting. The question of what type of graft to employ must now be considered. The ordinary

Fig. 1. Case 1. Three views showing result 6 months after Thiersch grafting extensive third degree burns of the legs

Thiersch graft has been favored by most authors for the covering of areas on the body which will not be subjected to trauma. The whole thickness graft or the pedicle graft has always been favored for regions in which a good cosmetic effect is desirable or in which the graft will have to withstand constant trauma.

Our experience has shown us that a very thick Thiersch graft placed on granulations prepared as advised will give under any conditions as good cosmetic and functional results as a whole thickness free transplant. The thick Thiersch graft obviously cannot entirely replace pedicle grafts in cases in which it is necessary to transplant whole skin with subcutaneous fat. The indications for and the limitations of this type of plastic surgery are not included in the scope of this paper. Whole skin free transplant grafts however especially if the size is large seem to us to be biologically unsound. They are very disfiguring to the area from which the skin is cut and are furthermore prone to fail because of poor viability.

For these reasons the Thiersch graft is by far the more useful type of free skin transplant. Thiersch grafting both takes and leaves epithelium. The ordinary Thiersch graft should be cut

so that the papillary layer of the skin is bisected. The cut surface heals spontaneously by generating epithelium which appears only slightly different from normal. By this technique large areas of

USE OF ULTRAVIOLET LIGHT IN THE PREPARATION OF INFECTED GRANULATION TISSUE FOR SKIN GRAFTING, THE VALUE OF VERY THICK THIERSCH GRAFTS

W. D. CATCHER, M.D., F.A.C.S., AND H. M. THURMER, M.D., INDIANAPOLIS, INDIANA

From the Department of Surgery, Indiana University School of Medicine

THE grafting of skin on infected granulation tissue has always been attended by a great number of failures. When the areas involved are large, it has often required many months to cover them. Following repeated failures, the persistent infection and increasing cicatrization of the wound render the surface progressively less favorable for the growth of epithelium. We believe that the method of skin grafting we are about to describe is a distinct improvement over those commonly in use. In our hands it has been almost uniformly successful and has brought about a great improvement in our results.

Granulating surfaces resulting from third degree burns or injuries which destroy large areas of skin are always infected. If healing has been delayed by the great size of the wound or by excessive sloughing, the granulations are oedematous and poorly supplied with blood. In cases of very long standing, the wound presents the appearance of a callous ulcer with a thick base of poorly vascularized scar tissue underlying cyanotic indolent granulations over which epithelium grows poorly or not at all. It is evident that under these conditions, skin grafts will not grow. The blood supply must be revived and the infection must be overcome.

PREPARATION OF GRANULATION TISSUE

The steps in preparation of the surface to be grafted will vary according to existing conditions. If the patient is anæmic or debilitated blood transfusion may be necessary to raise his general resistance. For an infected or sloughing wound, we first employ intermittent soaking in normal or hypertonic salt solution with continuous wet dressings of $\frac{1}{4}$ per cent chlorazene solution. The dressings are changed daily. If during the stage of sloughing the granulations become oedematous and indolent, they may be scraped away and given a fresh start. Often, however, we have found that such granulations may be rendered firm and vascular by means of a pressure dressing of dry gauze compressed against the wound with elastic bandage or adhesive tape.

When the wound is of too long standing, with a resulting thick fibrous base, it is necessary to

excise this tissue completely and allow a thin layer of granulations to develop on healthy tissue. The same procedures are essential in the correction of extensive scar contractures where wide excisions are necessary to relieve deformity.

When in any case these measures have insured an adequate blood supply to the granulations the problem of infection is still to be dealt with. In the presence of purulent exudates the grafts are floated loose and destroyed by proteolytic ferments. Even with lesser degrees of infection such that the granulations are covered by a thin whitish scum of coagulum grafting is liable to fail. The tissue must be firm, beefy red, and clean.

THE USE OF ULTRAVIOLET LIGHT

It occurred to us 3 years ago that superficial infection in granulation tissue might be effectively reduced by exposure to ultraviolet light. This idea was suggested by the use of ultraviolet light to sterilize water. Our observations lead us to believe that granulation tissue should not be subjected to heavy exposure. Accurate judgment as to the duration and number of treatments is acquired only by experience. Each case is an individual problem, and treatment will vary accordingly. We have used air-cooled lamps of standard make, average voltage 70 at close range (10 inch distance). The time of any one exposure may be as great as 5 minutes where the granulations are in a bad state. Treatments are given daily and the time is reduced to 1 or 2 minutes as the surface improves. It may also be desirable to secure a milder action by removing the lamp to a greater distance. The normal reaction is one which renders the granulations red, vascular and surprisingly free from exudates.

ADVANTAGES OF THE THIERSCH GRAFT

When by the procedures just described a thin but firm bed of beefy red non-infected granulation tissue has been built up and when a thin blue line of growing epithelium can be seen at the edges of the raw area, conditions are right for skin grafting. The question of what type of graft to employ must now be considered. The ordinary

and effectively discourages the exudates which otherwise tend to lift the grafts. Exudates which escape around them are absorbed into the superimposed layers of gauze. Because of this advantage, we do not favor the use of sheet rubber, oiled silk, or any other non absorbent material as an initial dressing. There need be no fear that the gauze will stick and pull loose the grafts. At the end of 5 to 7 days, when the dressing is changed, all viable grafts have grown firmly in place. The outer dressings are removed and the gauze soaked loose with physiological salt solution.

Subsequently we employ ordinary dressings wet with salt solution and changed daily, until the wound is again clean and growing epithelium is seen. A thin outer layer of the graft will peel off in the same manner that cornified epithelium normally sheds itself. All the growing layers remain intact and proliferation from the edges is prompt. At this stage vaseline gauze may be employed as the dressing until healing is complete. Vaseline gauze also makes an excellent dressing for the surface from which grafts have been cut. Grease dressings are never advisable on granulations which are being prepared for grafting. In general the treatment best suited for the preparation of granulation tissue is more or less discouraging to the growth of new epithelium. For this reason, an entire area should be prepared carefully to insure success. If there is doubt and the surface is great, test grafting of a small part is advisable. Otherwise the entire area should be grafted at one operation.

When the skin grafts have been placed upon areas of the body not suited to pressure dressings, we employ with good success an open method of treatment, protecting the grafts by a cage of screen wire for 3 or 4 days until they adhere firmly. Whenever possible, we prefer the pressure dressing for reasons already given. It is especially applicable for extremities. It should be noted further that whenever the grafted wound involves the flexure surface of a joint, full extension should be maintained until healing is complete. If there is any tendency to contracture the splint should be continued until all tendency to cicatrization has ceased. Children are especially prone to contracture. Splints are indispensable. If contracture is permitted, deformity is inevitable.

RESULTS

A successful Thiersch graft, such as we have uniformly obtained by this technique results in an epithelial covering far superior to the cicatrix which must result from prolonged granulation

This grafted skin acquires a soft velvet like contour and a flexibility which closely approximates the normal. Hairs are absent and there may be a slight increase in pigmentation. As time elapses the disfigurement becomes progressively less noticeable. Especially is this true of children in whom repair processes are most active. We have carried out these procedures in a large series of cases with most gratifying results. Approximately 100 patients have had skin grafting operations after radical mastectomy without a failure. In a number of extensive third degree burns we have produced healing with a minimal amount of scar and a minimum loss of time, the interval ordinarily not exceeding 2 months. Some of the possibilities of this technique are exemplified in the three cases reported herewith.

Case 1 is a man who was saved from death or permanent disability by massive skin grafting operations. The chief problem was to combat infection and prepare large granulating surfaces for grafting. Massive failure would have meant a loss impossible to restore. Homografting, that is, from one individual to another has never been successful to our knowledge. It is not within the scope of this paper to enter further into this subject except to regard homografting as a biological problem as yet unsolved. With a successful technique of Thiersch grafting, the necessity of securing a skin donor should be rare indeed.

Case 2 is a man disabled for 4 years because of unsuccessful skin grafting. Following the proper removal of the accumulated scar tissue, a well managed Thiersch graft gave a splendid result where a pedicled graft and whole skin transplants had failed.

Case 3 shows the extent of deformity which may arise from a burn scar contracture, emphasizes the urgency of maintaining extension, and demonstrates further the indications for Thiersch grafting.

CASE 1. No. 2545, Orville C. aged 33 years, was admitted to the Robert W. Long Hospital October 9, 1927, in a state of extreme emaciation with extensive third degree burns of 4 months duration. As the result of an explosion in a paint and lacquer shop both his legs had been burned from trochanters to ankles. The areas of first and second degree burn had healed. There remained large areas of third degree burn involving more than half of each leg on inner and posterior surfaces. In these regions there was unhealthy granulation tissue covered with purulent exudate.

He was emaciated and prostrated with septic temperature and rapid pulse from prolonged infection. The granulations were given daily exposure to ultraviolet light and frequent dressings with 1 per cent chlorazene solution. Due to these measures and a blood transfusion his condition rapidly improved. By the technique we have described the granulations were covered with Thiersch grafts of good

Fig. 3. Case 3. Two views taken before grafting. Leg deformity as shown. Web contracture of knee. Muscle contracture at hip due to bad position. View at right shows appearance 3 weeks following excision of scar and division of hamstring tendons.

Fig. 4. Case 3. Two views showing result 6 months after Thiersch graft. Deformity corrected. The scar is covered with phleboid skin and there is complete restoration of function. Leg can be fully flexed and extended.

growing epithelium are placed in close contact with a rich capillary bed of healthy granulation tissue. Since epithelium is a tissue which normally grows upon granulations and normally is nourished by osmosis permanent viability should be possible. It occurs to us that in the free transplanting of whole skin this principle is lost. When the deeper non epithelial layers of the skin are included in the graft a much more complex process of nutrition is required. More or less necrosis is to be expected. The end result may be total sloughing or, with better success, a graft largely replaced by scar tissue and covered with an epithelium not as good as that obtained in a successful Thiersch graft.

The very heavy Thiersch grafts to which we have referred are cut about twice as thick as the ordinary Thiersch graft. They are of leathery texture, and comparable in thickness to the deep small grafts of Davis, but may be cut to large size as recently described by Blair and Brown. The area from which they are taken regenerates epithelium from the lowermost points of the papillæ, from sweat glands and from hair follicles. The resulting scar is slightly less satisfactory than that of an ordinary Thiersch cutting. We employ these thick grafts to cover flexor surfaces, especially the popliteal space and other areas where trauma must be expected. A success-

ful graft of this type results in a surprisingly good quality of skin.

DRESSINGS

Dressings of every description have been advised for skin grafts. Since the chief factor in any case is the preparation of the surface to be grafted it is not surprising that fair success has been reported with the use of various dressings. For 2 years we have been obtaining uniformly good results with 90 to 100 per cent take in the grafts by means of a pressure dressing. The essential details of which were devised by Dr W. D. Little of this clinic.

A single layer of sterile gauze moistened with salt solution is laid directly on the grafted surface in good contact with the grafts and the small areas of granulation tissue which may remain uncovered between them. On top of this are placed numerous layers of loose dry gauze sufficient to absorb any exudates which work out around the grafts. With this dressing secured the pressure dressing is applied by means of large bunches of ordinary hospital wool held firmly under a final wrapping of all cotton elastic bandage. The entire dressing is left undisturbed for 5 to 7 days.

We believe this dressing to be correct in principle. The pressure holds the grafts in firm contact throughout the period required for union,

CHRONIC RECURRING TEMPOROMAXILLARY SUBLUXATION

SURGICAL CONSIDERATION OF "SNAPPING JAW" WITH REPORT OF A SUCCESSFUL OPERATIVE RESULT¹

JOHN H. MORRIS, M.D., NEW YORK

Assistant Visiting Surgeon, Fourth Division, Bellevue Hospital; Assistant Professor of Surgery, New York Post Graduate Medical School and Assistant in Surgical Research, Cornell University Medical College

THE appropriate term of "snapping jaw" has been applied to a certain group of functional derangements of the temporomaxillary joint which exhibits a peculiar susceptibility to minor disturbances of its mechanism. This disturbance of function is usually attributed to an abnormal periarticular relaxation which permits an undue mobility of the condylar head within its glenoid cavity. The simplest form of the condition is encountered with great frequency, and victims of it, although suffering no actual pain or discomfort, are nevertheless subjected to a constant annoyance as a result of the more or less conspicuous snapping noise emitted by the joint as the head of the inferior maxilla glides through its arc in response to such physiological demands as talking, yawning or the mastication of food.

Confined within these limits and manifested by such unobtrusive clinical symptoms, snapping jaw scarcely assumes the dignity of a surgical problem. Indeed in discussing surgical diseases of this joint, standard surgical texts limit operative indications to such conditions as ankylosis, arthritis, irreducible dislocations, and a few unusual fractures. Subluxation of the joint as a surgical consideration is either dismissed as of no importance or its existence is completely ignored.

However, ample evidence is at hand to support the contention that this minor derangement of the temporomaxillary joint may give rise to clinical manifestations which demand urgent and radical intervention. An appreciable number of cases is on record among them the one herein reported in which the commonly observed picture is complicated by attacks of acute severe joint pain by locking of the joint in various positions or by actual fixation of the inferior maxilla with the mouth in the wide open position. Relieved for the moment spontaneously or by some manipulation these attacks invariably display a disposition to recur with increasing frequency and severity, thus becoming not only a constantly menacing source of embarrassment but eventually threatening the integrity of the very highly important function delegated to this joint.

Malgaigne in 1835 collected a series of 76 cases of snapping jaw of which 54 were bilateral

and 22 unilateral, the common age incidence falling between 20 and 30 years.

Annonale reported 2 cases in 1887, both occurring in females, aged 38 and 18 years, respectively. In the first instance the patient's jaw became locked during a vomiting attack and thereafter she experienced characteristic manifestations of snapping jaw, frequently complicated by pain and fixation. The second patient found her jaw fixed in the wide open position following the act of yawning. Manual reduction corrected the condition but thereafter the patient complained of a slipping joint. Tartara saw in an infant, aged 15 months, a subluxation sustained during a convulsion and Pugh observed a similar case in a child 2 years old following a blow upon the lower jaw. Pringle suffered from the condition himself and had studied 4 other cases, 2 of which were in medical students. Ashurst operated upon a girl aged 16 years who for 2 years had complained of a painful unilateral subluxation with locking, which occurred during the act of eating or talking. During the latter portion of this period, it was necessary to keep the lower jaw bandaged owing to the fact that subluxations frequently occurred with the mouth closed. Blake describes a male patient, aged 27 years in whom the condition became so extreme that subluxation took place during sleep.

These and numerous other similar reports contributed by Perthes, Loessl, Podlaka, Schurtzel, and others indicate not only the frequency of the condition but give as well a conception of some of its clinical manifestations.

With the demonstration of such inherent potentialities, snapping jaw may, on occasion, assume a considerable degree of clinical importance and require the application of some surgical method for its relief. The appropriate measures to be employed, however, are still a matter of conjecture and the limited number of cases reported to date have not conclusively proved the superiority of any particular procedure. In fact, the methods advocated are well nigh as numerous as the patients operated upon and in most instances, have been ingeniously developed without the aid of precedent, to meet the exigencies of the moment.

¹Case presented before Surgical Section, New York Academy of Medicine, May 7, 1926.

thickness. The grafting was done in two operations the left leg on November 24, 1921, and the right 9 days later.

Grafts were cut from abdomen, thorax and back. For the entire surface the grafts showed fully 90 per cent take and there was practically complete epithelization on December 23 when the patient was allowed to go home for Christmas vacation.

Since the legs had been maintained in complete extension there was never any tendency to contracture. For several months there was cyanosis and circulatory stasis during which time the patient walked with crutches. With the aid of massage and passive motions the difficulty was relieved and perfect function was restored at the end of 6 months. At the present time function in the extremities is normal, health is excellent and the entire surface is covered with skin of good quality (Figs. 1, 2 and 3).

CASE 2 No. 28281 Mitchell P. aged 35 years was admitted to the Robert W. Long Hospital March 19, 1920 with a callous ulcer of 4 years' duration on the right popliteal space. His injury in 1912 was a gasoline burn involving the posterior aspect of the right leg. After 22 months in another hospital and repeated attempts at skin grafting he was released with an unhealed area in the popliteal space. There were three unsuccessful attempts to heal this ulcer with whole skin grafts; the last failure occurring at one of the best surgical clinics in the country. The patient was referred to us with the advice that some type of pedicled graft would be necessary. On previous occasions, however, a pedicled graft taken from the only accessible area of the other leg had failed.

Examination revealed a callous ulcer 3 inches in diameter in the right popliteal space. The ulcer was cyanotic, the epithelial covering over the posterior aspect of the leg was of poor quality and there were marked edema, cyanosis and induration. On April 1 the ulcer and the surrounding cicatrix were given extensive débridement removing dense scar tissue 2 centimeters deep so that the normal structures of the popliteal space bulged into the wound. The edges were beveled toward the periphery, the final wound being about twice the size of the original ulcer. This was dressed for 10 days with chlorazene packs and given 4 exposures to ultraviolet light in the last 4 days of that time. On April 11, 1920, there was a bed of excellent granulations upon which we placed five large thick Thiersch grafts. When the pressure dressing was removed at the end of 7 days the grafts had taken 100 per cent leaving only three narrow zones of uncovered granulation tissue. When healing was complete the leg was given massage and passive motion.

The patient was allowed to walk out of the hospital 1 month after the graft was done.

Observation on June 1, 1919, showed an excellent, pliable growth of skin, no cyanosis and only transient edema after 4 hours of walking. Complete restoration of function is to be expected.

CASE 3 No. 5904 Claude R. aged 7 years was admitted to the James Whitcomb Riley Hospital September

7, 1923 with a vicious contracture of the left leg from a burn of 6 months' duration. Five days later the popliteal contracture was given complete débridement. Tenotomy of all the hamstring tendons was necessary to obtain extension of the knee. The exposed great vessels and nerves were covered with two flaps of fat and fascia and the wound was allowed to granulate. Dressings and ultraviolet light were employed according to the described technique.

A cast and later a Thomas splint were employed to maintain complete extension. On October 3, 1923, the large area of healthy granulation tissue involving the popliteal space and posterior aspect of the leg was covered with Thiersch grafts of good thickness. Removal of the pressure dressing at the end of 7 days showed 100 per cent take in the grafts.

One month later the patient was discharged walking in a cast to prevent contracture. After 6 weeks the cast was discontinued. Observation in 6 months showed complete restoration of function. There was slight keloid tendency but the scar was soft, flexible and covered with skin of good quality.

CONCLUSIONS

1. By the methods we have employed Thiersch grafts cut to proper thickness and successfully transplanted give a better result than do whole skin grafts.

2. The factors which render granulation tissue unsuited for grafting are cicatrix formation and infection.

3. Exposure to ultraviolet light is a valuable adjunct in the preparation of granulations. The surface must be beefy red, vascular, and free from exudates.

4. Excellent results may be obtained by dressing the grafts under pressure with dry gauze, wool and elastic bandage.

5. For the grafting of small areas which will be subjected to trauma and for flexor folds about joints we employ very thick Thiersch grafts. Joints should be splinted in full extension until all tendency to cicatrization has ceased.

specialization eventually exacts its penalty in terms of a mechanism more susceptible to disorganization under physiological stress and conceivably accounts for the prevalence of internal derangements in this type of joint.

The temporomaxillary articulation is classed in works on arthrology as a diarthrosis, sub division ginglymo arthrodia, signifying a mobile joint capable of executing both a hinge like and a gliding motion.

The component osseous elements of the joint are the condyle of the inferior maxilla and the glenoid or mandibular fossa of the temporal bone. The former, in cross section, is oblong with long axis transverse and it is set a bit obliquely on the neck in such a manner that its outer edge is a little more forward and a little higher than its inner one. It is acutely convex from before backward and to a lesser degree, from side to side (Fig. 1).

The squamous portion of the temporal bone provides for articulation with the head of the inferior maxilla a glenoid fossa bounded in front by the articular eminence and behind by the tympanic plate. The posterior compartment of the fossa lodges a segment of the parotid gland while the anterior or mandibular compartment presents a deep, cartilage covered concavity the radius of curvature of which in the sagittal plane corresponds very closely to the radius of convexity in the same plane of the condylar head. The cartilage coating of the articular fossa is continued forward upon the articular eminence so that this joint surface, as represented by the cartilage covered area assumes on sagittal section a concavoconvex profile (Fig. 3).

Interposed between these bony articular surfaces is the extremely interesting interarticular fibrocartilage or joint meniscus the structure and relations of which have a particular bearing on the subject in hand.

This meniscus is a thin fibrous plate of oval form thicker at its circumference, especially behind, than at its center where indeed, a normal perforation is occasionally found. It is closely and intimately applied to the condylar head and so maintained in part by its circumferential attachment to the capsular ligament but more by its relation to the fibers of the external pterygoid muscle which gain an insertion to the neck of the condyle in front and to the corresponding anterior margin of the meniscus as well (Figs. 1 and 3).

A capsular ligament envelops the joint in a thin loose capsule passing from the margins of the glenoid cavity and the articular eminence immediately in front to the upper margin of the interarticular fibrocartilage and from the lower

Fig. 3. Vertical section of temporomaxillary articulation to show relations of the condyle, meniscus, synovial cavity, pterygoid muscle and glenoid fossa. (After Gray.)

margin of this cartilage to the neck of the condyle which it completely invests (Fig. 4).

The joint cavity is thus divided by the interarticular fibrocartilage into two separate and unequal compartments. Both of these compartments are provided with distinct synovial sacs, the upper one of which is much larger and more extensive, and its lining membrane is continued from the margin of the cartilage covering the glenoid cavity and articular eminence and reflected onto the upper surface of the fibrocartilage. The lower and smaller passes from the undersurface of the cartilage to the neck of the condyle (Fig. 3).

This delicate structure is supplemented by three important ligaments designed to stabilize the articulation and confine the mobile condylar head within normal limits. Of these, the external lateral ligament is attached to the outer surface of the zygoma in front of the joint whence it is directed obliquely downward and backward to secure attachment to the outer and posterior border of the neck just below and behind the head (Fig. 4). It quite obviously is designed as a check ligament to limit the posterior excursion of the head and thus tends, not only to prevent posterior dislocations, but endeavors as well to protect the neighboring middle ear.

The stylomandibular ligament extends downward and forward from the tip of the styloid process to the posterior border of the angle of the jaw (Fig. 5) and gains attachment to a point distal to the axis of rotation of the bone. Its mechanical advantage is consequently exerted (1) to check extreme anterior rotation of the jaw and (2) thus indirectly and simultaneously to limit the posterior excursion of the head. The internal lateral ligament, of lesser importance, is so disposed as to stabilize lateral mobility of the inferior maxilla but it, too, by reason of its insertion

Fig. 2 Sagittal section of the articular disc one half of which has been removed to show the central and anterior ridges with depression between them. The attachment of the external pterygoid muscle also is shown (After Pringle)

It is the intent of the present report to add to the existing meager knowledge of the subject merely another experience which may perhaps contribute a better conception of temporomaxillary subluxation and possibly lead to the development of standardized methods for its treatment.

Concerning the nature of this lesion the conclusion naturally first suggests itself that the disturbances observed are dependent solely upon simple complete recurring dislocations of the condyle of the inferior maxilla differing only in degree from the common traumatic dislocations, with which it was therefore classified for a considerable period of time.

In 1827 however Sir Astley Cooper directed attention for the first time to the possibility that relations intermediary between normal and complete dislocation might exist between the condyle and its glenoid cavity, i. e., incomplete luxation or, as he termed it, subluxation.

According to his conception subluxation of this particular articulation involved the separation of the interarticular fibrocartilage or meniscus from the condyle to which it is normally firmly attached, followed by the riding forward of the condyle, without its meniscus, onto the articular eminence. In short, the process was essentially an intrinsic internal derangement of the articulation quite distinct etiologically and pathologically from the result of external trauma as seen in the simple complete dis-

locations. As a result of Cooper's experience with 4 cases, he came to the conclusion that the disease was practically confined to the female sex in which general depletion and lowered resistance by determining an abnormal relaxation of the joint ligaments, became the actual inciting factors in this type of interarticular disorganization.

Even though the results of subsequent investigation seem to call into question this interpretation of the mechanism productive of snapping jaw, Cooper's observation derives its real importance from the fact that it established the identity of subluxation of the temporomaxillary joint in particular and directed attention to the significance of internal joint derangements in general.

This variety of dysfunction is, of course not confined to the temporomaxillary joint for its prototype is not uncommonly observed in such joints as the shoulder, hip and knee—in other words, in those articulations the functional demands of which have developed the need for specialization in structure.

It is pertinent at this point to recall certain biological principles, which have a practical bearing upon this subject. In general it may be stated that the survival of a species is dependent upon the integrity and efficiency of certain physiological processes which are vital to the individual of the species. Nature's methods of safeguarding and rendering more effective such vital functions are well demonstrated in race history as developmental specialization. Specialized functions require specialization in structure proportionate to the importance of the function concerned.

As applied particularly to articulations, we find that those joints the function of which has to do with locomotion, defense, the acquisition of food and its preparation for assimilation express these principles in terms of the highest mechanical development. The equipment of the knee, hip, shoulder, and temporomaxillary joints exemplifies in varying degrees an architecture designed to give the utmost in efficiency and mobility without sacrifice of stability, an ideal which is attained by an elaborate development of synovial membranes, articular cartilages and ligaments. Of these the temporomaxillary is unquestionably the most highly specialized, intricate, and efficient and may, perhaps for this reason be regarded as the most important from a biological viewpoint.

At the same time the increasing structural complexity which goes hand in hand with higher

separation of the meniscus from the condylar head followed by the riding forward of the latter, minus this meniscus, upon the articular eminence. Thus according to this theory, the gross pathology involved the separation of the meniscus from the head of the bone. Pringle, however, in discussing this point, recalls the fact that, although the generously proportioned superior joint compartment permits free movement in the horizontal plane between cartilage and the surface of the glenoid, the limited lower compartment permits only restricted rotary motion between the cartilage and head of bone. Therefore while it may be dragged freely in all directions over the condylar head, the cartilage is intimately attached thereto at its periphery and accordingly must accompany the condyle in any position assumed by it. For this reason, complete dislocation of the cartilage alone does not take place and explanation of the phenomena of subluxation on this basis consequently becomes unacceptable.

In offering an alternative explanation Pringle directs attention to certain significant features in the structure and relations of the cartilage. He refers to the fact that the cartilage as applied to the dome like head of the condyle presents in the coronal plane and extending over the summit of the dome a thickened ridge in front of which there is a corresponding depression. Hence, as seen from its lateral aspect it assumes a concavoconvex surface which fits accurately the reciprocal irregularities of the glenoid fossa. Furthermore, it will be recalled that the powerful internal pterygoid muscle gains an attachment to the antero internal aspect of the cartilage thus tending to exert at this point in the loosely applied structure a potential pull the direction of which is forward and inward (Fig. 2).

Utilizing these facts Pringle suggests the theory that under certain conditions e.g. a sneeze with the mouth in the wide open position a sudden violent contraction of the internal pterygoid muscle may act to displace the loosely applied cartilage so that the thick central ridge lies obliquely instead of transversely. The cartilage then assumes the rôle of a foreign body caught between the rolling condyle and the glenoid surface. The disc is crushed between the opposing bony surfaces and painful locking of the joint is prone to follow. These events produce stretching of the periarticular tissues promoting recurrence of the same phenomena and giving rise to the annoying snapping noise characteristic of the condition.

This theory is a satisfactory explanation of the causation of the symptoms noted in snapping jaw

Fig. 5 Internal aspect of temporomaxillary articulation to show internal lateral capsular and stylomandibular ligaments (After Gray)

and is founded upon actually demonstrable mechanical and anatomical conditions. It is most probable that the majority of clinical examples of this lesion owe at least their inception to some variation of the train of events described.

Nevertheless it is evident that whatever may be the mechanisms initially concerned, the sum total of their operation is periarticular relaxation and that several other factors also may enter into the production of this latter condition. The following case may be cited as illustrative of this point.

D. W., a robust male aged 23 years was first seen February 1, 1926 in consultation with his physician. In 1920 he had sustained an injury to his lower jaw which was said to have resulted in a fracture dislocation. Upon removal of the retentive dressing applied in treatment of this condition he observed that the left temporomaxillary joint exhibited an unwonted degree of mobility. As time went on this mobility became gradually more pronounced and every active motion of the lower jaw became associated with a loud snapping noise referred to this joint. Recently the right articulation began to display similar disturbance but to a lesser degree.

Eventually the noise emitted by the left joint became so prominent and constant as to intrude itself annoyingly into the conversation whenever the patient opened his mouth to articulate. So seriously did this state of affairs interfere with his occupation as an insurance salesman that some relief from the embarrassing situation became imperative.

Examination of the affected joint gave but little information. There was no tenderness to pressure and no deformity could be detected. The condylar head upon the left seemed slightly greater than upon the right. Passive motion of the lower jaw with muscles relaxed disclosed very definitely an abnormal laxity in both joints but was particularly marked upon the left. When active motion of the lower jaw took place as in opening the mouth a loud snapping noise was

Fig 4 External aspect of temporomaxillary articulation to show external lateral and capsular ligaments (After Gray)

in proximity to the axis of rotation of this bone, undoubtedly is a supporting factor in the movement.

It is therefore apparent that the mechanical disposition of the extrinsic ligaments, together with the posterior thickening of the capsular ligament which is strongest in this region represent elaborate precautions against the possibility of posterior displacement of the condyle. It is equally apparent that no analogous structure is provided to restrict the degree of posterior rotation of the angle of the inferior maxilla and in consequence the excursion of the condyle forward in proximity to the thinnest and weakest portion of the capsular ligament. These structural peculiarities unquestionably bear a causal relation to the prevalent forward luxation of this joint.

This anatomically complex structure is capable of translating itself into a versatility of movement which is seen in no other joint and which resolves itself into three chief and distinct types: (1) a hinge like motion about a transverse horizontal axis drawn tangentially to the upper articular surfaces of the condylar heads and taking place entirely in the inferior synovial cavity; (2) an anteroposterior gliding movement along a horizontal plane, taking place entirely in the roomy upper compartment between the upper surface of the meniscus and the glenoid cavity; and (3) an oblique rotatory movement made up of two components: (a) a rotatory movement about a vertical axis through each condylar head confined to the lower synovial compartment and (b) an oblique gliding movement confined to the

upper compartment, the meniscus gliding forward and inward on one side as it moves backward and inward on the other.

Normal mastication of food, incident to its preparation for the first step of physiological digestion, calls into play all the resources of this mechanism. As the mouth is opened in anticipation of the reception of food, the point of the jaw is depressed the angle begins to rotate posteriorly while the condyle and major portion of the ascending ramus move forward. The fixed point or axis of rotation of the inferior maxilla as a whole is represented by a horizontal line drawn through the two dental foramina.

In effect the mechanics of this movement suggest a close analogy with those of a lever of which the axis of rotation or fixed point corresponds to the fulcrum, the ascending ramus from the dental foramina to the joint surface corresponds to the short arm while the horizontal ramus inclusive of the angle, may be likened to the long arm. Depression of the point of the jaw, the long arm of the lever is at the outset compensated at the joint—the apex of the short arm—by a hinge like motion confined to the lower synovial compartment. But as the movement of the long arm carries through the end of the short arm, obeying the principle of levers, is called upon to travel through an arc proportionate to that described by the end of the long arm. At this point, since the hinge motion of the lower compartment is no longer adequate the upper compartment comes into action permitting the condyle with its meniscus to glide forward upon the summit of the cartilage-covered articular eminence. Normally the condyle never passes this summit for should it do so, it slips over with its meniscus, into the zygomatic fossa to become a true dislocation. Nevertheless it is to be noted that the margin of safety here is a very narrow one since there are no evident safeguards such as those observed posteriorly, to interpose a check upon excessive movement and possible dislocation.

As the inferior maxilla returns to its original position in the shutting movement of the jaw, the condyle glides back with its meniscus in the reverse direction utilizing the combination of the gliding hinge and rotary motions to give the cutting and tearing power to the incisor teeth.

These structural and functional details relating to the temporomaxillary joint are worthy of consideration in seeking to establish the true nature and etiology of its subluxation.

Cooper believed as noted above, that the causative factors in this condition comprised the

in his case of snapping jaw the classical triangular incision, while Blake resorted to a transverse incision along the zygoma only to find that he was unable to carry out the procedure planned through such exposure.

In the case herein reported I found the vertical skin incision to be quite suitable for purposes of joint exploration and believe that, at least from a cosmetic viewpoint, it possesses considerable advantage.

This incision is carried down to the deep fascia and here an expedient based upon the local anatomy may be utilized to safeguard the temporofacial nerve. Dissections of this region demonstrate that this nerve remains deep to the deep or external parotid fascia until it reaches a point well above the level of the zygoma, where it is seen to pierce this fascia to continue its course superficially (Fig. 6). It will be recalled also that the deep fascia of this region splits below into two layers to enclose the parotid in its fascial capsule, the external and internal leaves of which again unite at the zygoma to become continuous with the temporal fascia.

Keeping in mind these anatomical facts the operator may widely retract the vertical skin incision and transversely incise the external leaf of the parotid fascia for a distance of 2 inches parallel to and just below the zygoma. The nerve, since it is deep to the fascia at this point, is safe from injury and the gland, thus freed, may be retracted downward and forward carrying the nerve with it out of the field of operation (Fig. 6).

The actual method of treatment to be applied to the articulation itself in attempting correction of the symptoms of subluxation must necessarily depend upon the gross pathology encountered. Physiological considerations suggest that operative effort must be directed (1) to the meniscus itself which may call for fixation or removal and (2) to the unduly mobile condylar head and the abnormally relaxed capsule, the former requiring limitation of its excursion and the latter demanding some expedient to overcome periarticular laxity. I was fortunate in meeting conditions which responded to simple plication of the capsule. It is improbable, however, that such favorable conditions frequently exist and it appears evident from the large number and wide diversity of methods proposed that none has been universally satisfactory.

The following classification of methods operative and non-operative which have been suggested for treatment of subluxation of the inferior maxilla, has been compiled from the liter-

ature and gives some conception of the scope of efforts in this direction.

I Non-operative methods

A Dental technical procedures

1 Outside mouth

a Apparatus, fastened around chin and held in position by cap on head limits chewing motion and depression of point of jaw.

2 Inside mouth

a Splint, fastened to upper and lower jaw with interlocking catch hinge, is adjustable to limit motion of lower jaw (Schroeder).

b Hard rubber plate fixed to upper jaw and provided with process pointing to edge of masseter muscle or coronoid process limits excursion of latter (Fritzschke).

B Injection of corrosive fluids into joint (to produce shrinkage of capsule and promote adhesions)

1 Tincture of iodine (34 cubic centimeter tincture of iodine injected into joint posteriorly secured permanent cure in case of girl aged 20 years reported by Perthes).

2 Alcohol

II Operative method

A Treatment of capsule

1 Excision of portion of capsule is followed by suture to overcome redundancy (Perthes).

2 Simple plication of capsule after exploration of joint takes up redundancy and tightens joint.

B Utilizing fascial strip (turned down from temporal region to check excursion of head as described by Nieden)

C Treatment of meniscus

1 Fixation of disc by suture to periosteum of mandibular fossa (Haeber).

Fixation of disc in vertical position in front of condylar process (Konjetzny).

3 Removal of the articular disc (Ashurst).

Of the non-operative methods, those depending for their effectiveness upon the employment of some mechanical apparatus whether external or internal to limit the excursion of the lower jaw are open to serious objection. Externally applied mechanisms of the type described above are obviously impracticable, while those splints devised for internal use give rise to pressure ulcers, periostitis, general discomfort, and pain.

Nieden remarks that resort to methods of this sort indicates either that operative measures must be quite ineffective or that they are too little known, the latter explanation being in his opinion the acceptable one. Perthes however reports a permanent cure in the case of a girl, aged 16 years, treated 6 months by means of a hard rubber splint of the Fritzschke type.

The injection of corrosive fluids into the joint to secure shrinkage of the capsule and to promote adhesions has some basis in reason and Perthes reports a case in which a cure was obtained by injecting tincture of iodine into the joint capsule posteriorly. This raises the interesting question as to how much the factor of irritation contributes

audible throughout the room as the head of the bone rode over its articular surface. All motions were carried out without pain and there was no limitation to any normal movement.

X-ray examination demonstrated normal joint outlines. With the mouth wide open the left condylar head rode forward farther on the articular eminence than did the right but no true dislocation could be shown.

Although he was advised that surgical measures offered a very dubious prognosis for cure of this condition the patient was insistent that some attempt at operative relief be undertaken.

Operation was performed on February 1926 at the Post Graduate Hospital. General anesthesia was used. A vertical incision 2 inches in length with its upper extremity overlying the root of the zygoma was made just in front of the auricle. The incision was carried down to the deep fascia and the auriculotemporal nerve and superficial temporal vessels were retracted posteriorly. A transverse incision was made along the inferior margin of the zygoma and carried forward through the deep or external parotid fascia. The parotid gland now could be retracted downward and forward carrying with it the temporofacial branch of the facial nerve. The joint itself was easily exposed without danger of injury to important neighboring structures. The capsule was found to be extremely relaxed and loose permitting an unusual degree of mobility to the condylar head within its glenoid cavity. The capsule was incised vertically to expose the interior of the joint which could be readily explored due to the laxity of its capsule. The joint meniscus could not be found and the articular surface of the condyle was roughened and ebarnated. For the purpose of limiting the mobility of the condylar head its articular surface was scarified and after closing the capsule a series of reefing stitches of chromic gut were inserted. The wound was closed without drainage and the lower jaw immobilized by means of a bandage.

The incision healed uneventfully. On the seventh day after operation the bandage was loosened to permit some motion of the jaw. On the tenth day the retentive dressing was completely removed and ordinary motion was encouraged. At the end of the second week all functions could be carried out without pain. The joint was perfectly stable. abnormal mobility appeared to be corrected and the annoying snapping noise had completely disappeared. When last seen 3 years after operation the patient had no complaints and was well pleased with the results obtained.

Peri articular relaxation appears to have been the etiologic factor in the symptoms described in this case. Relief of the symptoms was accomplished by joint scarification and plication of the lax capsule. It is probable that the peri articular relaxation was directly attributable to the loss of the stabilizing action of the joint meniscus whose absence may in turn be traceable to the effects of trauma sustained when the jaw was fractured 6 years previous to the onset of the snapping jaw. It may be surmised that such an injury could have produced fracture or crushing injury of the meniscus sufficient to determine its atrophy and complete dissolution.

Concerning technical details, it is worthy of note that this joint although superficially placed is surprisingly inaccessible for satisfactory surgical approach and its adequate exposure presents

somewhat of a problem. On the one hand, cosmetic demands limit the incision as to length and location, on the other certain restrictions are imposed by the proximity of important structures requiring protection. Among the latter may be mentioned the facial nerve (temporofacial branches), superficial temporal vessels, auriculotemporal nerve and internal maxillary artery.

The facial nerve, after leaving the stylomastoid foramen, passes downward outward, and forward through the substance of the parotid gland to divide, just posterior to the ascending ramus of the inferior maxilla, into two main terminal groups: the temporofacial and the cervicofacial. The former running forward and upward in front of the external auditory meatus passes close to the joint on its antero-inferior aspect (Fig. 6). A line drawn on the surface from the tip of the mastoid to the outer canthus of the eye represents roughly the highest branch of this group of nerves. Close to and in front of the external auditory meatus the superficial temporal vessels and the auriculotemporal nerve in their vertical course to the temporal region pass just posterior to the articulation although on a more superficial plane.

Thus as pointed out by Henderson and New the articulation occupies roughly the center of a triangular area: base upward, bounded by the temporal vessels behind and the temporofacial nerves in front. This triangular area is therefore devoid of superficial structures of importance and through it the joint may be safely exposed.

The internal maxillary artery is deeply placed, passing close to the inner side of the neck of the inferior maxilla, and is therefore not liable to injury during simple arthrotomy procedures.

The conventional incision described for exposure of the joint has been planned with radical excision in mind. Murphy, Lihenthal, Henderson and New and Annonale employed incisions which, save for unimportant modifications are identical in principle, i.e., each is a curved hook-shaped or right angled incision with one limb parallel to the zygoma and the other carried downward in front of the pinna to secure a triangular flap. Burdick for purposes of joint resection has modified this incision by the addition of a posterior limb carried back over the ear and is of the opinion that the sacrifice of the temporal vessels thus entailed is more than compensated by the increased effectiveness of the exposure so obtained.

In operations limited to arthrotomy however a simple vertical incision in front of the pinna has usually proved to be quite adequate for the purpose in hand. Nevertheless Ashhurst utilized

treatment of both capsular and meniscus derangements if satisfactory results are to be obtained.

It is worthy of note that modern joint surgery in general, under the influence of accumulating experience and perfected technical detail, has shown a tendency to widen its scope of operability. Operative indications, which were formerly limited to the more grave pathological conditions, have been gradually extended to include a variety of derangements the minor character of which did not justify the hazards imposed by the older methods. The acceptance of the minor joint lesions for radical surgical treatment indicates the highest degree of confidence in the safety and efficiency of the methods employed and offers as well the most convincing evidence of the advances made in this field.

The temporomaxillary joint, however, has been slow to profit by this development and there still exists a very evident reluctance to apply to this joint the principles which have proved their safety and effectiveness in analogous minor lesions of the knee, hip and shoulder.

Glancing over the list of measures proposed for treatment of temporomaxillary subluxation, one is impressed by the number of methods and the diversity of principle represented. Under ordinary circumstances such a state of affairs spells the complete failure of all suggested methods to solve satisfactorily the problems presented and this interpretation may not be unjustified in this instance. Nevertheless, it appears to the writer that the true explanation must be sought in the failure to recognize the pathological physiology of this condition. If the choice of treatment be predicated upon a study of the normal mechanics of the joint and of the factors underlying subluxation the selection of the method will be limited to those few operations emphasized above which are competent to cope with the physical principles involved. Wider usage of these methods will prove their practical utility and will demonstrate that numerous cases of temporomaxillary subluxation which have been habitually rejected may be accepted for treatment with every assurance of a satisfactory result.

SUMMARY

In conclusion, therefore the present status of temporomaxillary subluxation may be summarized as follows:

1. Temporomaxillary subluxation is a definitely distinct entity the pathological condition of which is characterized by a distortion of the normal relations of the joint meniscus leading to

capsular relaxation. Resulting disturbances in joint mechanics are responsible for a variety of joint dysfunction best known as snapping jaw.

2. Commonly seen as a painless, noisily functioning joint the efficiency of which is not at all impaired, it is occasionally encountered in the form of chronically recurring attacks of pain and locking requiring immediate treatment.

3. There exists an unexplained reluctance to apply to this joint the radical operative measures which have become the accepted treatment for analogous minor lesions of other joints.

4. Failure to take into consideration the pathological physiology of temporomaxillary subluxation has been responsible for a large number of proposed methods of treatment representing a wide divergence of principles.

5. Two methods of treatment are emphasized which are based upon sound surgical principles and upon a study of the mechanics of the joint.

6. Utilization of these methods should standardize treatment and demonstrate the practicability of accepting a larger group of these cases for radical operation.

Fig 6 Schematic drawing from dissection of parotid region. Horizontal incision has been made along lower border of zygoma through the external leaf of the parotid fascia. The parotid is then turned downward and inward after the temporo-facial has been dissected free (note groove) in order to permit latter to assume normal relation to the neck of condyle. Note temporo-facial nerve piercing fascia above condyle.

Fig 7 Showing plan of Nieden's operation. Flap of the temporal fascia turned down and sewed to capsule of joint (After Nieden)

to produce cure in joints subjected to the trauma of such operations as capsular plication.

Of the operative methods the procedure of Nieden is based upon the soundest surgical principles. In this operation the joint capsule is exposed through a vertical incision which is then extended upward and backward thus exposing the temporal fascia. A strip of this fascia with base above the zygoma is turned downward in such a manner as to permit suture of the free end into the joint capsule thus limiting the excursion of the condylar head (Fig 7).

Nieden employed this operation successfully in the treatment of a case of bilateral subluxation and was able to demonstrate after operation the functioning of the cheek ligaments whose pull could be plainly felt beneath the skin as the condylar head moved forward during the act of rotation of the inferior maxilla.

This operation and that of simple plication of the joint capsule undoubtedly offer the most effective means available for correction of subluxations dependent upon capsular relaxation and are therefore the methods of choice in these cases. Some writers believe however, that capsular relaxation represents a secondary manifestation of pathology residing in the meniscus and consider that, to be adequate, treatment must be directed at the primary condition.

Haber fixed the disc by suture to the periosteum of the acetabulum and Konjetzny resorted to a more elaborate procedure to fix the disc forward on the condyle. After exposing the joint, he separated the disc from its anterior relations with the capsular wall, the lateral and medial relations being carefully preserved. Some of the upper fibers of the external pterygoid muscle are separated from the condyle and the disc is then displaced forward on the articular head of the bone until it is in a vertical position where it is fixed by sutures. Ashhurst has gone to the extreme of completely removing the disc and reports good results therefrom.

The rationale of fixing the meniscus to the periosteum of its acetabulum is apparent in view of what has gone before and it is equally apparent that operative displacement or actual removal of the cartilage is not free from harmful results. Knowing that this structure equalizes the movements of the condyle and serves by virtue of its elasticity as a buffer between the articular surfaces of the joint its deliberate forward displacement seems scarcely justifiable under ordinary circumstances. Concerning its actual removal, it may be pointed out that in the case here reported absence of the cartilage seems to have been the factor leading to capsular relaxation and subsequently to subluxation.

In the final analysis it must be said that every case of subluxation must be a rule unto itself and it is probable that the majority of instances will present pathological conditions which will require

treatment of both capsular and meniscus derangements if satisfactory results are to be obtained.

It is worthy of note that modern joint surgery in general, under the influence of accumulating experience and perfected technical detail, has shown a tendency to widen its scope of operability. Operative indications, which were formerly limited to the more grave pathological conditions, have been gradually extended to include a variety of derangements the minor character of which did not justify the hazards imposed by the older methods. The acceptance of the minor joint lesions for radical surgical treatment indicates the highest degree of confidence in the safety and efficiency of the methods employed and offers as well the most convincing evidence of the advances made in this field.

The temporomaxillary joint, however, has been slow to profit by this development, and there still exists a very evident reluctance to apply to this joint the principles which have proved their safety and effectiveness in analogous minor lesions of the knee, hip and shoulder.

Glancing over the list of measures proposed for treatment of temporomaxillary subluxation, one is impressed by the number of methods and the diversity of principle represented. Under ordinary circumstances such a state of affairs spells the complete failure of all suggested methods to solve satisfactorily the problems presented and this interpretation may not be unjustified in this instance. Nevertheless, it appears to the writer that the true explanation must be sought in the failure to recognize the pathological physiology of this condition. If the choice of treatment be predicated upon a study of the normal mechanics of the joint and of the factors underlying subluxation, the selection of the method will be limited to those few operations emphasized above which are competent to cope with the physical principles involved. Wider usage of these methods will prove their practical utility and will demonstrate that numerous cases of temporomaxillary subluxation which have been habitually rejected may be accepted for treatment with every assurance of a satisfactory result.

SUMMARY

In conclusion, therefore, the present status of temporomaxillary subluxation may be summarized as follows:

1. Temporomaxillary subluxation is a definitely distinct entity the pathological condition of which is characterized by a distortion of the normal relations of the joint meniscus leading to

capsular relaxation. Resulting disturbances in joint mechanics are responsible for a variety of joint dysfunction best known as snapping jaw.

2. Commonly seen as a painless, noisily functioning joint the efficiency of which is not at all impaired, it is occasionally encountered in the form of chronically recurring attacks of pain and locking requiring immediate treatment.

3. There exists an unexplained reluctance to apply to this joint the radical operative measures which have become the accepted treatment for analogous minor lesions of other joints.

4. Failure to take into consideration the pathological physiology of temporomaxillary subluxation has been responsible for a large number of proposed methods of treatment representing a wide divergence of principles.

5. Two methods of treatment are emphasized which are based upon sound surgical principles and upon a study of the mechanics of the joint.

6. Utilization of these methods should stand ardent treatment and demonstrate the practicability of accepting a larger group of these cases for radical operation.

REPORT OF A CASE

IRA I KAPLAN, D.S. MD. NEW YORK

Attending Radiation Therapy, Bellevue Hospital

SO much confusion and controversy exist regarding the effect of X rays on the female and her offspring that many physicians are prone either to withhold the therapeutic use of the X ray, or to use it only as a last resort in hopelessly diseased conditions. It is well known that the X rays have proved beneficial in the treatment of pathological gynecological conditions where a repressive action is desired, and its use in such cases is considered proper procedure. But in the treatment of functional female disorders, especially where subsequent pregnancies are desired, such use has not as yet met with universal approval. The occasional unfortunate malformation of offspring born of irradiated mothers has been heralded as a positive contra indication for its use in the case of women with childbearing possibilities. An attempt has been made to apply the conclusions of radiation's ill effects on lower animals to humans but as yet no proof has been authenticated justifying such interpretations of these phenomena, nor are we sure that the response of tissues of the different species to identical irradiation is the same.

As proof of the evil effects of radiation Murphy cites his study of statistics of malformed offspring of irradiated mothers, and there are indeed many instances (16) reported in the literature of the birth of abnormal children following irradiation of the mother. In all these cases however, radiation was given during the course of pregnancy, and we may explain these occurrences from our knowledge that as radiation is most effective in destroying embryonic tissue the fetus is the first to suffer. That a radiated fetus is usually impaired *in utero* has been shown by Ries Zappert, and Kames, although Kane reports a normal child following radium therapy during pregnancy. In its employment for the treatment of functional disturbances of the ovary and for sterility however we attempt to limit the radiation action primarily to the ovary and that normal children may be born following such radiation of the ovary has been reported by Rubin, Rongy, Martius, Doederlein, the present writer, and others. Whether or not an ovary so irradiated as to suppress the menstrual phenom-

ena for a more or less extended period of time can recover so as to produce again healthy ova which are capable of fertilization and development into normal children is not so definitely proved, yet such occurrences as have been reported especially by Doederlein and Schmitt, would seem, however to bear out this assumption.

In connection with this question, one must consider the permanency of such suppression of ovarian function. Not all the factors which limit our ability to suppress ovarian function by X rays are determined. Beclere suggests that there is an age limit to permanency of roentgen castration. Stern, in his work on irradiation of fibroids, noted the difficulty in producing amenorrhoea in young women. Penzoldt is of the opinion that the injury to the ovum may continue up to 4 months after irradiation of the ovary and therefore impregnation within that time may lead to the formation of an imperfect fetus but ova occurring with later menstruation may be normal and allow for natural impregnation and subsequent normal fetal development.

Titus has reported normal pregnancy in the case of carcinoma of the cervix treated by radiation. In 1928 I reported a case of twin pregnancy occurring after a temporary amenorrhoea of 7 months, removed by operative procedure and as far as histological examination could show the developing embryos were evidently normal before operation.

It is well known that pregnancy tends to debilitate patients suffering from acute tuberculosis especially where frequent pulmonary hemorrhage occurs. For this reason in such conditions abortion is usually advised. Until now surgical emptying of the uterus has been the method employed but following upon the report of the successful work done by Weyer and Mayer in therapeutic abortion by X ray irradiation this latter method has been suggested by our service at Bellevue Hospital, for the handling of such cases.

In the case reported herewith there existed a severe acute pulmonary tuberculosis with recurrent hemorrhages.

M. F. married and 30 years entered the hospital, February 1927 complaining of pains in chest and hæm-

orrhages from the mouth. She was 3½ months pregnant. She has one living child 8 years old and has had three miscarriages. On account of her pulmonary condition she was advised to have her pregnancy terminated. She received roentgen ray treatment over the pelvis. The dosage was 75 per cent anteriorly and 50 per cent posteriorly. A skin erythema dose was delivered by high voltage heavily filtered X rays over a period of 14 days. Spontaneous abortion failing to occur in 6 weeks the uterus was surgically emptied through simple vaginal hysterotomy on April 11, 1927. Following her operation she did not again menstruate and did not return to the clinic. When she did return on April 6, 1928 there were evident signs of pregnancy in our opinion of 2 to 3 months. The question then arose as to the advisability of permitting her to carry on. Inasmuch as the temporary amenorrhoea had benefited her general condition and no pulmonary hemorrhages had occurred during that time it was decided to let her proceed with the pregnancy, provided that by reason of the previous irradiation the fetus was not damaged and would develop normally. We felt reasonably sure no damage had occurred to the fetus and she so assured the mother. She proceeded normally with the pregnancy and on October 27, 1928 gave birth to a perfectly normal male child weighing 7½ pounds. There was no difficulty in the delivery. Today 14 months following birth the child is hale and hearty and is altogether normal in development.

CONCLUSIONS

Permanent amenorrhoea in young women is not certain to be produced with X rays.

Not all ova may be destroyed by the X ray castration in young women and any such ova not destroyed may normally ripen, become impregnated, and develop into a normal healthy child.

Abnormality in a child so born has not been noted.

PREMEDICATION FOR LOCAL ANÆSTHESIA WITH INTRAVENOUS BARBITURIC COMPOUNDS¹

G DETAKATS MD MS FACS CHICAGO

From the Department of Surgery Northwestern University Medical School

THE search for improvement in local anæsthetic methods must necessarily take two directions. Prolongation of the duration of the usual procaine epinephrin anæsthesia is one aim of further progress. This subject has been taken up in a previous communication (2) and a further report on the use of the suggested quinine derivative will be made in the future (3).

The preparation of the patient for an operation under local anæsthesia is another important problem. The psychic reaction of the patient, his fear and nervous tension in the operating room, may render the best local anæsthesia unsuccessful. This is particularly true of the nervous, irritable patient, especially the hyperthyroid. The usual preparation with morphine atropine may not always satisfy in patients under high tension. Morphine is an excellent analgesic but, in the absence of pain it may only nauseate the patient or he may become highly sensitive and irritable. Atropine causes a dryness of the throat and while the suppression of the bronchial secretion and the diminution of vagal reflexes are welcome under general anæsthesia the discomfort of the atropinized conscious patient is considerable. The use of scopolamine in doses of 1/100 grain to 1/50 grain is a great help but may occasionally produce toxic symptoms. Hallucinations, restlessness, and poor co-operation have been observed in youthful hyperthyroid patients. Scopolamine is most useful in prostatic cases in older patients, who slumber peacefully under a sometimes imperfect sacral block.

For several years I have been trying to find a suitable drug which would produce somnolence or superficial sleep without lessening the co-operation of the patient, and producing a deep anæsthesia. A number of papers from French and German clinics report deep surgical anæsthesia following the intravenous use of barbituric acid compounds. An article by Cleisz lists the French literature up to 1924. He describes 40 obstetrical cases and believes that the injection of 6 to 10 cubic centimeters of somnifen a mixture of diethyl and dipropenyl barbituric acid is the best analgesic method in childbirth. A number of other French gynecologists praise the value of this barbituric mixture. In Germany the method has been given a thorough trial by Siegert who in-

jected from 2 to 8 cubic centimeters of somnifen intramuscularly. There were many untoward symptoms and he concluded that the method was not applicable in gynecology.

From this and other reports it seemed wise to me not to aim at a deep surgical anæsthesia but rather to use small doses in preparation for local anæsthesia.

It is sufficiently known that the safety margin of the hypnotics of the barbituric acid series varies a great deal. In a study of 350 albino rats Nielsen, Higgins and Spruth determined the safety margin of barbituric compounds as the difference between the minimum effective dose and the minimum fatal dose, expressed in the percentage of the minimum fatal dose. From this study it appeared to me that barbital and luminal in particular had a comparatively small safety margin and that neonal was best fitted for my purpose (Fig 1).

METHOD OF EXPERIMENTS

In the first series of experiments, conducted in 1925, 10 patients were injected intravenously with 2 cubic centimeters of a 20 per cent somnifen solution (Table 1). This uniform dose was given in order to observe the relation of the sedative effect to age, sex and weight.

While youth, female sex, and light weight may increase the effect of the drug to a certain extent, the individual response seemed to outweigh any other factor. The maximal drop in pulse was 14 points, in respiration 5 points, in systolic blood pressure 11 points, and in diastolic blood pressure 7 points, as an average in 10 cases. This drop is within the normal limits of what occurs in sleep and started 10 to 15 minutes after the injection. An immediate drop after the injection, which would mean a direct influence on the vasomotor and respiratory centers, did not occur in this series.

There was one complete failure (Case 10) in a patient with inoperable carcinoma of the uterus who had been taking morphine and sedatives for a long time. In a girl, aged 18 years, dehydrated and under weight (Case 2) a deep sleep followed the injection. In the other cases somnolence or light superficial sleep was induced in 9 minutes and lasted 48 minutes on the average. In both

¹Presented at the meeting of the Society of Clinical Surgery, October 23, 1926 in Chicago.

cases of hyperthyroidism the effect wore off more rapidly, probably owing to the more rapid elimination in these patients. Case 7, after a superficial sleep for 10 minutes, got greatly excited, tossed about in bed, and showed a typical paradox reaction. She had been dismissed from an insane asylum 4 weeks previously. Such reactions will occur with morphine, luminal, and scopolamine too. In Case 9 an interesting amnesia was obtained in regard to the operation, although during the operation the patient answered clearly my inquiries concerning the recurrent nerve.

On the whole, there was a definite effect, without any untoward symptoms, to be noted in the series. The effect, however, wore off too soon and its action was difficult to foretell. It must be remembered that the dose was only one fourth of that recommended for deep surgical anesthesia.

In the second series neonal, in amounts varying from 20 to 60 centigrams, was given intravenously (Table II). There are interesting points to be noted here. In a case of hyperthyroidism (Case 13) we obtained a good effect which was produced very rapidly and wore off in 20 minutes. The dose was only 20 centigrams. The same patient with the same dose was greatly excited in the operating room and a general anesthesia had to be given. In the case of a man with degenerative stigmata absolutely no effect was obtained with 30 and 50 centigrams (Case 14).

In Case 17 a patient who had carcinoma of the cecum with metastases was given 60 centigrams of neonal intravenously. The effect was instantaneous. He fell into a deep surgical anesthesia, with no corneal reflexes which lasted 50 minutes, and then slept whenever left alone during the next 14 hours. His systolic blood pressure dropped from 138 to 96, the diastolic from 110 to 82. His pulse remained full and regular, dropping only 0 points. The respiration dropped 6 points. His condition did not look alarming except for a slight cyanosis of his finger tips. Cyanosis was observed also in Case 14, that of a man who was operated upon under local anesthesia for an inguinal hernia. The cyanosis could not have been due to cardiac failure in either case but must have been due to an incomplete oxidation of hemoglobin.

In the third series of experiments subcutaneous injections were tried (Table III). Two cubic centimeters of a 15 per cent solution of neonal were injected into 7 patients. The injections were painful and left marked infiltrations for several days. One patient, although co-operative during thyroidectomy, had a complete amnesia concerning the operation. She developed a generalized

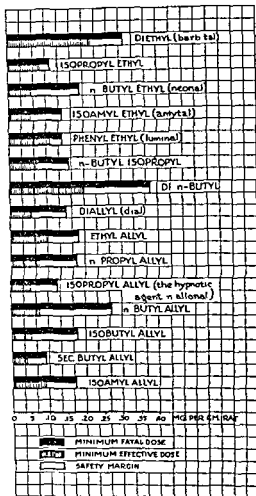

Fig 1. Safety margin of barbituric compounds from Nielsen, Higgins and Spruth.

urticaria, probably the effect of medication, on the fourth day after operation. Three patients showed no effect at all. Another three were hardly affected.

In the fourth series oral medication was tried (Table IV). In addition to the customary dose of 40 centigrams (3 grains) of neonal or allonal the night before the operation, I administered 20 centigrams three times on the day preceding the operation. Thus the patient received 20 centigrams in the morning, 40 centigrams at noon, and 40 centigrams in the evening. If necessary an other dose of 40 centigrams was given 2 hours before the operation. The patient thus received a gram of neonal in 24 hours, which is a considerable dose because the drug tends to accumulate in the body. In this series, 5 patients were not

affected at all and only 3 showed a real sedative effect. The disadvantage of keeping the patient in a somnolent state the day before the operation will be discussed later.

DISCUSSION

A report on the 35 cases shown in the tables would hardly seem warranted. However, as I

have discontinued this premedication and as, recently, renewed interest is being shown in intravenous hypnotics publication seems worth while in spite of the paucity of data.

The outstanding feature of the barbituric acid series particularly in intravenous dosage is the difficulty of foretelling the individual response. The patient's age, sex and weight influence the

† See red as explained in footnote to Table I

dosage to some extent but more important is the amount of anxiety which is to be overcome. An 18 year old girl with exophthalmic goiter became quite sleepy after the injection of 2 cubic centimeters of 10 per cent neonal (Case 12). The same patient a few days later received the same dose and was taken to the operating room where she became greatly excited and had to be put to sleep (Case 13). A similar experiment was made on a woman aged 54 years who reacted differently in her room from what she did in the operating room (Case 28).

The intravenous dosage in this series was about one fourth to one fifth of what had been recommended for obtaining deep surgical anesthesia. In Case 17 however a dose of 60 centigrams of neonal (4 cubic centimeters in 15 per cent solution) resulted in deep surgical anesthesia for 50 minutes, followed by a deep sleep for 14 hours.

While the pulse and blood pressure did not drop to an alarming degree a slight cyanosis was present. It was after this experience that I decided to give up the intravenous medication. In a young woman, weighing 56 kilograms, a dose of 40 centigrams of somnifen produced great restlessness, excitement, flushing of the face and dryness of the throat. Such individual and previously inestimable reactions make very difficult the use of intravenous sedatives, at least that of the two drugs which I employed. The effect wears off, in most cases, very rapidly, whereas the anesthesia sets in very quickly.

The subcutaneous medication was soon abandoned because of the pain at the site of injections and because of the slow absorption of the drug into the blood stream which made impossible its accumulation in satisfactory concentration. Perhaps intramuscular injections could be tried as

used by Siebert, to obviate the pain accompanying subcutaneous injections

The protracted oral medication resulted in just as many different individual responses as did the other forms of administration. Furthermore to produce a sedative effect, the patients were kept in a somnolent state an entire day before operation which hardly seems desirable. Their nutrition is thus impaired and the glycogen storage of the liver cannot be so well maintained. Prolonged sleep after the operation is equally undesirable. The patients are more apt to develop pulmonary complications and their nutrition, unless subcutaneous and rectal medication is resorted to is impossible. It is well known that patients who take barbitol for suicidal purposes quite frequently develop pneumonia.

On the basis of these few experiments I hesitate to say that analgesia or light sleep produced by barbituric acids is not feasible. With larger doses, I could readily have induced deep anæsthesia as was obtained in one case. I feel, however, that the advantage of inducing a rapid surgical anæsthesia by the help of intravenous medication is offset by the uncertainty of the effect, by the prolonged sleep as in true barbituric acid poisoning, and by the inability to stop or counteract the effect of the anæsthetic. This of course is the difficulty with all intravenous and rectal hypnotics.

There is only one type of case in which intravenous administration of the barbituric series seems well worth while. Hofvendahl advised intramuscular injections of 2 to 4 cubic centimeters of somnifen in cases of cocaine poisoning. Tatum and his co-workers found that the minimal fatal subcutaneous dose of cocaine in the dog was 26.7 milligrams per kilogram. This minimal fatal dose could be raised to above 100 milligrams per kilogram weight with the prophylactic administration of a mixture of barbital sodium and paraldehyde. Hence a fourfold increase in tolerance to cocaine resulted. Convulsions were completely and instantaneously controlled by an intravenous injection of the barbital paraldehyde mixture. In addition, however, Dragstedt and Lang found that atropine would exert the same protective influence in case of cocaine poisoning.

It might be well worth while to consider an intravenous injection of one of the soluble barbituric acid derivatives, such as somnifen, neonal, or amytal, in cases of acute novocaine poisoning, with convulsions, which almost invariably is the result of an intravenous injection. On the basis of Dragstedt and Lang's study it would appear that atropine could also be used.

SUMMARY

An attempt to produce, in patients operated upon under local anæsthesia a state of somnolence or light sleep by means of intravenous subcutaneous, and oral doses of hypnotics of the barbituric acid series is described. Because of great individual variations, this attempt was not successful and was given up after trial in 35 cases. It is possible that larger doses and other derivatives may give a more uniform effect. The protective action of the barbituric compounds against poisoning with cocaine and its derivatives is pointed out.

NOTE—The patients were selected from my service at the Surgical Clinic of the University of Budapest and at the Wesley Memorial Hospital Chicago. Drs. Allen B. Kanavel and Charles A. Elliot kindly permitted the use of some of their cases for which many thanks are due.

THE ANTHROPOLOGY OF THE NEGRO, ITS BEARING ON THE MORTALITY IN HEAD INJURIES

A REVIEW OF SIX HUNDRED CASES

J CALVIN WEAVER, M D ATLANTA GEORGIA

Asistant Professor of Surgery Neurosurgical Department School of Medicine Emory University

WITH the development of fast moving, high powered automobiles and the simultaneous appearance of a tragic disregard for law and the rights of others, the number of head injuries is rapidly increasing year by year, and the negro is receiving more than his proportionate share of such injuries. This is the result not only of his lesser degree of judgment—in many instances decreased by alcoholic intoxication—but also of his at least equal, if not greater, amount of indifferent recklessness.

For generations head injuries, especially fractures of the skull, have been viewed by the layman particularly as a most melancholy affair. There is no gainsaying the fact that even with the more scientific management of today, head injuries frequently have a tragic ending.

When one contemplates, from an anatomical point of view the infinite care with which the brain and spinal cord have been protected—the skull, enclosing the entire brain thickened where the impact is most likely to land the dural covering the strongest membrane in the body limiting turgescence and affording physiological rest, and the choroid plexus, a safeguard against infection—it prompts the conclusion that the brain, with its myriads of delicate nerve fibers is, of all the organs of the body least capable to care for itself.

My first memory of fear was occasioned by a negro idiot, Buck King by name in my native county of Upson. He had flat feet, his skull was of the scaphocephaloid type, and his lips were thick and protruding—the lower lip even drooping. His head was his only weapon and he revenged all his imaginary grievances by pinning against a wall the person whom he took to be the offender and butting him in the abdomen. My knowledge of this characteristic was no doubt the foundation of my well grounded opinion that a negro head would withstand much punishment. This idea seems prevalent throughout the southern states, and doubtless has existed for many years for in Dr S Weir Mitchell's *South of George Washington* the following incident illustrates this belief.

I had been told, of a Sunday morning of a great flock of ducks of the kind called canvasback and much esteemed. It was against our habits to

shoot on this day, but towards evening, the temptation being great, I went to the shore and was about to push off, when Peter, using the liberty of an old family servant, said I would make Mr Fairfax and my brother, then like myself at Belvoir, angry if I went. When he held on to the prow to stay me, I suddenly lost my temper and struck him with an oar on the head. He fell down and lay in a sort of a shake. I thought he was killed, and had he been white I must surely have put an end to him, but the blacks have thick skulls, and presently he got up and staggered away, his head bleeding."

Prompted by this statement and the knowledge that the Surgeon General's Library possessed no literature on this particular phase of head injuries, I concluded it would be interesting and timely to take advantage of the excellent opportunities afforded me to make a clinical study of a long run of head injuries in negroes, as compared with an equal number of similar cases in whites, in order to determine if there were any clinical foundation for this prevalent idea that a negro's head was more difficult to injure than a white man's.

It is an established rule in physics that a hollow sphere of smaller diameter will stand more stress and strain than a sphere of equal thickness but of greater diameter. That being true, it stands to reason that if the smaller sphere is also thicker, the resisting strength will be increased in direct proportion to the thickness. As to the size and thickness of the negro skull, no less an authority than Hrdlicka, of the Smithsonian Institution, says "It is quite true that the skull of the American negro and that particularly where there is some scaphocephaly, is thicker than that of a white man. The excess, however differs on the average I should say the negro skull is at least one third thicker than that of the average white American. As to the size of the negro skull it is generally smaller than that of the white man, stature for stature."

A H Keane (5), of London says "The chief points in which the negro either approaches the *Quadrumana* or differs most from his congeners, are among others, No 3, Weight of brain, as

indicating cranial capacity, 35 ounces, highest gorilla 20 ounces, average European 45 ounces No 8, Exceedingly thick cranium enabling the negro to butt with head and resist blows which would inevitably break any ordinary European's skull."

Davis makes the following statement "The skull is thinner in the white than in the negro race" while Brinton in *Races and People*, states that cerebral or cranial capacity has been proved by investigation to average less in the negroes than in the whites. To be more exact, the average weight of the white man's brain is 1,475 grams, of the negro's brain, 1,331 grams.

Trotter in writing on the vulnerability of the brain mentions Spencer's pioneer investigations of cerebral hemorrhage in the newborn some 30 years ago and continues "We have seen that the European skull does not protect the enclosed brain from injury so efficiently as does the African skull. This must be because the latter is the stronger and more rigid. From the anatomical point of view this superior strength is evidently not very striking, since as far as I know, it has attracted but little attention and led to no attempt being made to measure it. From the functional and medical point of view the superior strength of the African skull is at once obvious and is plainly a very important racial character. The relative slightness and flexibility of the European cranium is then a leading character of the race and brings with it gross functional disadvantages in the resistance of injury."

Thus we are again face to face with the inevitable law of compensation while the Caucasian is endowed with better reasoning power than the negro's to enable him to avoid injury the skull of the negro offers much greater resistance to injury than does the skull of the white man.

Since it is known that a hollow sphere of a certain diameter withstands more stress and strain than a sphere of larger diameter that the highest authorities agree that the negro's skull is not only smaller but also thicker than the white man's that the relative slightness and flexibility of the Caucasian's skull brings with it gross functional disadvantage in the resistance of injury that Bean in his measurement of 103 brains and study of 10,000 individuals has classed the southern negro with the Guinea Coast negro the most ancient and the most classical negro type—it is a logical deduction that study of a large series of head injuries in negroes in the South would show the effects accurately with a decidedly small death rate as compared to that in an equal number of such injuries in the whites.

With a view of obtaining the most accurate statistics possible, 300 cases in the white race have been compared with 300 cases in the negro. To these two groups of cases there has been applied the same classification of injuries resulting from practically the same causes and the same underlying principles have governed the type of treatment in both groups.

Only cases showing definite brain damage such as bloody spinal fluid fractures, unconsciousness, semi-consciousness, bleeding at ears, paralysis, exophthalmos, tinnitus, aphasia, nystagmus, vomiting have been considered.

The same routine study has been made in every case a rough neurological examination, several blood pressure readings at short intervals, roentgen ray examinations of skull showing antero posterior and lateral stereo-copic views, spinal puncture to detect blood in the fluid, spinal fluid pressure reading with an Ayer manometer and ophthalmoscopic examinations of eye grounds.

TREATMENT

Frequently patients with head injuries when first seen are in a state of profound shock. Regardless of the type of injury, the shock must be combated until the patient reacts favorably, before routine examination is attempted.

In head injuries two types of disturbance should be considered and examination when completed should enable one to classify a given case as one or the other of two groups (1) that caused directly by the force of the blow and showing immediate symptoms, such as hemorrhage, concussion with temporary unconsciousness and depressed fracture with possible localized paralysis, torn dura and contused brain and (2) that resulting from external force but never coming on instantaneously but after certain intervals manifesting themselves either by hemorrhage or gradually developing edema of the brain. In other words head injuries may be divided into two main groups (1) operative and (2) non-operative. In the operative cases surgical interference is resorted to only when there is something to be removed such as a large blood clot, depressed bone badly damaged brain tissue or a subdural accumulation of fluid. Among the non-operative cases are those of simple concussion or potential brain damage with or without fracture which experience teaches will recover with the help of dehydration and a hypertonic diet—the larger group of cases. Given a patient with a head injury who is semi-conscious or unconscious possibly with a linear fracture perhaps with bleeding from one ear, with bloody spinal fluid but with blood pressure nor

mal or only moderately elevated, one may reasonably expect recovery with dehydration and hypertonic diet. Adults are given $\frac{1}{2}$ ounce of a saturated solution of magnesium sulphate every 2 hours for 24 hours, then the same dose every 4 hours for another day, gradually lengthening the intervals daily for 1 week, when the magnesium sulphate may generally be discontinued. The dose for children should be regulated according to age, 1 to 2 drachms every 4 hours. Should magnesium sulphate cause too frequent evacuations, they may be controlled with paregoric or a small dose of codeine. If the patient cannot swallow, 10 cubic centimeters of a 10 per cent solution of magnesium sulphate may be given intravenously daily.

The diet should be a combination of hypertonic and dry very sweet fruit ades, salty broths dry foods and no plain water.

Spinal punctures should be made daily until spinal fluid clears up. Luminal or bromides are to be given for extreme restlessness.

A bleeding ear should never be syringed out. Instead it should be wiped out with sterile cotton, a few drops of a suitable antiseptic introduced, and the canal kept plugged with sterile cotton.

Patients with wild delirium must sometimes be restrained, they should be isolated from all relatives and kept quiet by retention enemas of 2 drachms of paraldehyde in milk or water according to circumstances.

Frequently the irritative stage of a large hæmorrhage closely resembles alcoholic excitement the venous engorgement resulting from increased pressure causes the patient to become irritable, excited, and even resentful. Careful watching of these patients for several hours may prevent a very embarrassing situation.

Patients with ruptured meningeal artery and depressed fracture should be operated upon. A torn dura and contused brain is often found associated with such fractures. One of the delayed conditions is a subdural accumulation of bloody fluid which manifests itself either by increase of intracranial pressure or by localized irritative symptoms, such as the jerking of a hand or foot.

Probably the type of case which most urgently calls for operative interference is the middle meningeal hæmorrhage in which the patient shows a temporary unconsciousness followed by an interval of consciousness, a slow bounding pulse following a slightly rapid small pulse, a gradual relapse into unconsciousness, with sterorous, snoring breathing and perhaps a gradually developing hemiplegia or contralateral convulsions. These patients demand immediate sub

temporal decompression with ligation of the ruptured meningeal artery. The patients with subdural accumulation of fluid also call for this type of operation, in which the dura is opened to allow the fluid to escape. A typical case of several days' standing might be relieved by a small trephine opening with a small opening in the dura.

Depressed fracture should be trephined away, the dura opened, clots removed, and damaged brain tissue removed by catheter suction. A short piece of a No. 20 F catheter on a Luer syringe is used. After all damaged brain has been removed the dura should be tightly closed.

Occasionally, in an infant, because the dura is closely adherent to the skull, a depressed bone will tear the dura, allowing the fluid to leak out and cause a hydrocele of the scalp. Opening the scalp and suturing the tissues tightly over the rent will relieve the situation until the suture lines unite and the fontanelles close.

Scalp wounds are often considered too lightly. They should be regarded as potential brain abscesses. The scalp should be shaved over a generous surrounding area, which is then thoroughly cleaned with the patient under novocain (1 per cent) and adrenalin (5 minims to 1 ounce) anesthesia. The ragged edges of the wound should be trimmed carefully away and the galea closed with fine catgut or interrupted silk sutures. The outer skin also is closed with interrupted silk sutures, which should be removed in 2 or 3 days. Neither through and through sutures nor colloidion dressings should ever be used.

From Table 1 it is seen that with conditions as nearly alike as possible in 300 cases of white patients and 300 of colored patients, 83 of the former resulted in death while only 48 of the latter terminated fatally, making the death rate in the white cases 27.6 per cent and in the negro cases 16 per cent.

It is particularly noticeable that there were 71 massive injuries among the whites as compared to 31 injuries of the same type among the negroes while there were 48 depressed fractures among the negroes and 33 among the whites. The latter difference may be accounted for by the fact that the force of the blow was expended in only fracturing the skull in the negro cases, while a massive injury resulted in the white cases—conclusive proof in itself that the skull of the negro will withstand at least twice as much stress and strain as the skull of the white man.

Some of the valuable lessons learned from the study of this long run of cases are as follows:

1. A patient in a state of profound shock should be treated first for shock.

TABLE I—SUMMARY OF CASES

<i>Massive injuries</i>		White	Negro
Ages in years			
1 to 5		5	2
5 to 10		7	2
10 to 20		14	6

until the patient regains consciousness, in order to avoid pneumonia.

4 Morphine should not be given for severe headache following a head injury, for the drug depresses respiration and may disguise a dangerous meningeal hemorrhage.

5 The patient should not be allowed up too early, or the result may be an intractable headache.

6 A normal pulse rate and blood pressure may be misleading in a case in which meningeal hemorrhage is suspected. A dangerous hemorrhage can come about with a blood pressure of 118 and a pulse rate of 80.

7 Care should be taken not to overlook a contrecoups hemorrhage in an unconscious patient. The scalp wound, or fracture, may be on one side and the hemorrhage on the opposite side.

8 The depletion of a patient whose system is already impoverished by the loss of a large amount of blood may result fatally.

9 Operation upon a patient with a fast falling blood pressure will prove fatal.

10 Great care must be taken to distinguish between the irritating stage of a large hemorrhage and a state of alcoholic excitement. Often it is absolutely impossible to distinguish one from the other for the time being.

11 Puncture wounds of the cranium such as wounds from ice picks and knife blades, should be explored immediately.

Though the much greater death rate of the whites might be taken to presuppose a greater vulnerability of the brain in the white race, the excess of massive injuries in the whites makes it clear that 'the vulnerability is due to the failure of the protective function of the skull.' Since this failure of the protective function brings with it gross functional disadvantages in resistance to injury, we may assume with Trotter that 'it has some deep and real significance in compensation'. As he further says, it 'paid the European, so to speak, to develop a type of cranium which put him at a serious physical disadvantage in contest with his primitive competitors and even with contemporary races of today. What can have been the price he got in return that prevented the transaction from being the bad bargain it so manifestly might have been but was not?'

BIBLIOGRAPHY

2 X-ray pictures should not be taken until the patient reacts from shock.

3 If the patient is unconscious or semi-conscious and the head injury is complicated by a fractured limb, a body cast should not be applied

RELATION BETWEEN ACUTE INFECTIONS OF THE UPPER RESPIRATORY TRACT AND INFECTIONS OF THE KIDNEY

FOR many years attention has been called periodically to the apparent frequency of pyelitis in children coming with or subsequent to acute infections of the upper respiratory tract. However, the precise relationship between these two factors and the question of whether indeed there is any relation at all has been obscure.

The organisms concerned with the throat infection are commonly various cocci while the organism which appears to be the causative agent in the kidney infection is most commonly the colon bacillus. Most painstaking work by Helmholtz and others has failed to explain the illusive relationship. Again Rose and other workers following the lines which he has indicated have concerned themselves with the relation of chronic foci such as those in tooth and tonsil to infections of the urinary tract, but again the organisms concerned have commonly been widely different and the exact relationship has remained ob-

scure. In sharp contradistinction to these facts which have defied accurate correlation, is the well known relation between acute infections of the skin and bone with acute infections of the kidney. It is a matter of common knowledge that patients with boils, carbuncles, and acute osteomyelitis occasionally develop acute infections of the kidney with the staphylococcus, which is the causative agent of the primary infection. Here the relationship is generally clear and definite and the organisms found in both lesions are the same.

For several years we have been interested in observing a group of patients, most of whom have perhaps accidentally, been young adults of both sexes who, coincident with some acute infection of the upper respiratory tract, commonly a tonsillitis, have had the following clinical picture. At some stage during the throat infection, never at its beginning, the patient has pain varying from one of moderate intensity to one of great severity occurring in one or the other, rarely in both, renal regions. This is accompanied by definite costovertebral tenderness occasionally by spasm of the anterior abdominal muscles, commonly by nausea, occasionally by vomiting. The fever rises sharply, often to 103 or 104 degrees. The leucocytosis which has heretofore been moderate rises definitely, often reaching 20,000 or more. In these patients, by ordinary routine methods of examination the urine is habitually normal. However, careful examination of highly centrifuged, very fresh specimens which in the female must be obtained by catheter and in the male must be the terminal portion, will regularly show cocci in large numbers. In the overwhelming majority of

these patients, the fever persists for a few days, the tenderness, leucocytosis and cocci in the urine remain for the same period. Then all the symptoms gradually subside, the cocci disappear, and careful check up has appeared to show that the patient had entirely recovered.

We have come to believe that this clinical picture is considerably more common than has been generally supposed, that such attacks, often relatively mild, are fairly common and that they are in fact evidence of acute renal infections, we believe of the cortical type, which go on to spontaneous recovery.

I desire to call attention to this group since I think it will bear wider study but I also wish to call attention to a group of cases which follow from this clinical picture and which seems to me may possibly throw light upon the whole question of renal infections through the blood stream in the previously undamaged kidney. A certain proportion of these cases, instead of going on to spontaneous recovery continue to show the clinical picture before suggested except that the fever continues the kidney can be demonstrated to be definitely enlarged, and pus in small quantities not rarely appears in the urine. At the end of two or three weeks the process begins spontaneously to recover but commonly enough, colon bacilli will appear in the urine as the cocci are disappearing and as the pus begins to show. There is here, I think, a suggestion that the colon bacillus is more often than we have believed, a secondary invader, its rapid growth in the urine may easily be misleading since the bacilli can increase enormously during the time the urine remains within the body. In this way they will obscure the examination of the urine as made by centrifuge, smear and stain, a method upon which we have come to rely more than upon culture. However, the

possibility of overlooking cocci in the presence of an overgrowth of colon bacilli is perhaps equally as likely in culture as in smear.

As far as I know there is very little evidence of the condition of the urine in children with acute upper respiratory infections until pus is found and a pyelitis more or less acute is well established. It seems to me not impossible that the organisms involved in the upper respiratory infection may in fact be those which first invade the kidney, first reduce its vitality and make it a congenial abiding place for the more or less ubiquitous colon bacilli. The field is, I think, one which will continue in the future, as it has in the past, to repay careful study.

HUGH CABOT

HYSTERICAL LITHIASIS

TO the various types of urinary calculi which are usually described in the literature should be added a form of lithiasis, or rather pseudo lithiasis which is not generally recognized and which from its nature may well be termed "hysterical lithiasis." This unusual manifestation of abnormal psychological process is manifested by symptoms simulating acute renal colic. In order to complete the deception, the patient will produce a stone shortly after the colic, which to the casual observer may be mistaken for renal calculus. In addition, one patient following the pseudo colic, was able to demonstrate hematuria, which on examination proved to have its origin in a self inflicted periurethral abrasion. Although renal colic is simulated by some patients in order to secure a desired drug in most instances this unusual form of invalidism is assumed to obtain attention and sympathy. Two of the patients had previously passed true renal calculi and one patient had had a stone removed from her kidney, so that they had no difficulty in

simulating actual renal colic. Several patients inserted a calculus into the bladder prior to roentgenographic and cystoscopic examinations. One patient carried a small bag filled with pebbles, which she surreptitiously placed in the lumbar area at the time of roentgenographic exposure. That it is easy to confuse the symptoms accompanying this form of psychoneurosis with those of true lithiasis is shown by the fact that in none of the cases had the condition been recognized at first and in each instance several physicians had treated the patient in good faith for actual lithiasis.

As a rule the stones which are claimed to have been passed can be recognized as foreign material by anyone who has previously observed renal calculi. They frequently consist of small, round pebbles, and in order to keep up the semblance of veracity the patient usually will select the same type. In several instances the stones selected were irregular

and glistening. One patient presented pieces of chalk, and another bits of plaster which were dug out of the wall with the finger nail, and when crumbled resembled somewhat a soft phosphatic stone. On the other hand, urinary calculi are sometimes observed which have such a bizarre appearance that their origin may be doubtful. If there is any doubt as to the nature of the stone a chemical analysis will, of course, identify it.

Although the deception will be indignantly demed by most patients when first informed of the situation, the cure will usually be miraculous. Several patients, however, were known to continue their stony career. One patient claimed to have passed over 200 stones at regular intervals. The possibility of pseudo lithiasis should be considered with every case of chronic stone forming kidney and an analysis should be made of the stones to determine their organic origin.

W F BRAASCH

these patients, the fever persists for a few days, the tenderness, leucocytosis and cocci in the urine remain for the same period. Then all the symptoms gradually subside, the cocci disappear, and careful check up has appeared to show that the patient had entirely recovered.

We have come to believe that this clinical picture is considerably more common than has been generally supposed, that such attacks, often relatively mild are fairly common and that they are in fact evidence of acute renal infections, we believe of the cortical type, which go on to spontaneous recovery.

I desire to call attention to this group since I think it will bear wider study but I also wish to call attention to a group of cases which follow from this clinical picture and which seems to me may possibly throw light upon the whole question of renal infections through the blood stream in the previously undamaged kidney. A certain proportion of these cases instead of going on to spontaneous recovery continue to show the clinical picture before suggested, except that the fever continues, the kidney can be demonstrated to be definitely enlarged, and pus in small quantities not rarely appears in the urine. At the end of two or three weeks, the process begins spontaneously to recover but commonly enough, colon bacilli will appear in the urine as the cocci are disappearing and as the pus begins to show. ROBERT F WEIR
1838-1927

MASTER SURGEONS OF AMERICA

ROBERT F WEIR

FOR a surgeon, the year 1838 was a good time to be born. Within the years of Dr Weir's lifetime, surgery made most astonishing and important advancement, and during this period Dr Weir witnessed the surgery of three American wars, and he himself achieved much. To live to be ninety years old is of itself some achievement. It is fortunate for the historian that the subject of this sketch left some private personal reminiscences of his early life which, through the kindness of his only child and daughter, Mrs La Montagne of New York City, we are permitted to record.

I had graduated, the youngest in my class from the just established New York Academy (later the College of the City of New York) and had started as a clerk with my father, who was an apothecary in Grand Street. Dr H B Sands, who later achieved great eminence, was also the son of an apothecary. During the two or three years I was acting as a clerk, I rose from taking down and putting up the store shutters to become quite expert in the manufacture of unctures, etc., and acquired, thanks to a pleasing and diligent perusal of Wood and Bach's *Dispensatory*, quite a fair knowledge of medicines and their actions on the human body. Perhaps this training inclined me to the practice of medicine, but I have always been convinced that two incidents determined my career. The first was the experience I obtained from the painful ingrowing toe nail of my big toe. It plagued me so badly for several months until my father sent me one Saturday to the office of Dr James R Wood, whom I had frequently seen in our store and who was generally known by all the neighborhood as 'little Dr Jimmy Wood'. His office was at the corner of East Broadway and Market Street (and they were fashionable streets then). There he held once a week a sort of clinic for his numerous students. Thither I went in due time and was ushered into his sanctum. He examined my stripped toe and while explaining to the embryo medicos the nature of the trouble, slyly took up a pair of pincers and quickly placing one jaw of this under my nail, clamped the upper jaw to and pulled the nail out. I gave a jump and a wild yell, but it didn't hurt so much as I thought it would, since the nail had been considerably loosened by the prolonged inflammation and suppuration. I went home relieved, and telling my father of it, I said I'd like to be able to do like that. (This impression was augmented when a few months later his father sustained a Pott's fracture and was treated by the same Dr Wood.) The next day I announced my firm determination to become a surgeon.

How interesting it would be if other great surgeons had left biographical notes of the early mainsprings of their careers!

Dr Weir entered the office of Dr Gurdon Buck (of Buck's extension fame) as pupil and assistant and became a student at the College of Physicians and Sur-

ROBERT F WEIR
1838-1927

geons "Dr Buck was a large man with a face somewhat German in aspect, slow in action and in speech, but having a thoughtful mind and fertile in surgical expedients" Dr Weir remained with Dr Buck three years. He tells a story of how one day, in giving ether for him, he diligently palpated the right eyeball of the patient (the method then in vogue to tell if the patient was under the anæsthetic), only to find after embarrassing cries and struggles of the patient, that he was the possessor of a glass eye! Later Dr Weir acted as Dr Buck's first assistant when he put on his first Buck's extension at the New York Hospital.

Dr Weir tells of an amusing incident at the graduating exercises of his college. The seats of the auditorium had recently received a heavy coat of varnish—too recently to become thoroughly dry. When the audience started to arise at the conclusion of the exercises, they found that they were almost glued to their seats. Dr John C Dalton who gave the address remarked that the students followed his words with fixed attention. Dr Weir offered as his graduating thesis, "Hernia Cerebri," for which he received a prize of fifty dollars.

In 1856 Dr Weir became an interne, or "junior walker" as it was then termed, at the New York Hospital which was started by Dr Bard away back in 1769.

It is interesting to read Dr Weir's account of the method of procedure at the New York Hospital for what were considered major operations at the time when he was house surgeon (about 1858).

The senior walker was expected to lay out the instruments they had been resting on a velvet lined shelf or were bedded in velvet lined slats in an adjoining closet. He would make inquiries of the nurse, who was at other times a ward nurse, about the sponges which, having been washed out from a previous operation, had been kept in a wooden pail of fresh water. Fine, beautiful and soft looked they when taken from the pail out of the water and placed in a basin for the nurse or one of the walkers to hand to the surgeon during the operation. Sometimes the surgeons washed their hands previously—sometimes not. Fingers laden with germs in large quantities on them or under the nails were stuck into the wounds we made and we further introduced (alas all this was unconsciously done) infectious and often fatal germs by the brilliant and apparently clean instruments we employed. After we had done all this we tied blood vessels with strings with long ends so that we might pull them out when they loosened themselves from the tied arteries. Furthermore, we dressed our wounds with wax cerates kept in jars open to germ laden dust and smeared over lint with foul spatulas."

In 1861, Dr Weir, desiring to enter the regular U. S. Army Corps, went up for the required examination. Concerning this, here are Dr Weir's own words: "During the examination I thought my chance of passing was gone when the chairman of the board asked me in sharp tones to give the treatment for pneumonia. But, he said, 'you have not mentioned blood letting. Wouldn't you employ it?' 'No,' I replied, 'I wouldn't.' 'But, Dr Weir, if I had pneumonia, wouldn't you bleed me?' 'No,' I firmly replied, 'that day has gone by.' 'Then I wouldn't like to have you for my doctor,' retorted he. But his bark was worse than his bite, for I passed."

On the way to Frederick, Maryland, Dr Weir was received by Lincoln at the White House, and was again presented to him when Lincoln came to Frederick.

The hospital at Frederick of which Dr Weir was chief was in proximity to the battlefields of the Shenandoah, South Mountain, Antietam, and Gettysburg. He saw it rise to a capacity of 3,000 patients and his assistants increased in number to 25 exclusive of the "medical cadets." From 1862 to 1865, Dr Weir had charge of the "United States of America General Hospital" at Frederick, Maryland, one of the Government's largest hospitals, and for his services was publicly thanked in the general orders of the Surgeon General's office. It is interesting to read in a recent personal communication from Dr W. W. Keen

At the battle of Antietam I was in charge of the Ascension General Hospital in Washington. I was ordered to Frederick, Maryland, in the neighborhood of Antietam and was Weir's first assistant in the administration of the hospital there, more especially in the supervision of all the capital operations. Either he or I had to approve of them before they were done because many of those who had patriotically volunteered were without a fundamental knowledge of surgery.

Weir was a capital operator, careful, judicious and resourceful. I have hardly known a better one. He also ingeniously suggested that in certain cases where the appendix had to be removed, the stump should be sewed first in the abdominal wall leaving the aperture of the stump in the abdominal wall. By this means we would be able to wash out the whole of the great bowel at any time and to any extent, and when the necessity ceased the small opening of the appendix in the abdominal wall was closed. He was indeed a Master Surgeon.

In the *Transactions of the American Surgical Association* for the year 1907 appeared an obituary notice written by Dr C. L. Gibson of New York City.

Dr Weir was president of the American Surgical Association 1900-1903. He had not been active a number of years before his death and had survived a brilliant group of surgeons who have left their impress on American surgery—notably Sands, Markoe, Thomas Ball, McBurney, McCosh, Hartley and Gerster. His Civil War record was marked by extraordinary achievement. He was always an indefatigable worker in research and was always in the front rank of progress—a distinguished leader, and many of the brilliant members of the American Surgical Association owe much of their development to his personal example and interest.

His greatest activity was in an epoch when pioneer work was being done along many lines of surgery and he had his share of success. He was one of the early workers in brain surgery. He made a great many contributions to surgical literature.

Dr Weir was a handsome man of striking personality and his fine character invited much affection and loyalty, especially of his younger associates. He was also a great traveler and his reminiscences and experiences are most interesting and valuable.

Dr M. Allen Starr, who was intimately associated with Dr Weir for so many years in college work, addressed the New York Academy in 1927 as follows:

As Professor of Surgery in the College of Physicians and Surgeons from 1873 to 1903, he taught many of the men of this country, now distinguished, who came from all parts to attend his clinics and to watch his operations and he imbued them with enthusiasm for their profession as well as sound knowledge of its principles. His wide experience gained chiefly in the Civil War in which he served as surgeon in charge of the hospital

at Frederick Maryland, his ample knowledge of surgery gained by familiarity with home and foreign literature, his skill in the varied lines of operative work, all combined to place him in the front rank of the surgeons of his time. And his genial nature, delightful personal manner, wide interest in art and letters and life outside his profession added to the esteem and affection with which he was held by his friends. He visited Europe many times and also went to Japan and China.

As attending surgeon in the New York Hospital from 1876 to 1903, he was an indefatigable worker without regard for financial return, for at that period the hospital was given over to charity patients and *private wards were not opened* (italics mine). This industry is evident by the very long list of his publications in the medical press during these years, more than a hundred being mentioned in the *History of the College of Physicians and Surgeons* published in 1900. During this period the introduction of Lister's methods of antiseptic, and later aseptic surgery was the subject of the greatest interest and Professor Weir was among the first to adopt, urge, and teach modern methods which eventually revolutionized surgical procedure. While his chief work was in abdominal surgery, he was the first in this country to operate for a brain tumor, under the direction of Sequin, and the success of that operation led him to make many contributions to the surgery of the head and brain. There is hardly any field of surgery in which his published articles do not increase knowledge. And his diagnostic wisdom and good judgment combined with his skill in operative procedure added to his reputation and in many lines made him the chief authority of his time.

He was elected president of the American Surgical Association in 1900, member of the International Surgical Association, president of the New York Surgical Society, of the Practitioners' Society, of the New York Academy of Medicine, and of the Greater New York Medical Society. In 1895 he was made a corresponding member of the Société de Chirurgie de Paris, and in 1905 an honorary fellow of the Royal College of Surgeons of England. Of this latter appointment it is interesting to note that Dr Weir, Dr Keen, and the Prince of Wales received this honor at the same time. It was the first occasion that an honorary degree had been bestowed by that body.

During his extensive practice in New York City, he had associated with him as partners Dr Robert Abbe, Dr Gibson and Dr Ellsworth Eliot, all whom became eminent. Dr Eliot, in a personal communication, writes "Dr Weir never developed a hobby although he tried hard on the tennis court and whist table. By his internes he was affectionately called 'Bobbie' and of this he was aware."

A few months after the organization of the American College of Surgeons in Washington, D. C. Monday evening, May 5, 1913, Dr Weir at the first convocation held in Chicago, November 13, 1913, was made an Honorary Fellow. The only other surgeons so honored were Sir Rickman J. Godlee, London, William Stewart Halsted, Baltimore, William Williams Keen, Philadelphia, and John Collins Warren, Boston.

Many honors were bestowed upon Dr Weir, he had appointments on the staffs of many hospitals and belonged to the principal medical societies of his time.

OLD MASTERPIECES IN SURGERY

ALFRED BROWN M.D. F.A.C.S. OMAHA, NEBRASKA

THE PHARMACEUTICAL AND SURGICAL PHILONIUM OF VALESCA DE TARANTA

IN Europe from the beginning of the Middle Ages instruction in and practice of the sciences passed gradually into the hands of the clergy. Naturally of all the sciences surgery and secondarily medicine suffered the most. The dictum that the Church abhors blood prevailed and such surgery as there was was performed by itinerant charlatans and mountebanks. The literature of medicine save for the little that was preserved by the Benedictines was practically lost. The hospitals and schools established by the Romans became little more than homes or resting places for the poor and indigent. Then a change for the better began. Constantine Roger Roland and the four masters began their work at Salerno. The former translated the works of the ancients and re-established the result of their labors as a new literature in Europe. Roger and Roland wrote individual works and with the swing of medical education and instruction to the north Montpellier became the outstanding school and Guy de Chauliac and John Arderne wrote their individual works in surgery. But still there was no general compendium or textbook so to speak and the literature was hard to find and when found only fragmental.

Valesca de Taranta was a Portuguese who had studied in Lisbon and was attracted to Montpellier where he continued to study. He says that he began to practice medicine in 138 and as he precedes his discussions of diseases throughout his book by a short description of the anatomy of the part involved one may gather that he had taken advantage of the fact that from 1376 on a dissection of the body of a criminal was permitted annually at the school of Montpellier. So this school even though under the management of the unmarried clergy who composed its faculty was rising out of the fog of the dark ages and endeavoring to expand to a more modern conception of science. Valesca continued to practice at Montpellier and became one of its pre-eminent men and probably one of the professors at the school for he was appointed later Archiater of King Charles VI of France. During the latter part of the fourteenth century, he began to write and published his first book *Tractatus Epidemialis* in 1401. Nothing more came from his pen until he had been thirty six years in practice when he finished his great work *The Philonium*. One of the reasons he wrote the book

was to furnish to the profession a complete practice of medicine because he noted and deplored the paucity of books at this time. Daremberg states that in the preface to an early edition he says "where will one find the books of Hermes of Rufus of Andromachus of Paul of Oribasius?" He then goes on to explain that it is his intention to write a complete treatise which will gather all the information contained in these books in one volume, namely adding that it would be free from all errors and then enters into a description of the superstitions of which the *Philonium* is full. He appears to have been greatly impressed with the importance from a superstitious standpoint of the number seven, a belief prevalent at the time. He calls attention to the fact that there are seven cardinal sins, seven spirits, seven petitions in the Pater Noster, seven days in the week, seven planets and many other important sevens. Consequently he divides the *Philonium* into seven books which treat of diseases of the human body in an orderly sequence from the head to the feet.

At a later period the exact date of which is unknown he wrote his smaller treatise *The Surgical Philonium concerning the method of cure of external affections*. In this he discards the head to foot method of division and considers surgical affections from the standpoint of pathology and symptomatology beginning with abscess, phlegmon, erysipelas, carbuncle, etc. and ending with a thirty first chapter which describes hemorrhage from wounds.

Valesca de Taranta was one of the first of the physicians of the late middle ages to attempt to gather the material of the ancients in an accessible form and he succeeded fairly well. His knowledge of the ancient literature was considerable for his quotations from nearly all the early authors of importance are multitudinous. He includes both the ancient Greeks and the Arabians and does not neglect the writers just previous to his own time. It is not at all surprising therefore that when printing came into vogue his work should become popular. It was first printed in 1490 including both the medical and surgical parts preceded by an introduction by Joannes de Tornamira, Chancellor of Montpellier. During the sixteenth century no less than ten editions were necessary to supply the demand. By the time the eighteenth century was well under way however later books had become more popular and Taranta's *Philonium* appeared for its last printing in 1714.

REVIEWS OF NEW BOOKS

THE book entitled *Robert Jones Birthday Volume*¹ is a collection of surgical essays by various authors. The preface by Sir Berkeley Moynihan is a masterpiece. These papers were written by the closest personal and professional friends of Sir Robert Jones. It is an expression of the high regard which these men maintain toward their friend colleague and in many cases their teacher. Each paper was written by a man who writes with authority on his subject. The papers are clearly written, well illustrated, and the subjects well chosen. The volume is a worthy tribute to the great Sir Robert Jones.

The chapter on the history of orthopedic surgery is interesting. Osgood gives a summary of his opinion on the association of intestinal stasis and spinal and sacro iliac arthritis. Putti describes two cases of tumor of the femur. His operative procedure is ingenious and his points in diagnosis and treatment of bone tumors are valuable. Jansen's discussion of the dissociation of bone growth is very good.

Hey Groves' paper on the treatment of congenital dislocation of the hip discusses the open operative reduction. His anatomical considerations are very good. Allison discusses open operations for congenital dislocation of the hip. Elmslie writes on fibrous cystic diseases of the bones.

Holland gives a complete exposition of the accessory bones of the foot describing 24 conditions.

The late Clarence Starr summarizes his valuable teachings on acute infections in bone emphasizing the points in diagnosis and the principles of treatment. Mitchell discusses spiral fractures.

Platt treats the subject of nerve disturbances in the elbow region. Fairbank describes 8 types of cervical coxa vara. Aitken discusses curvature of the spine. Bristow's contribution is on the subject of cysts of the semilunar cartilages of the knee. Smith discusses sidelights on knee joint surgery.

McMurray's paper on the diagnosis of internal derangements of the knee is highly authoritative. Bankart discusses dislocations of the shoulder joint enumerating 7 complications. Calve's classical description of osteochondritis vertebralis infantilis is in French. Wheeler describes bone grafting in Pott's disease. Girdlestone discusses arthrodesis of the hip. Evans writes on astraglectomy. Dunn's discussion on arthrodesis of the tarsus is very valuable. Trethowan discusses fracture dislocation of the ankle and Lynn Thomas contributes an appreciation. P. L.

fessor Eyster. This is a new and worthy addition to bedside study. It is important enough to warrant widespread attention, and should be read by all internists.

It seems proved that measurement of the venous pressure is an indirect but specific determination of the functional status of the heart, and as such it is an aid in replacing clinical opinion by objective measurement. Certainly the value of arterial pressure measurement is so great that it is hard to imagine doing without it. Doctor Eyster's instrument for measuring venous pressure at the bedside is shown and explained, and the technique of its use is fully given. His observations suggest that venous pressure measurement may be of greater immediate importance in heart failure than arterial blood pressure. But in addition to this practical aspect which is well presented, he makes an exact analysis of circulatory dynamics in heart failure that is fascinating to anyone interested in this most important and common problem. PAUL STARR

THE fourth volume of the *Oxford Monographs on Diagnosis and Treatment*² concerns a field in which there is very widespread interest i.e. diseases of the thyroid. It is written, as are the other volumes in this series by men who have personally contributed greatly to the advancement of knowledge in the field covered. The volume is introduced by an interesting historical review of earlier clinical observations. The anatomy and functions of the gland thyroxin a classification of thyroid disorders and a consideration of the use of the metabolic rate are presented in the next chapter. Then follows a general discussion of methods of treatment with an illuminating account of surgical sequelae. The remainder of the work covers colloid goiter exophthalmic goiter, adenomatous goiter and hypothyroid states.

In general this is not a personal critique but an impartial presentation of commonly held views. The material is supported by many references throughout the discussion and a considerable list of titles follows every chapter. Several illustrative cases accompany each clinical problem presented. This volume certainly gives a broad and, at the same time thorough view of modern knowledge of thyroid disease. PAUL STARR

TO one who has spent approximately a quarter of a century in the fascination of similar work, this small volume on *The Treatment of Fractures*³ betrays expressions of disappointment and walls of complaint against the non recognition of the value

A COMPACT monograph⁴ on the physiology, technique of measurement and practical importance of venous pressure has been written by Iro

¹ THE ROBERT JONES BIRTHDAY VOLUME: A COLLECTION OF SURGICAL ESSAYS BY VARIOUS AUTHORS. New York and London: Oxford University Press, 1915.

² THE CLINICAL ASPECTS OF THYROID DISEASE. By J. A. E. EYSTER, M.D. New York: The Macmillan Company, 1919.

³ THE DIAGNOSIS AND TREATMENT OF DISEASES OF THE THYROID. By J. H. HARRIS, M.D., and EDWARD P. KICHARDSON, M.D. New York and London: Oxford University Press, 1919.

⁴ THE TREATMENT OF FRACTURES. By LORENZ BOELLER, M.D. Author used English the edition by M. L. STEINBERG, M.D. M.D. Vienna: Wilhelm Maudrich, 1919.

of preparedness and efficient care in the treatment of fractures. One wonders why in the analysis of surgical values the study and treatment of fractures are belittled. Certainly the gross mortality, the functional and economic loss and the unhappy influence of these lesions on human life are as great as the other more frequently discussed major causes of death.

This book bears the stamp of individuality. It is divided into two parts, the first covers general remarks on the treatment of fractures, the second covers specific fractures. The discussion on pseudo arthrosis is particularly good. Open operation on recent fracture is frowned upon. For the average reader there is considerable imbalance in the space allotted to the various bones, skull fracture for example having a scant two pages.

The author's hobbies are well expounded, namely, local anesthesia for reduction, almost constant use of skeletal traction, zinc gelatin dressing and the application of unpadded plaster-of-Paris dressings to fractured limbs.

On the whole the translation of the second part is better than the first part. The value of the book lies principally in the illustrations, the expression of one man's experience and in its use as reference for anyone who has watched the author work.

KELLOGG SPEED

THE general scheme of the book on *Diseases of the Larynx*¹ is that of most texts on diseases of the throat. However it has the added advantage of including diseases of the oesophagus and large

¹DISEASES OF THE LARYNX AND THOSE OF THE TRACHEA, LARGE BRONCHI AND OEOPHAGUS. By HAROLD FARR II, M.B. (Lond.) F.R.C.S. (E.C.). New York and London: Oxford University Press, 1929.

bronchi. Endoscopy in its various phases is dealt with exceedingly well for a small text. The illustrations are well done and the latest work on surgery of the larynx is well delineated. The conciseness of the text recommends it for the student.

JOHN F. DELUX

THE third edition of *1 Manual of Proctology*² by T. Chittenden Hill is practically the same as the previous one. Little new material is added. In the chapter on ulcerative colitis the work of Bargen and Logan is mentioned but the author does not give his experiences with this form of treatment.

The injection method of treatment of internal hemorrhoids is fully described, the different solutions discussed with preference given to the 5 to 10 per cent solution of quinine and urea hydrochloride as originated by Tirrell in 1916. It is plainly pointed out that this form of treatment is unsuitable for external hemorrhoid and the excessively hypertrophied, fibrous internal hemorrhoid.

The chapter on cancer of the rectum has been revised. The selection of suitable cases for operation together with the pre-operative and postoperative treatment is fully discussed. The operation of choice is the one developed by Jones, which is described in all its details and accompanied by numerous illustrations.

Every subject in the field of proctology is treated in a clear and condensed form free from many unnecessary details. It is unquestionably a very valuable book in teaching the subject of proctology.

CORRESPONDENCE

A GENERAL CONSIDERATION OF CESAREAN SECTION

To the Editor: In the June 1929 issue of *Surgery, Gynecology and Obstetrics* in an article entitled "A General Consideration of Cesarean Section," I made the statement that the proportion of abdominal deliveries to vaginal deliveries at Jefferson Hospital was 1 to 6. These figures were quoted from a source which I had every reason to believe accu-

rate and reliable. My attention has since been called to the fact that they are entirely incorrect and that the actual incidence of cesarean section at Jefferson Hospital including all services is only 2.8 per cent.

I would ask that you publish this letter in your correspondence columns in order that the injustice done unwittingly to this excellent institution may as far as possible be rectified. C. JEFF MILLER

AN INQUIRY INTO THE BASIC CAUSE AND NATURE OF CERVICAL CANCER

THE PATHOLOGY OF CERVICITIS (EROSION OF THE CERVIX) AND THE RELATION BETWEEN
CERVICITIS AND CERVICAL CANCER¹

K. A. BAILEY M.C. M.D. CH.B., MANCHESTER, ENGLAND

INTRODUCTION

IN this work, I have made a routine examination by histological methods of 850 specimens of the cervix uteri. My object has been two fold (1) to ascertain the precise pathology of so called cervical "erosion" and (2) with a thorough knowledge of this pathology as a basis to inquire into the problem of the inception of cervical cancer. I think that all authorities agree as to the definite relationship between these two conditions, just as they are apt to disagree as to the exact nature of this relationship.

In this country the question of the pathological life story of "erosion" of the cervix has been to some extent neglected. The all important subject of cancer in this situation continually takes precedence. Articles upon the histological features of this latter condition are often bereft of much of their scientific value on account of an associated vagueness in respect of the pathology of an "erosion" present in conjunction.

Although therefore my main endeavor is to elucidate as far as possible the problem of the inception of cancer of the cervix, I have

realized that without a searching investigation into the probable antecedent state, as a preliminary—by which at any rate the pathology of that condition may be thoroughly understood—it would be useless to make this attempt, that is, without having what I consider to be the essential basic knowledge.

To this end, therefore, I have collected this series of specimens—removed for all causes at St Mary's Hospital—and have examined them individually by serial section. By this means the various histological features described in the text have manifested themselves over and over again. The histological appearances and cell reactions described are repeated in this series so many times that their constancy is, in my opinion, irrefutable. The photographs shown are merely the best obtainable of the type.

The construction to be placed upon the behavior of the tissues under the varying conditions, however, remains to be decided, and upon this aspect I dwell, of course, at some length.

This work is, therefore, divided into two parts. Part I deals with a consideration of the pathology of cervical "erosion" to which I have added a discussion of the pathology of ulceration of the cervix, and Part II with the relationship between "erosion" and cancer.

The material from which I have compiled this work has been collected from specimens removed at operation by members of the Honorary Staff of St Mary's Hospital. I wish to record my thanks to them for the facilities they have accorded me.

In the preparation of this article I have been assisted by a grant from the Manchester Committee on Cancer.

There is no doubt that a certain histological "no man's land" exists between these two conditions. I have attempted to bridge this by continued and closely applied routine examination throughout this long series of cases. The "precancerous" phases belong to this section, histological appearances which are ever debatable epithelial characteristics which are regarded as "significant," "suspicious" types, and so on. Many of these aspects will be found to be included in the description of what I believe to be conditions far removed from the cancer phase. The distinction between histological appearances of indefinite malignancy has interested me, and I trust that some light may hereby be thrown upon this controversial matter.

This histological "no man's land" does not present itself as a separate entity. It is impossible to deal with it in its order—between discussions of "erosion" and "cancer." Many of its aspects belong to the pathology of "erosion" proper (including ulceration). The problem of the onset of the cancer phase must be approached from a wider standpoint than from the limited investigation of an indefinite interstage. The actual nature of epithelial behavior under all conditions, throughout the life history of "erosion" to that of definitely established cancer, must be elucidated in order inevitably to include this interstage—to take it in the pathological stride.

The epilogue consists in a discussion of certain important features in early but definitely established cancer without in any way encroaching upon the subject of cancer pathology. The object of this work ends as soon as cancer begins. However, the last link is necessary to complete the chain.

HISTOLOGICAL NOTE

The histological appearances of the normal cervix uteri have been uniformly described by many authors.

"A fibromuscular structure the portio vaginalis of which is covered by squamous epithelium which merges at the internal os with the high columnar epithelium lining the cervical canal beneath which glands of a compound racemose type are situated in a

stroma closely resembling that of the general fibromuscular wall of the cervix into which it insensibly passes." Such is—in outline—the normal histology generally agreed upon (7).

It is also laid down that the squamous epithelium covering the portio is normally devoid of cellular downgrowths—such as is observed in the squamous epithelium of normal skin—between the papillae. The basal layers of the cervical squamous epithelium, therefore, normally present a fairly even surface to the subepithelial fibromuscular structures immediately in contact.

Erosion of the cervix or the catarrhal patch of Barbour is considered to be a pseudo-adenomatous condition and has been classified into the *congenital* type and the *inflammatory* type. The subclassification of *simple*, *papillary*, and *follicular* erosions in no way interferes with the general pathology of the condition which in all cases is due to an overgrowth of the cervical lining elements on to the portio (displacing the epithelium of the affected area) on account of a glandular and epithelial hyperplasia secondary to an infection which is evidenced by a round cell infiltration in the immediate vicinity.

Watson (8) says that the commonest cause of erosion is laceration of the cervix resulting from childbirth. Wilson (8) also says that in many cases of erosion of the cervix there are no signs of inflammation present, histologically, and the appearances suggest that the usual covering of the vaginal portion of the cervix has simply been replaced by one continuous with, and similar to, that which normally lines the cervical canal.

He remarks: "It is at least probable that among the manifold changes consequent upon the formation and healing of erosions, some may ultimately be discerned that definitely predispose to the occurrence of cancer that represent in fact precancerous conditions comparable to those found in certain other situations."

Bonney states that in all cases of early cervical cancer examined by him, there was evidence of erosion and cervicitis and that the precarcinomatous state is one of chronic inflammation characterized by the presence

Fig 1 A nulliparous erosion associated with a mild inflammatory reaction

Fig 2 Stage 1 Histological appearance of an inflammatory erosion

of lymphocytes and plasma cells in the subperitoneal tissue, together with the disappearance of elastin and collagen and with epithelial hypertrophy.

Wilson concludes that the exact relation between the precarcinomatous state and the inception of cancer still calls for elucidation, it may be, of course, that the one condition passes immediately into the other or even that the precarcinomatous condition is already malignant, on the other hand it is probable that the real precarcinomatous condition is one that merely prepares the ground so to speak, in which the cancer seeds are enabled to germinate, or, further, it is conceivable that the condition represents the first attempt of the body to protect itself against cancer that is already implanted or is in process of evolution.

Gilbert Strachan says "the lesion is essentially inflammatory and when first seen the inflammation is usually chronic in type. According to varying estimates it is present in greater or lesser degree in 75 to 80 per cent of parous women and in about 25 per cent of nullipare." The slight degree of erosion seen in virgins is due to a persistence of the fetal conditions in the cervix where the gland bearing columnar epithelium is not confined to the cervical canal but extends partly on to the portio producing a red area around the external os. However, in other cases of erosion in nullipare and virgins, Strachan considers the causal factor to be an infectious one consequent upon the lowering of the

normal acidity of the vaginal secretion in conditions of anæmia and general ill health. In nulliparous non virgins and some parous women, gonorrhœa is the cause of infection.

In most cases a greater or lesser degree of cervical laceration is present, but it is to be recognized that the extent of the subsequent erosion bears no relationship to the degree of laceration. A very small laceration may be followed by extensive erosion and vice versa. It is the virulence of the infecting organisms that counts.

In speaking of the process of infection, Strachan says "The subepithelial tissues become hyperæmic and œdematous, with redness and swelling of the cervical mucosa. This is accompanied by an increase of the excretion from the cervical glands, which appears clinically as a mucoid or mucopurulent secretion to which the general name of leucorrhœa is given. As a result of the epithelial infiltration a certain number of the squamous epithelial cells surrounding the external os are raised from their bed and finally cast off, thus leaving a red raw circle around the os. This raw area becomes covered by columnar epithelium which has been stimulated to grow out from the cervical canal. Racemose glands are carried out along with the epithelium and may proliferate greatly, producing the condition described by Eden as pseudo adenoma, and usually called an 'erosion'."

He later says "Many authorities stress the point that this so called erosion does not

Fig 1 A nulliparous erosion associated with a mild inflammatory reaction

Fig 2 Stage 1 Histological appearance of an inflammatory erosion

of lymphocytes and plasma cells in the subperitoneal tissue, together with the disappearance of elastin and collagen and with epithelial hypertrophy

Wilson concludes that the exact relation between the precarcinomatous state and the inception of cancer still calls for elucidation, it may be, of course, that the one condition passes immediately into the other, or even that the precarcinomatous condition is already malignant, on the other hand it is probable that the real precarcinomatous condition is one that merely prepares the ground, so to speak, in which the cancer seeds are enabled to germinate, or further it is conceivable that the condition represents the first attempt of the body to protect itself against cancer that is already implanted or is in process of evolution

Gilbert Strachan says "the lesion is essentially inflammatory and when first seen the inflammation is usually chronic in type. According to varying estimates it is present in greater or lesser degree in 75 to 80 per cent of parous women and in about 25 per cent of nulliparae." The slight degree of erosion seen in virgins is due to a persistence of the fetal conditions in the cervix where the gland bearing columnar epithelium is not confined to the cervical canal but extends partly on to the portio, producing a red area around the external os. However, in other cases of erosion in nulliparae and virgins Strachan considers the causal factor to be an infectious one consequent upon the lowering of the

normal acidity of the vaginal secretion in conditions of anaemia and general ill health. In nulliparous non virgins and some parous women, gonorrhoea is the cause of infection

In most cases a greater or lesser degree of cervical laceration is present, but it is to be recognized that the extent of the subsequent erosion bears no relationship to the degree of laceration. A very small laceration may be followed by extensive erosion and vice versa. It is the virulence of the infecting organisms that counts

In speaking of the process of infection, Strachan says "The subepithelial tissues become hyperaemic and oedematous, with redness and swelling of the cervical mucosa. This is accompanied by an increase of the excretion from the cervical glands, which appears clinically as a mucoid or mucopurulent secretion to which the general name of leucorrhoea is given. As a result of the epithelial infiltration a certain number of the squamous epithelial cells surrounding the external os are raised from their bed and finally cast off, thus leaving a red raw circle around the os. This raw area becomes covered by columnar epithelium which has been stimulated to grow out from the cervical canal. Racemose glands are carried out along with the epithelium and may proliferate greatly producing the condition described by Eden as pseudo adenoma, and usually called an 'erosion'."

He later says "Many authorities stress the point that this so called erosion does not

Fig 3 Stage 1 Inflammatory erosion a somewhat farther advanced state

represent an ulcer," and that the red strawberry appearance is due to the deeper inflamed tissues being seen through the columnar epithelium. But parts normally covered by columnar epithelium—the uterine cavity or cervical canal—do not present this red appearance. Again, a more or less dense infiltration of lymphocytes is always found below the surface indicating the presence of a chronic infection and this would hardly persist if the surface were completely covered over. Further, there is in every section examined an area between the columnar covering on the one side and the squamous on the other where there is no surface epithelium and where the condition represents essentially a chronic granulating area.

Strachan says "the most important sequel of erosion is undoubtedly carcinoma. The continued irritation of the epithelium of the damaged mucosa would appear to be a predisposing factor in the production of epithelioma of the cervix. This condition usually occurs in a parous woman who is likely to be the subject of cervical erosion, in many cases the transition from the one condition to the other can be traced both clinically and histologically and there is little doubt but that erosion is the main predisposing factor in the production of carcinoma of the cervix.

Carey Culbertson of Chicago recently contributed a paper to the *Journal of the American Medical Association* in which he reviewed the subject of cervical erosion. He concludes

that the sequence consists of (1) infection with resultant inflammation and (2) leucorrhœa and papillary erosion. Erosion of the follicular type, he says, is really an additional process, usually ascribed to attempts at spontaneous healing.

Culbertson's discussion of the part played by leucorrhœa in the production of erosion is interesting. He says "That erosion is the direct result of a more or less continuing excessive discharge is undoubtedly. One practically never sees an erosion in the absence of a vaginal discharge, and its presence is evidence that there is an excessive cervical secretion whether the patient complains of it or not. But such an explanation is not, in itself sufficient. There are profuse discharges in which erosion is not seen. Thus, the lesion is not common in the virgin with retroversion uteri or descensus uteri and leucorrhœa, nor is it seen to develop in the occasionally profuse discharge occurring in pregnancy. In certain leucorrhœas, in other words, the flat epithelial cells of the portio are preserved. In others these cells macerate and disappear thus giving the cylindric mucus secreting cell opportunity to proliferate and start the formation of the simple erosion. There must be some other factor in addition to the presence of the leucorrhœa itself, or, what is more probable, certain changes must take place in the nature of the discharge in order to produce erosion."

It will be seen from this that although Culbertson acknowledges the effect of leucorrhœa itself upon the production of erosion, he does not consider the question of the relative irritative qualities of leucorrhœal discharges in this respect.

In discussing the precancerous nature of various erosions Culbertson quotes Stone who applied the term 'pre cancerous' to those changes which show a variable quantity and quality of the other histological criteria of cancer. Culbertson however considers that atypical healing in the follicular type of erosion produces changes often differentiated with difficulty from the alterations typifying malignant disease. In this connection he shows photomicrographs exhibiting such conditions as the plugging of distended gland

Fig 4 Low and high power photomicrographs Stage 2 Cervical erosion so called papillary erosion The first

attempts at repair on the part of columnar epithelial elements Proliferation in the presence of irritation

spaces by squamous epithelial cells, extensive and massive round cell infiltration with disintegration on the surface, and describes as definitely malignant sections of tissue showing diffuse thickening of the surface epithelium with relatively short irregular downgrowths from the basal layers. Of course I should like to see the actual sections in these cases—but even without these I am sure that I have many similar sections in my own series and, as I hope to describe later this appearance does not suggest itself to me as malignant, but as the result of healing in the presence of irritation—the irritation slowly diminishing allowing the healing to complete itself. The type of cell is too adult the irregularity of basal growth too uniform and too simple to suggest to me the presence of that influence which is at the basis of all malignancy.

In 1925 Philip J. Reel discussed the relationship between cervical erosion and cancer.

He says "For all practical purposes the frequency of cancer of the cervix in the virgin is negligible. Here, of course, the cervix has not been tormented by the presence of old lacerations, scar tissue formation or, as in some instances, even a low grade infection, but, on the other hand, it is highly probable that a certain percentage of these have endured the irritation of the congenital types of erosion over a considerable period of time."

It seems to me, in connection with the above,

that Reel rather stretches a point in speaking of the "irritation" of congenital erosion. The erosion in these cases, according to observers is due to a purely anomalous position of the cervical lining, not to chronic irritation. Reel reiterates the well known fact that cancer of the cervix is by far most prevalent in those women who have borne children and in whom are found to a greater or lesser degree the results thereof, namely, laceration, scar tissue, erosion, and secondary infection.

C. H. Mayo says "the part played by chronic irritation in the development of cancer is positive and definite to a degree. The danger of cancer is increased by all irritation and traumatism which demands a continued cell repair, and it is in proportion to that demand. Ultimately exhaustion of cell control bodies occurs modified by age limitations and chemical surroundings. Such areas offer an increasing opportunity for the half of a dividing cell to revert to the unicellular type of life and to become parasitic and cancerous."

Reel attributes the irritative nature of "congenital" erosions to the action of the acid secretions of the vagina upon the misplaced epithelial lining with "consequent secondary infection" which is more virulent in a situation of this nature on account of the fact that such misplaced tissue does not possess the normal degree of immunity.

Fig. 5 A somewhat more advanced picture of Stage 2. The glandular downgrowths have penetrated deeply and show more proliferation of pre-existing cervical glands and less inflammatory reactions. No glandular distention. Small areas of more flattened surface epithelium are shown.

Fig. 6 Stage 3. New squamous epithelium is beginning to replace the columnar epithelium. There is rarefaction of the denser tissues. Deep glandular elements are apparent but little distention is as yet evident.

Reel attaches importance to the exposure of cervical membranes to acid media such as occurs in eversion of the cervical lips—in the production of erosion.

Reel agrees with Eden and Lockyer in preferring the term 'proliferative adenoma of the cervix' to erosion on account of the gross appearance suggesting tissue gain rather than loss. He discusses purely the relation between erosion and cancer and like other observers assumes that all erosions are in effect precancerous states and that treatment—whether medical or surgical—should be immediately carried out on diagnosis. Facilities should be such as to render this practicable as early as possible. Reel like other authors dealing with cervical erosion—even when its association with cancer forms part of the problem—accepts or agrees with the pathology of erosion as expressed by others—as a type of proliferative adenoma, papillary, adenomatous or follicular according to local histological conditions—a redundant area of proliferated cervical lining—lying on the surface of a corresponding area of the portio which has been stripped of its superficial epithelium by chronic inflammation.

This is, of course, a well recognized condition, but one which I think does not play such an important part in the production of cancer as, what I call, a "true ulcerative" type of erosion, a condition to which the

name "erosion" can well be given in that there is definite tissue loss, the erosion area lying at a deeper level than the epithelium of the portio. The actual glandular and columnar cell proliferation in these cases is relatively small and the penetration of the irritant relatively great as compared with proliferative erosions.

Findley again lays great stress upon the treatment of the "precancerous states," namely erosions and eversions of the cervix and endocervicitis as the best means to combat the onset of cancer. He remarks that there seems to be no consensus of opinion as to what constitutes precancerous lesions of the cervix and he quotes the opposed views of such pathologists as Schottlaender and Rick in their interpretation of the various cell changes observed by them. Again Frank asserts that these 'radical pathologists classify as beginning cancer conditions which lacking as we do absolute histological criteria of early malignancy, may as well prove to be harmless epithelial proliferation.'

However, Findley does say 'while recognizing the occurrence of epidermization as a benign lesion I would regard extensive changes of this sort as the precursor of cancer. In all cases where great irregularity in cell form and size, atypical mitosis and hyperchromatism are found the diagnosis of malignancy is established.'

I think that Moench discusses the question of cervical erosion with great lucidity. In definitely differentiating between the pathology of the various cervical conditions which are at present known as "erosions," he draws clear distinctions between them.

His chief conclusions are as follows:

1 The so called congenital erosion due to an anomaly of growth should be called congenital pseudo erosion.

2 The term "endocervicitis" should be replaced by the term "cervicitis" as corresponding more nearly to the morphology present.

3 The inflammatory erosion of the cervix has a stage of actual true erosion and three stages of healing in which it is covered, first, by no epithelium at all, then by columnar epithelium, and in the last two stages by squamous cell epithelium.

4 An ectropion may be due to marked, especially acute, inflammation, or may be due to laceration and eversion of the cervical lips.

Moench thus differentiates definitely between inflammatory erosion and the other conditions such as ectropion, eversion, and congenital erosion, which are loosely called erosions.

From a study of my cases, I am completely in accord with Moench in these distinctions and also in his description of the pathology of inflammatory erosion. This condition however, as Moench describes it, fulfills my conception of proliferative inflammatory erosion according to my classification.

In his description of inflammatory erosion Moench considers that the "rather unstable balance between the columnar and squamous cell epithelium" in the region of the external os due to the epithelial changes which occur embryologically at this point has a marked influence upon the frequency of inflammatory cervical erosion. I agree with him as to the derivation of the primary covering of columnar cell epithelium over the eroded area in that it originates by direct extension from the cervical canal epithelium or from some of the superficially lying cervical glands "which easily can, and do, reach the surface of the portio"—and not, as Ruge and Veit

believed, as an extension from the basal cell layer of the squamous cell epithelium. In speaking of the last stage of healing in which the squamous epithelium completely covers the erstwhile eroded area, Moench quotes Meyer in saying "In this way squamous epithelial downgrowths occur which to the inexperienced, may give the impression of malignancy." This is in entire agreement with my own observations and substantiates my belief that it is from the actual type of cell which is concerned in atypical distributions of epithelium that the diagnosis of malignant activity is to be made. As I shall point out later, the process of healing by epithelium in the presence of continued irritation cannot show other than atypical formations.

With regard to the recurrence of cancer in the cervix, the difficulty is recognized of definitely being able to state the actual site of commencement in the great majority of cases.

For instance, the endocervical type, which predominates, may have its origin either in the basal layers of the squamous epithelium covering the portio or in the columnar epithelium of the cervical canal, and it is nearly always impossible to observe from which of these elements any given cancer has sprung.

Wilson (8) says "That Cancer takes its origin in intimate relations in space with pre-existing epithelium is certain, but that its inception is due to a 'metaphasia of the normal epithelium' has not been proved." He also asserts that there is present a distinct line of demarcation between the normal surface epithelium covering the cervix and any squamous epithelioma in connection with it. There is no histological proof, he says, of a gradual transition between the one and the other. He, however, admits the occurrence of epithelial downgrowths in the vicinity of the malignant tumor, but regards this as due to irritation. Wilson even remarks "It, therefore, appears better to drop the term squamous epithelioma, which implies development from the epithelium covering a definite part of the cervix, and to speak of solid alveolar carcinoma of the cervix."

Bonney has stated that the external os is implicated in every case of cervical cancer, but Wilson says that only 50 per cent of his early cases began at the external os.

In reviewing cancer statistics, B. P. Watson points out that in 1922 and 1923, cancer of the uterus accounted for 16.5 per cent of all deaths in females from cancer in England. The percentage of deaths from cancer of the breast slightly exceeds this figure. He says: "In attempting to diminish the incidence we must not be discouraged by the fact that we do not yet know the ultimate cause of cancer. There are many diseases such as malaria, sleeping sickness, and yellow fever, the incidence of which was diminished before their ultimate cause was known, simply by controlling one factor which appeared to play a part in their causation. The nature of all the agencies which have to work together before cancer can develop in the uterus we do not know, but one condition—namely, irritation—is so constant in cancer of the cervix that it must be recognized as one of the etiological factors."

"Frankl's statistics show that 97 per cent of all cancers of the cervix occur in women who have borne children. The number of pregnancies and labors plays a secondary role. The fact that a woman has had one child predisposes her to cancer of the cervix; that predisposition is almost certainly due to injury of the cervix. If that injury is followed by chronic infection and catarrh as is so frequently the case after deep lacerations, the predisposition is increased. We know that cervical catarrh occurs in nulliparous women as the result of infection and even in virgins in whom infection can be excluded, and these may be the nulliparæ who develop cancer."

Watson, therefore, stresses the importance of the surgical treatment of cervical laceration and inflammatory states of the cervix in the firm belief that the incidence of cancer would be diminished thereby.

Statistics all over the world agree upon this point of multiparity as a predisposing cause to cancer. Leipmann reports that cervical carcinoma in nulliparæ was found by Kroemer to occur in only 1.77 per cent of

cases, by Koblauch in 4.6 per cent, and by Theilhaber and Edelberger in 2.9 per cent.

Cullen also collected 50 cases of squamous cell carcinoma of the cervix and found that 49 of these had borne children and that half the patients were mothers of 5 or more children. Cullen also states that Howard A. Kelly has seen only 3 nulliparæ who had carcinoma of the cervix, and in 1 of the 2 an instrumental dilatation had been previously performed. Cullen, therefore, believes that trauma by instrumental dilatation of the cervix is a possible factor in the development of carcinoma of the cervix.

In this connection Lillian K. P. Farrar investigated the period of time after the last pregnancy at which cancer of the cervix developed, and in her series found this to occur in less than 5 years in 11.1 per cent, between 5 and 10 years in 9.2 per cent, between 10 and 20 years in 41.7 per cent, between 20 and 30 years in 24.4 per cent, and she concludes that repeated injury in successive pregnancies is a point of significance as a predisposing factor. In fact Dr. Farrar considers that cervical lacerations are themselves directly responsible for the onset of cancer and in common with other authors advocates the routine repair of the cervix either by primary or secondary operation.

With regard to these views, I consider that one cannot legitimately dogmatize upon the fact of cervical laceration being the predisposing cause of cancer without first demonstrating that cancer originates in or near the laceration, and this of course is not the case. Although the vast majority of cancer cases in a series show cervical lacerations following childbirth, I consider that this particular injury is of such common occurrence, in fact almost of necessity occurs in greater or lesser degree in association with parturition that failing this pathological proof of cancer incidence the significance of the constant presence of old lacerations in cervical cancer might conceivably be much less than some authors aver. A laceration is an apparent injury and as such perhaps is blamed in excess of its deserts.

The specific nature of cancer growth has exercised the minds of many authors in the

past Ewing in America, Schottlaender in Germany, and Blair Bell in this country are well known authorities

Blair Bell looks at the central problem of cancer from as wide a standpoint as possible and regards it as comprising "a complete understanding and control of that divergence from the normal, both from preventive and curative points of view" and not "as a quest after the so called cause or causes of cancer" He seeks after the "specific process" rather than the specific cause and regards malignant neoplasia as a specific process in itself, but not necessarily due to a specific factor Blair Bell is skeptical in regard to the idea that a single specific causal agent or a combination of two specific causal agents or factors is inevitably responsible for malignant neoplasia, as suggested by the work of Gye on account of the fact that the majority of investigators agree that such factors are numerous and together establish the conditions necessary for the development of cancer In his work, therefore, he has concentrated upon a consideration of the *nature of cancer* as a specific process rather than an investigation into the character of the exciting stimuli

In studying the theories of Blair Bell and Gye in respect of cancer growth, however, I have often thought that, whereas Gye strives to elucidate the mystery of a causal agent at the one end of the scale, and Blair Bell extracts the very essence of the growth process at the other, the intermediate fact of a possible specific influence affected maybe by the former thus resulting in the production of the latter has been overlooked

Blair Bell says that malignant neoplasia arise from cells of impaired function, 'unhealthy cells,' and that whatever causal factor whether metabolic or extrinsic, can permanently impair a cell, without killing it, may be regarded as a predisposing cause or 'exciting factor' of malignant development

He moreover asserts that phosphatides and other lipins are present in larger quantities in malignant growths than in normal somatic tissues Gye and Cramer (4) showed in rat tumors that the phosphatide content

varied as the rapidity of the growth, and shows by experiment that the cells of malignant neoplasia possess a higher water content, a higher phosphatide value, and a higher phosphatide cholesterol ratio than either normal tissue cells or innocent tumor cells, and approximate in these respects to the cells of the chorionic epithelia which are themselves "normal malignant" cells or cells of restrained malignancy Permeability of the cell membrane is favorable to rapid growth and is an essential to malignancy This property is associated with a high phosphatide cholesterol ratio and a high water content is evidence of it

In this research, Blair Bell has aimed at discovering the essential difference in type between the normal and malignant cell and has made use of the cells of the chorionic epithelium, normally present during development of the fetus, but normally possessing functions without parallel in other cells of the human body and demanding characteristics definitely associated with malignancy in adult tissues, as we understand it, and moreover assuming a supermalignant activity on the loss of that control, an understanding of which would mean so much in the elucidation of the cancer problem

Blair Bell further found that the metal lead had an affinity for the phosphatides and cholesterol contained in cell protoplasm and that its action upon the normal chorion epithelium was a specific one, a coagulation necrosis being brought about within the cells His lead treatment for cancer, therefore, is based upon these experiments, the direct aim being to cause an arrest and destruction of the growth by inducing necrosis of its cells or combining the lead with their phosphatide contents

Blair Bell thus defines malignant neoplasia as "a specific growth process in that it is a reversion on the part of the starving cell to the nutriment seeking proclivities of its ancestral type, the chorionic epithelium"

Recently W Schiller has discussed the diagnosis of very early carcinoma of the cervix He is satisfied that just as in the later stages a superficial extension may precede deep penetration of the neoplasm at

right angles to the epithelial covering, so in the very earliest stages the neoplastic change, which (he asserts) invariably commences near the external os proceeds centrifugally along the surface of the cervix

In a series of 135 cases in which the uterus was removed for other reasons, Schiller found that early evidence of carcinoma occurred in 4

Schuller defines the pathological cytology as "anaplastic atypia and polymorphism" of the epithelial cells. He says that in the very earliest stages the epithelium is as definitely marked off from the underlying connective tissue as in normal conditions, but both in the basal and superjacent layers neighboring epithelial cells and their nuclei are of differing size and shape, with variable staining properties. The nuclei are relatively more numerous than in the healthy epithelium, from which the early carcinomatous area is marked off by a sharp and unusually oblique line of demarcation.

Neither absence of mitoses nor absence of penetration of the epithelium deep into the connective tissue excludes the diagnosis of carcinoma. Inflammatory infiltration beneath the carcinomatous zone is usually noted.

Thus certain of Schuller's findings are in agreement with my own. For instance, I am sure that the beginning of carcinoma occurs in the region of the external os. The cell changes in early carcinoma are similar to those observed in my series. As to the "oblique line of demarcation" between the carcinomatous and unaffected areas, I am not wholly in agreement as to this being of a purely pathological nature.

More recently still, at the International Cancer Conference certain distinguished speakers discussed the latest theories as to the etiology of cancer.

James Ewing favored the irritation theory. He said "It seemed clear that cancer arose only on tissue which had become altered by chronic irritation." He declared that there was no one exciting cause of cancer, nor one great secret in the cancer cells.

Archibald Leitch discussed certain specific irritants which appeared to be able to produce cancer under certain conditions and in certain hosts.

J. B. Murphy dealt a severe blow to the virus theory of cancer. He asserted that fractional precipitation of the proteins from extracts of the Rous chicken sarcoma results in the production of a purified fraction which is capable of reproducing tumors in fowls. This active fraction had also been isolated from tissue of normal fowls free from contact with tumor bearing animals, a fact which negatives the specific virus theory. Murphy, therefore, considered that one had to deal with endogenous chemical substances rather than with extrinsic living viruses.

J. McIntosh on the other hand considered that the virus theory had been regarded too lightly.

A. Borrel also supported the virus theory. Many other speakers of international repute contributed to the discussion which, however, terminated in a stalemate between the biological and parasitic theories—a position which has so long prevailed. Experimental cancer production has not yet reached the stage of consistency. The unknown "agent" has not yet been elucidated. Production of cancer by the direct injection of the specific agent presumed to be present in certain extracts, or by the indirect method of irritation by chemical irritants, has not yet resulted in any one fact being common to all. The adherents of both the great etiological theories therefore are still able to stand firmly by their separate and distinctive views.

I THE PATHOLOGY OF CERVICITIS—EROSION OF THE CERVIX

Much has been written concerning the pathology of cervical erosion, much, that is, by American and Continental authors. In this country, however, gynecologists and pathologists have tended to evade this subject. I can find little evidence in British journals of a systematic inquiry having been carried out in respect of it. B. P. Watson's account, as published in Eden and Lockyer, (8) is a standard description.

My series of 850 specimens of the cervix uteri removed for all causes, including that of cancer, contains 822 instances of cervical erosion in its various phases and a study of these has led me to adopt definite views as to the pathology of these phases. In the main I am in agreement with certain American observers but I feel that a wide enough view has not been taken in respect of certain factors in the life history of this condition.

CONGENITAL EROSION

The reddened patch observed to envelope the external os in the nulliparous and presumably non-infected cervix has been long accepted as being due to an anomalous growth of the mucous membrane lining the cervical canal whereby it fails to recede during infancy from its encroachment on to the portio.

I have not verified or disproved this view myself but I can assert that cases of this type in my series show definite evidence of an associated inflammatory reaction which presumably then would be of a secondary nature. Whether this reaction is due to the effects of bacterial infection or chemical irritation one cannot say. In any case this fact has no important bearing upon our view of the pathology of erosion—the basic factor concerned being in all cases, a typical acute, subacute or chronic inflammatory infiltration in contact with the affected area. I therefore prefer to use the word *irritation* in place of *infection* throughout as a term which embraces the effects of either bacterial or chemical contact.

Moreover the type known as congenital erosion is by comparison relatively rare and

is consequently, from the point of view of this work, of much less importance as a precursor of cancer than the great group of inflammatory erosions with which I am about to deal.

Histologically there is no reason to distinguish between this type and the proliferative erosion which is brought about as the result of irritation. The inflammatory reaction is there or has been there. Whether it is the cause of the lesion, or secondary to it, depends upon one's acceptance of the etiological theory.

Plate 1 A The gross appearance of the nulliparous erosions. This is taken from a case in which there were 2 or 3 small uterine fibroids present in the uterus. Panhysterectomy was performed in a nullipara. Such specimens are, of course, difficult to obtain, as removal of the cervix is not a recognized form of treatment for erosion in the nullipara, and panhysterectomy is also a rule infrequently performed in these patients.

Figure 1 shows the histological appearance in this case and demonstrates the evidence of an old inflammatory reaction in association.

INFLAMMATORY EROSION

The so-called erosion proper or inflammatory erosion of Moench has long been a recognized pathological and clinical entity. American rather than British observers have studied this most important subject of gynecological pathology. A study of my cases which exhibit instances of this condition has led me to agree to a large extent with these observers. I have studied the subject of cervical erosion as a preliminary to, and as part and parcel of, my inquiry into its relationship to cancer of this situation and I propose to deal briefly with its various phases as I believe they occur.

STAGE I THE PRIMARY EFFECTS OF IRRITATION
(A TEMPORARY PHASE OF TRUE EROSION)

The irritant during the first stage is acute or subacute and is evidenced by the presence of a localized reddened patch of affected surface tissue near the external os.

Microscopically it is observed that the squamous epithelium of the portio has had no time to react to the inflammatory irritant. There are no hypertrophic downgrowths of it or other associated proliferations of its cells which occur as its specific reaction to the more chronic irritations. Instead the epithelium is stripped off bodily at the level of its lowermost layer of cells and lifted up by the invasion of masses of large and small blood cells and others composing the exudate excited by the inflammatory reaction. The glandular elements situated in the region of the external os have also no time as yet to proliferate so that the affected area of the portio is characterized by a comparatively thin layer of inflammatory material—which has itself not yet had time to penetrate the muscular tissues of the cervix to any appreciable extent—bounded by a strip of partially desquamated but otherwise normal squamous epithelial covering, which is continuous at its further end with as yet unaffected epithelium on the one side and the glandular elements near the internal os on the other.

I found that cases in the early stage were the most difficult from which to obtain a specimen on account of the fact that the condition had progressed to chronicity as a rule before the patient came to operation, that is for removal of the cervix. Patients exhibiting early cervical irritation, *per se*, are of course treated by other means, so that I possess in my series only 8 cases which show this early stage at all well histologically.

Figure 2 shows the histological appearance presented in the early stage.

Figure 3 shows a slightly farther advanced degree of the same stage. Here the irritant goes somewhat deeper and there is a commencing activity on the part of the cervical glands to react by proliferation. As yet, however, the surface irritation predominates and there is no attempt to recover the affected area by new epithelium.

I consider that during this first stage only, one might justly term the condition erosion. There is actual loss of surface epithelium now with no replacement. There is a replacement of the firm surface muscle tissues by semiliquid inflammatory material. The af-

ected area is truly eroded. But this stage is a relatively temporary one as compared with the long standing stages of chronicity which follow, and which themselves are known, erroneously in my opinion, as variations in type of cervical erosion. On the other hand, this early and temporary stage which is pathologically a true erosion is generally termed acute cervicitis which of course is a correct nomenclature.

STAGE 2. EPITHELIAL REACTION TO INFLAMMATORY IRRITATION, PROLIFERATION AND REPAIR

The second stage marks the limit of the inflammatory ascendancy—the moment at which its advance is checked by the epithelial defending elements.

The evidences of the inflammatory reaction are definitely lessened. The surface exudate is less, although it still contains a number of leucocytes, and it is intimately associated with the new surface epithelial covering which is identical with, and derived from, the columnar epithelium lining the cervical canal and cervical glands. The affected cervix now presents the typical appearance associated with this condition. A roughly circular area around the external os is reddened and slightly raised above the level of the portio. This area is soft and "velvety" to the touch and may bleed on examination. It is caused by a true redundancy of abnormally situated columnar epithelial elements in association with the products of a subsiding inflammatory reaction.

Microscopically it is observed that the products of inflammation are much lessened and are now intermingled with a new surface covering composed of a single layer of high columnar epithelial cells from which glandular downgrowths into the subjacent rarefied areas have taken place. The epithelium lining the cervical canal has responded to the inflammatory irritant and has proliferated in an effort to repair at the same time exercising its specific function in the manufacture of new glandular elements. These downgrowths vary in depth, and between them the sparse connective tissues of the

inflamed cervical surface persist in varying amount. This gives the appearance of small, papillary projections with central connective tissue cores and has resulted in the term "papillary erosion" being applied to this state. At this stage then the new surface elements do not penetrate the underlying muscle to any extent—the depth of the erosion along most of its extent being only that of a single short glandular downgrowth. In the region near the external os, however, where the normally situated cervical glands are placed, the depth increases somewhat owing to a localized proliferation of the actual glands themselves, whereby they spread outward and upward to the surface at its nearest point. As yet, however, even the more deeply situated of these glands have not had time to enlarge by distention and the epithelium lining all these new downgrowths remains of the high columnar type. The general appearance of this stage is one of great epithelial activity in the presence of a continued but less virulent irritation (Fig. 4).

A battle is now waged between the invading inflammatory elements and the defensive epithelial tissues, until a stage is reached at which the glandular downgrowths have reached their furthest penetrative limit and the inflammatory reaction has considerably lessened in activity. Absorption of some of the older exudative material is beginning to take place with consequent rarefaction of the basic surface tissues. Here and there small thin strips of a flattened epithelium can be discovered on the very surface of the affected area. There is however, no glandular distention among the new elements all of which communicate freely with the surface. The pre-existing cervical glands in the region of the external os have reacted to the irritant to their utmost extent and have proliferated as far as possible to merge gradually into the new glandular formations. This is the turning point between destruction and repair, and is characterized by the obvious lack of necessity for further epithelial activity, the irritant being now inefficient to effect this phenomenon. Figure 5 shows an example of this end phase of Stage 2.

STAGE 3 REPLACEMENT OF COLUMNAR BY SQUAMOUS EPITHELIUM ON THE SURFACE OF THE AFFECTED AREA COMMENCEMENT OF FINAL REPAIR

This stage is one of immense interest histologically in that it exhibits a range of variations in accordance with the conditions under which it takes place. The recovering of the affected surface by squamous epithelial cells—cells which are much less resistant to maceration than columnar epithelial cells—can take place to perfection only in the complete absence of irritation. Many of the variations shown in the development of this stage are due to the different degrees of irritation still present at the time of healing. Others are due to recurrence of the irritation in greater or lesser degree, as the result of re-irritation, after healing has partially taken place and others are again the outcome of regenerative growth in non-resistant areas. A cursory glance at certain of these variations, especially if one is not accustomed to the study of gynecological pathology, will undoubtedly result in an erroneous impression being conveyed as to the innocence or otherwise of the epithelial growth as here depicted. The general histological picture presented by this stage is one of gradual encroachment on the part of a highly sensitive epithelium in its purpose of covering an area still smarting from the recent attack by a severe irritant, which has been checked by proliferation of columnar epithelium.

This epithelial encroachment is made as the result of new cells growing from the basal layer of the nearest unaffected squamous covering upward toward the adjacent columnar epithelial surface and lifting this simple layer up in lever fashion, thereby gradually replacing it. The new squamous covering at this stage is only two or three cells in thickness but proliferation is seen to take place as the advance proceeds until the actual growing edge may assume almost a normal thickness of say 20 cells. In parts also the columnar epithelium becomes overrun and the new squamous cells encroach partially or wholly into the glandular downgrowths.

It is a noticeable constant feature of this stage that the tissues immediately beneath

the columnar epithelial elements are greatly rarefied. This is due to the absorption of the products of inflammation which have occupied this area up to this time. Here and there, however, one may discern isolated subepithelial situations which are still under the influence of the inflammatory irritant. These are not covered by new squamous cells. The growing edge proliferates actively from its basal layers on approaching such a situation and ends as a bulbous mass exhibiting cellular downgrowths of varying extent according to the degree of irritation experienced. The gradual, cautious, and timid advance of these cells is well exemplified in the early stages of their repair work. Only where the ground is safe will they venture. Their proliferation by cell division, with the formation of a more rounded, almost hexagonal type of cell possessing a deeper staining nucleus and cytoplasm—altogether a less stable type of cell—in situations that have relatively little effect upon the columnar epithelial elements, is remarkable (Fig 6).

To recapitulate then the salient histological features of this stage are (1) the irregular, relatively thin strips of new squamous epithelium on the affected surface encroaching on to the area covered by columnar epithelium, (2) the rarefaction of the denser subepithelial tissues, (3) the almost total disappearance of inflammatory reaction, and (4) the relatively deep penetration of the glandular downgrowths which, however, show little or no dilatation as yet.

Figure 7 also shows this stage. The glands here have penetrated deeply a fact from which one may gauge the age of the condition. The superficial areas are rarefied, but although new squamous epithelium has appeared on the surface there is no dilatation of the lumina of the glands. It will be noticed that here there is practically no evidence of irritation. The new squamous epithelium has been able to effect its work of resurfacing the portio without interference. There have not even been any temporary difficulties to overcome in this respect, as is evinced by the absence of cellular downgrowths from the deeper layers of this new covering.

Now with regard to Stage 3, one often

observes that this initial attempt to heal is thwarted as the result of surface infection being locally too irritant to admit of new squamous cell encroachment. It is obvious that the attempt to recover the portio by new squamous epithelium is begun as soon as the irritability of the causal agent has dropped to a certain degree in the neighborhood of unaffected squamous epithelium, compatible with the ascendancy of new cells which would emanate from it. As I have before explained, this level is of necessity very low as the new squamous cells are unable to tolerate the effects of irritation in any amount without proliferative activity. The growing edge of the new epithelium therefore, often encounters a point at which the surface irritation is still too active to tolerate its presence, with the result that further advance is prevented and the furthermost cells of the new epithelial covering proliferate into a bulbous end in response to the irritation experienced on approaching the vicinity of this area, this notwithstanding the fact that new columnar epithelium proliferated from the old cervical lining is in actual contact with the inflammatory zone, engaged in fighting down its destructive effects. Here is a proof of the relative stability of columnar epithelium as compared with the squamous type of this region. The further advance of the new squamous cells is prevented until subsidence of the irritation has reached the necessary point for tolerance.

STAGE 4 THE STAGE OF ULTIMATE HEALING

The fourth stage is that at which complete ascendancy has been gained over the surface tissues by the new epithelial covering. From what I have just said it will be realized that this phase may not be completed without some temporary setbacks being experienced by this epithelium. We therefore see many cases in which ultimate success has been won in the process of healing at the expense of localized proliferative downgrowths of these cells. Occasionally one may even still observe the fading effects of localized irritative obstacles in the association of scattered infiltrative areas connected with the basal cells of these downgrowths.

Fig. 7 Stage 3 slightly more advanced. New surface epithelium with greater continuity but relatively thin. Rarefaction of surface tissues. Deep glandular penetration. Great diminution of inflammatory reaction. Little dilatation of glands.

Fig. 8 Stage 4. Ultimate healing has taken place in the presence of localized irritation which is due to isolated irritative foci. There are epithelial downgrowths from the deeper layers. Dilatation of glands beneath epithelium.

This phenomenon of healing in the presence of irritation is extremely interesting histologically and accounts for numerous appearances resulting from cell behaviors which have a bearing upon the cancer problem.

It is sufficient at this moment, however to exemplify my meaning by referring to Figure 8 which shows this aspect of Stage 4. It will be seen that the new epithelium exhibits isolated downgrowths as the result of proliferation of the cells of its deeper layers—a responsive reaction to the experience of an irritant of low degree.

Irritations, or low grade infections, such as these, however are as a rule not sufficient permanently to stay the advance of the healing cells relatively simple as this is, and in many cases the only evidence that such a temporary difficulty has occurred at all is the presence of one or more cellular downgrowths from an otherwise evenly based squamous covering.

In Figure 8 one may observe the difficulty experienced by the new squamous epithelium in performing its function, but it has obviously succeeded in this, notwithstanding the continued presence of some irritant probably of an infective nature. At one point the squamous cells have had recourse to proliferation resulting in a marked increase in the number of layers of cells. In this situation the chronic irritation is still evi-

denced by a round cell infiltration in association with the deepest layers of the epithelial cells from which it is also plain that the proliferation originates.

In this section there are irregular cellular downgrowths along the whole length of the epithelial covering, and it is everywhere noticeable that the deepest and most active are in association with areas of scattered round cell infiltration, an irritation of poor degree but sufficient to call for the reactive changes in these new cells.

This stage is characterized by the presence of dilated gland spaces situated beneath the new covering, the result of mechanical blocking of their ducts by the squamous cells. Here and there the new cells can be seen to have grown wholly or partially down into the lumen of glandular structures opening freely on to the surface.

The histological appearances presented by Stage 4 may therefore differ in a variety of minor ways according to the type of cellular reaction present.

In some cases complete healing has obviously taken place with no difficulty on the part of the new epithelium. The primary infection has apparently subsided evenly and quickly. This is evinced by a uniform and relatively thin layer of squamous cells covering the old erosion area, which now appears as a mass of scattered glandular structures,

the columnar epithelial elements are greatly rarefied. This is due to the absorption of the products of inflammation which have occupied this area up to this time. Here and there, however, one may discern isolated subepithelial situations which are still under the influence of the inflammatory irritant. These are not covered by new squamous cells. The growing edge proliferates actively from its basal layers on approaching such a situation and ends as a bulbous mass exhibiting cellular downgrowths of varying extent according to the degree of irritation experienced. The gradual, cautious, and timid advance of these cells is well exemplified in the early stages of their repair work. Only where the ground is safe will they venture. Their proliferation by cell division with the formation of a more rounded, almost hexagonal type of cell possessing a deeper staining nucleus and cytoplasm—altogether a less stable type of cell—in situations that have relatively little effect upon the columnar epithelial elements, is remarkable (Fig 6).

To recapitulate then the salient histological features of this stage are (1) the irregular, relatively thin strips of new squamous epithelium on the affected surface encroaching on to the area covered by columnar epithelium, (2) the rarefaction of the denser subepithelial tissues, (3) the almost total disappearance of inflammatory reaction and (4) the relatively deep penetration of the glandular downgrowths which, however, show little or no dilatation as yet.

Figure 7 also shows this stage. The glands here have penetrated deeply, a fact from which one may gauge the age of the condition. The superficial areas are rarefied, but although new squamous epithelium has appeared on the surface there is no dilatation of the lumina of the glands. It will be noticed that here there is practically no evidence of irritation. The new squamous epithelium has been able to effect its work of resurfacing the portio without interference. There have not even been any temporary difficulties to overcome in this respect as is evinced by the absence of cellular downgrowths from the deeper layers of this new covering.

Now with regard to Stage 3 one often

observes that this initial attempt to heal is thwarted as the result of surface infection being locally too irritant to admit of new squamous cell encroachment. It is obvious that the attempt to recover the portio by new squamous epithelium is begun as soon as the irritability of the causal agent has dropped to a certain degree in the neighborhood of unaffected squamous epithelium compatible with the ascendancy of new cells which would emanate from it. As I have before explained, this level is of necessity very low as the new squamous cells are unable to tolerate the effects of irritation in any amount without proliferative activity. The growing edge of the new epithelium, therefore, often encounters a point at which the surface irritation is still too active to tolerate its presence, with the result that further advance is prevented and the furthermost cells of the new epithelial covering proliferate into a bulbous end in response to the irritation experienced on approaching the vicinity of this area, this notwithstanding the fact that new columnar epithelium proliferated from the old cervical lining, is in actual contact with the inflammatory zone, engaged in fighting down its destructive effects. Here is a proof of the relative stability of columnar epithelium as compared with the squamous type of this region. The further advance of the new squamous cells is prevented until subsidence of the irritation has reached the necessary point for tolerance.

STAGE 4 THE STAGE OF ULTIMATE HEALING

The fourth stage is that at which complete ascendancy has been gained over the surface tissues by the new epithelial covering. From what I have just said it will be realized that this phase may not be completed without some temporary setbacks being experienced by this epithelium. We, therefore, see many cases in which ultimate success has been won in the process of healing at the expense of localized proliferative downgrowths of these cells. Occasionally one may even still observe the fading effects of localized irritative obstacles in the association of scattered infiltrative areas connected with the basal cells of these downgrowths.

Fig 11 left A discrete chronic ulcer of the cervix
Note that the demarcation is very definite

Fig 12 Retrogression of ulcerative activity Shallow granulation area—no penetration Blunt epithelial down growths containing a large percentage of old cells Commencing proliferation of cervical glandular elements

erosion and distinct pathologically though linked clinically with the erosions hitherto discussed

Ulceration of the cervix may not completely involve the region of the external os. Indeed in some instances this area is not affected at all, the ulcer in these cases remaining discrete and located to the surface epithelium of the portio

Plate 1 D shows this type of ulceration

It is rare however to find the external os completely free from involvement, but readily understandable that this virulent form of irritation may be occasionally detected in this phase before extension from a primary focus on the portio has taken place sufficiently to envelope it

My series shows instances of this ulcerative erosion and I have remarked it as a relatively common condition in association with the damaged and hypertrophied cervix usually removed during the operation for uterine prolapse

The salient features of the gross aspect of this condition, which definitely differentiate it from proliferative erosions, are (1) the depressed nature of the affected area, (2) the overhanging epithelial edges in immediate contact, and (3) the smooth granular surface coated with chronic exudative material

Histologically this state presents a very characteristic appearance. The surface of the affected area is entirely denuded of epithelium

and is composed of a mass of granulation tissue exhibiting varying degrees of organization. The actual surface elements are relatively dense and penetrate to approximately the depth of normal epithelium. A highly hemorrhagic zone lies immediately beneath the surface granulation and below this the tissues are infiltrated to varying depths by masses of lymphocytes, leucocytes, and macerated epithelial cells, according to the degree of activity of the irritant present. The causative agent is obviously of such a virulence as absolutely to negative any attempt at healing on the part of the adjacent epithelium. Even the glandular elements of the cervical canal are unable to encroach within this area. Epithelial tissue is unable to exist in association with this virulent and deeply destructive irritant

In the early stages of proliferative erosion we saw the rapid and wholesale destruction of the surface epithelium, followed by healing as the patient's resistance successfully combated the attack. Here it is apparent that the process is a more continued one the irritation continuing to chronicity, with failure of the healing process. The areas adjacent to the normal epithelium contain masses of half destroyed and macerated squamous cells. However, in active ulceration there is no subsidence on the part of the irritant, no rarefaction of the subjacent tissues due to absorption of inflammatory

Fig 9 Stage 4 A healed erosion Healing on the part of new squamous epithelium with no difficulty in the absence of surface irritation

Fig 10 Ulcerative erosion involving the external os A depressed granular area Irritative epithelial downgrowths

varying in degrees of dilatation and situated at varying depths below the surface amongst rarefied tissues

Figure 9 shows this appearance well This is the state commonly known as a healed erosion Here the process has been relatively simple The irritant responsible for the primary erosion has subsided and only minute traces remain The new squamous cells have been able to perform their function without molestation There are no proliferative downgrowths either into the subjacent tissues or into the surface glands, the ducts of which, however, have nevertheless been efficiently occluded by means of the thin overgrowths of cells

In describing the histological characters of cervical erosion as they have appeared to me in studying my series of cases, I have pronounced little that is at variance in any way with the accepted views of this condition The authors indicated in my historical note record appearances very similar to those that I have described

I have, however, studied this question, not as a finite state in itself, but as an important preliminary aspect of the development of cancer in this situation As I have said elsewhere, I believe the cervix uteri to be the organ of the body in which the study of cancer growth can best be investigated, and as a means to this end I have preferred to carry out a systematic inquiry into the pathology of a condition which all must recognize as a precursor of that state

In the process of this investigation I have, of necessity acquired certain views upon the condition of cervical erosion which I will summarize in due course Of these views however, I must now indicate one in order to complete this description It is to the effect that I believe a condition of *ulcerative erosion* or *true erosion* to be pathologically akin to the erosion already described and therefore to be a condition which should be classified together with its allied state

This condition is entirely distinct pathologically from that just described It nevertheless constitutes an erosion a true erosion, of the cervix and is commonly met with clinically The type of cervix seen to be chiefly affected is the hypertrophied lacerated, and cicatricial one of the multipara Such a cervix is often observed to be the seat of a chronic ulcerative condition whereby the affected area becomes definitely depressed below the level of the surrounding epithelium of the portio This ulceration may or may not involve the area of the external os but most frequently does

The gross appearance reveals an irregularly outlined depressed, and granular area smooth and discolored to a reddish yellow by the surface exudates partly or wholly involving the portio in the region of the external os which itself is usually heavily distorted by lacerations and scars

Plate 1, C, indicates the gross appearances of this erosion which appears even to the naked eye, as a destructive lesion, a true

Figure 13 shows an old dormant ulcer allowing itself to be healed by a single layer of columnar cells which have appeared on its surface. These have undoubtedly emanated from cervical epithelium which has proliferated to the vicinity.

By this time, however, there is definite loss of tissue so that a completely healed ulcer is essentially a depressed scar.

Ulcerative erosion differs only from the proliferative type in that the primary destructive agent is of greater virulence that is relative to the patient's powers of resistance. Whereas in the one case the invader is rapidly expelled and healing is effected without appreciable loss of tissue, in the other the process is delayed at the price of tissue loss. Epithelium in the vicinity reacting to irritation while being inadequate to cope with the prolonged attack. The lesion produced, ulcerative or proliferative erosion, varies directly as the relative strength of the irritant or inversely as the degree of resistance of the patient to it. In this way only can a localized irritation attain to chronicity. The lesions are therefore essentially the same from an etiological standpoint and should be classified on the same pathological basis.

SUMMARY

In this part of my work I have attempted to describe in some detail the pathology of so called erosion of the cervix. As I have said elsewhere my object in doing this has been to elucidate a subject in all its phases, which is recognized to be a definite stepping stone in the production of cancer. I consider that it is only by tracing the life history of erosion step by step that one may acquire the necessary knowledge of associated cellular changes that is essential in the study of its all important sequel. To this end therefore I have extracted the necessary details from my series of 850 specimens which have gone to the formation of I fear, a somewhat prolonged and labored dissertation.

In summarizing this part of my subject I am unable to resist joining with many previous authors in an attack upon the old nomenclature. The term 'erosion' is an entirely erroneous one in this connection from

the pathological standpoint. This term was primarily applied as a facile description of the gross appearance of certain aspects of the condition only, purely a clinical nickname instituted in the days when the science of morbid anatomy, as applied to gynecology was by no means as advanced as it is today, and in any case, as a clinical term contrary to the laws of medical terminology today, founded as it is upon a pathological basis. The pathology of this condition determines its etiology from an infective or irritative source and of these two I have no doubt that the former is a correct assumption. In either case however, a typical inflammatory reaction of some degree is always in association and therefore the term *cervicitis* is the only applicable one.

Now we know that infection limited to the cervical glands results in an appearance differing from that under discussion, hence necessitating a distinct nomenclature. Also Moench definitely states the congenital origin of certain erosions seen in the virgin and assigns to them the term *congenital pseudo erosion*. In this connection I would say that cases of this type in which one could definitely dissociate the element of infection histologically must be very rare. In my series I have only 3 specimens of the virgin cervix in which there can be no question of infection. A definite erosion is not present in any. However, I do not dispute the view held by Moench. My own is that this class is a very minor one.

I would therefore, assert that the correct nomenclature in the group of cases hitherto known as proliferative erosion is *peri or ular cervicitis*, that the ulcerative erosion which I have described should be termed *ulcerative cervicitis*, and that infection limited to the cervical glands is properly termed *glandular cervicitis*.

Broadly speaking, this lesion (erosion) is produced by the effect of the inflammatory reaction, locally applied in the region of the external cervical os, for varying lengths of time, and the reaction of the involved tissues to it. A temporary attack, or one the virulence of which is quickly combated by the patient's resistance results in a temporary

Fig. 13 Commencing healing of old ulcer. A single short layer of columnar cells on the surface of the ulcer

exudates, no healing. The only cellular reaction discernible, and this is so constant as to be typical, consists of a series of irritative downgrowths from the deeper layers of the adjacent surface epithelium. This is due to the spread of the irritant beneath the surface of the epithelium radially from the central focus and its continued action upon the adjacent epithelial cells. Lymphocytic and leucocytic infiltration can be seen in contact with these epithelial downgrowths which, of course, are totally inadequate from a healing point of view, but as one would expect represent on the part of the highly sensitive basal cells of the squamous layer a typical reaction to chronic irritation. Indeed partial or total destruction of many of these cells takes place concurrent with proliferation. This fact can be observed in the scattered masses of disintegrated squamous cells lying in intimate contact with the proliferative downgrowths in cases in which the virulence of the infection continues.

An ulcerative erosion therefore may be recognized histologically by its salient features which are (1) a depressed granular area extending deeply into the subjacent tissues presenting a relatively dense structure and containing no epithelial structures and (2) associated with a highly irritative type of adjacent squamous epithelium due to ineffective proliferative downgrowths from the basal layers.

Figure 10 shows ulcerative erosion involv-

ing the external os and demonstrates the type of adjacent epithelium found in association with this condition.

In these cases in which the ulcerative state is localized to the portio the demarcation is very definite, the depressed nature of the lesion is very obvious and the chronicity well marked.

Figure 11 shows an example of this class of discrete ulcer, of which of course there may be various sizes and shapes.

By an "active ulcer," I mean an ulcer which is the site of an irritation which is continuous in such virulence as to bring about increasing loss of normal tissue while presenting all the histological characteristics of acute irritation. In such a case there is nowhere any evidence of subsidence on the part of the causative agent. This, however, does eventually occur in certain cases, but in the type of patient whose resistance is such as to tolerate ulceration or may be on account of the extreme virulence of the agent concerned the retrogressive process is necessarily slow. One does however observe the more chronic less active type of ulcer which presents the appearance associated with gradual absorption of the old inflammatory products and cessation of penetration.

Figure 12 demonstrates this type well. Here the virulence of the causal agent is lessened to a point at which the patient's resistance can effect a cure by healing. In such a case one sees that the exudates are confined much more to the surface and that a rarefied zone lies immediately beneath, indicative of absorption of the erstwhile penetrative elements. Moreover the adjacent squamous epithelium is unaffected by immediate leucocytic infiltration, the subepithelial tissues being again rarefied and the cellular downgrowths being now blunter at their points and containing a large percentage of older cells.

At a later stage when the irritant has been slowly overcome and the ulcer has become more or less dormant one may observe the first attempts to repair the wounded surface. This is as usual undertaken by columnar epithelium, a further proof of the resistant nature of this type of cell.

ANNULAR PANCREAS¹

NELSON J HOWARD M D SAN FRANCISCO CALIFORNIA

THE term "annular pancreas" is applied to a developmental anomaly in which a firm ring of pancreatic tissue completely encircles the first part of the descending portion of the duodenum. It has a clinical as well as a morphological significance.

Becourt in 1830 first recorded this anomaly. Moyses, Ecker, Tiedeman, and Auberg have described the condition, Ecker being the first to apply the name ring or annular pancreas to the unusual finding. Symington, Generich, Thieken, Thatcher, and Summa have also contributed to our knowledge of the structure and anatomical relations of the annular pancreas, and its embryological development has been studied by Baldwin, Lecco, and Cordes.

At an early period in the human embryo, two outgrowths develop from the alimentary canal, one projecting dorsally in the dorsal mesentery and the other arising in common with the choledochus ventral to the primitive alimentary canal. This ventral pancreatic anlage has two offshoots, a right and a left, although the latter soon disappears. Through the rotation of the duodenum about its axis the dorsal and the ventral anlagen approach each other and fuse, so that they lie behind and to the left of the duodenum.

The dorsal anlage develops to form the body and tail of the pancreas which lies transversely in the abdomen behind the stomach, while the ventral anlage grows to become the caudal part of the head of the pancreas which is enclosed within the duodenal loop. At the fusion of the dorsal and ventral anlagen an anastomosis between the ducts of the two portions of the embryonic pancreas occurs, and although the ventral anlage forms eventually only a small part of the gland, the duct of the ventral anlage becomes the main pancreatic duct or duct of Wirsung, while the duct of the dorsal anlage becomes the accessory pancreatic duct of Santorini (Fig 2).

It was Thieken who first suggested "If the ventral and dorsal anlage of the pancreas did not unite as they ordinarily do, but each developed independently, there would be pancreatic tissue on either side of the intestine, and, as growth proceeded, the bowel would soon be completely surrounded by glandular tissue." Shortly thereafter, Baldwin described a specimen of adult human pancreas showing non fusion of the primitive dorsal and ventral anlagen of the pancreas, together with an insufficient rotation of the ventral anlage around the duodenum. He was fortunate also, while studying a series of adult human pancreas, in discovering one specimen of annular pancreas. In a careful study of this case of annular pancreas he found in the head of the pancreas the beginning of a duct which formed no connection with the accessory pancreatic duct but which coursed from left to right with increasing caliber ventrally through the ring of pancreatic tissue surrounding the duodenum to the head of the gland posteriorly, where it passed dorsal to the common bile duct and opened into the main pancreatic duct. This fact indicated to him that the ring of pancreas encircling the duodenum was a persistence of the left half of the ventral anlage or an excessive growth of the right half of the same anlage.

In a most precise and exhausting study of two specimens of annular pancreas, Lecco utilized the embryological development of the pancreatic ducts to determine the mode of origin of the annular pancreas. According to Lecco the annular pancreas differs from the normal gland in possessing a portion which arises from the dorsal portion of the head of the adult pancreas and encircles the duodenum. The arrangement of the ducts of the annular pancreas is similar to that of the normal pancreas, and the smaller variations of arrangement occurring in the annular pancreas find a parallel in almost identical variations in the normal pancreatic ducts (Fig 3).

¹ From the Department of Surgery Stanford University Medical School

primary destructive phase (Stage 1), which represents a true erosion of the normal surface, followed by epithelial reactive activities progressing to healing (Stages 2, 3, 4, 5). An attack of greater virulence or one of which is relatively weakly combated by the patient's powers of resistance results in a prolonged battle between the invasive element and the involved tissues. The resistance is slow. The virulence of the invader is but slowly overcome. Loss of tissue combined with penetration of the irritant is concurrent with organization of the exudates and the attenuation of the causal agent. A state of chronicity exists, which is represented by a typical appearance and is attended by typical epithelial reactions, ulceration. This state that of ulceration represents true erosion of the normal tissue surface, as also does the temporary Stage 1 of the proliferative type. These two conditions then might truly be spoken of as erosions if necessary, although the term from a scientific point of view remains crude.

I will have failed in my purpose if I have been unable to convey the impression of histological accuracy in the discussion of this subject just concluded. It has been toward a thorough understanding of the tissue reactions concerned in cervical erosion that I have concentrated in my study of this condition, and to that end I have preferred to trace its histological life history step by step. At this stage therefore the various aspects of erosion in all its phases, its degrees, its associated cellular activities (which I shall speak of later), its histological eccentricities almost are now understood as the result of this routine examination. The ultimate sequel to erosion is malignancy, but there is the phase between these two which must be

bridged—the pre malignant phase which must contain the primary malignant reactions. In this work I have aimed at the recognition beyond doubt of these earliest manifestations of cancerous change, in the hope that some light may thereby be thrown upon the origin of this disease.

bile stained material and peristaltic waves in the stomach were visible through the lax abdominal wall. There was no jaundice. A diagnosis of congenital pyloric stenosis was made, but at operation the stomach and pylorus were found to be normal. Beyond the pylorus the duodenum was continued as a thin white cord having the size and appearance of a goose quill which could be rolled under one's finger, and which penetrated a hard irregular tumor that proved to be the head of the pancreas. The tail and body of the pancreas were normal in size and consistency. Below the pancreatic head the duodenum quickly regained its normal appearance. Because of the atresia of the duodenum a posterior gastro-enterostomy was done. The child had an uninterrupted convalescence.

CASE 2 Reported by Reynoldo Dos Santos. A young woman 26 years of age had suffered from stomach trouble since the age of ten. At that time epigastric pain after meals with occasional vomiting and pyrosis was noticed. The pain was often relieved by eating. During the last 2 years of her illness, the pain and vomiting had become more frequent and retention of food was present, the vomitus occasionally containing food taken several days previously. Frequent hæmatemesis and tarry stools appeared and the pain became so severe that even water was not tolerated. A diagnosis of duodenal or pyloric stenosis with ulceration was made, and at operation a posterior gastro-enterostomy was performed. The patient improved rapidly and was eating a soft diet when bilateral pneumonia caused her death on the ninth day after the operation. An autopsy revealed two ulcers on the posterior wall of the stomach which was greatly dilated and a duodenum which was completely modified in its relations. The first portion ascended to the head of the pancreas where it was fixed by a ring of pancreatic tissue, which constricted the duodenum to a diameter of 1.5 centimeters. From the postero-inferior portion of the pancreatic head there arose a prolongation of the gland 1 centimeter thick, which completely encircled the duodenum. The entire pancreas was distinctly lobulated and hard to palpation and a microscopic section showed a chronic interstitial pancreatitis. The gall bladder and ducts were normal.

CASE 3 Benedetti reports an interesting case of annular pancreas in an Italian soldier who died with symptoms of acute intestinal obstruction which had developed in the course of severe sepsis due to shrapnel wounds. At autopsy the obstruction was found to be due to compression of the duodenum by a ring of pancreatic tissue which was swollen and edematous. The stomach was so dilated that its greater curvature descended three fingers breadths below the umbilicus. It was filled with fluid which could not be forced through the duodenum but on releasing the pancreatic ring the stomach emptied readily into the small bowel. Benedetti mentions that Lerat in a case of high intestinal obstruction made a pre-operative diagnosis of annular pancreas

and at operation this was found to have caused sudden obstruction due to acute inflammatory changes in the pancreas.

These 3 previously reported cases which came to surgical intervention were operated upon because of symptoms of acute intestinal obstruction. The case we wish to record, Case 4, manifested the symptoms of chronic duodenal ileus or obstruction as described by Higgins and by Wilkie.

A female aged 46 years, single, was admitted to Lane Hospital, April 21, 1928, complaining of abdominal pain of 2 weeks' duration. The patient's past history revealed that in April 1922 she had been admitted to the Stanford Clinic with a complaint of continuous headache and pressure upon the top of her head severe enough to cause insomnia. These symptoms had been present since May, 1921. Her teeth had been extracted and a nasal operation had been performed at another clinic without benefit. No history of nausea or vomiting was obtained at that time but the patient stated that her stomach was easily upset by unpleasant sights or odors. Her appetite had always been very poor and she did not enjoy eating.

A physical examination revealed no unusual findings. During the examination the patient stated she often felt a dragging sensation in the left lower abdomen. She was found to have a refractive visual error which was corrected by glasses. Wassermann reaction was negative. A spinal puncture revealed no abnormal findings in the cerebrospinal fluid. Her basal metabolic rate was at the low limit of normal. Following an examination of the nose and throat, in which there was found crusting in the ethmoid region and a marked discharge of purulent material from the posterior nasopharynx, a tonsillectomy re-opening of the ethmoid cells and washing of both antra were performed but without relief. Six injections of autogenous vaccines made from nasal washings were ineffectual in relieving her symptoms. In 1923, the patient was given a series of treatments with ovarian extract without benefit.

The patient returned to the Stanford Clinic April 20, 1928 with an entirely new complaint, namely that of an acute pain in the right lower quadrant of the abdomen of 2 weeks duration, not related to eating, defecation or menstruation. The pain varied in intensity from sharp to dull did not radiate and was localized 2 inches to the right of the midline and 2 inches below the umbilicus. Temperature on admission was 37.2 degrees C, pulse 80, respiration 20 and blood pressure 130 systolic, 86 diastolic. The head, neck and chest appeared normal on examination. The abdomen was moderately distended, with no muscle spasm but with the definite area of tenderness noted above. No masses could be felt and the liver, spleen and kidneys could not be palpated. Vaginal examination

FIG. 1. Annular pancreas, author's case. The peritoneum has been stripped away the transverse colon pushed down to expose the second portion of the duodenum and the constricting annular pancreas. During the operation the patient strained under light anesthesia causing the stomach and duodenum to fill with air and the dilated proximal duodenum ballooned out to the right producing the diverticulum which is shown in the gastric roentgenogram. *S* Stomach, *L* liver, *D* duodenum, *P* pancreas, *RP* annular pancreas, *TC* transverse colon. Dotted line extent of diverticulum.

Lecco shows in his illustrations that the annular pancreas owes its origin to an anomaly of the ventral pancreatic anlage (Figs 4 and 5). Elizabeth Cordes described a case of annular pancreas that differed from those previously cited by having no communication between the branches of the ducts of Wirsung and Santorini both of which opened by separate ampullæ into the duodenum. She also concluded that the annular pancreas arose as an abnormality of development of the ventral pancreatic anlage (Fig. 6).

Anomalies of development have decided clinical interest particularly when they interfere with normal function. Of 11 cases of annular pancreas which were accurately described or in which careful drawings were published, 10 showed a constriction of the duodenum at the level of the pancreatic ring. In the remaining case, described by Cordes

there was a small duodenal diverticulum on the medial side of the duodenum between the orifices of the common bile duct and the duct of Santorini. In one case, that of an infant 3 days old there was atresia of the duodenum. The duodenum was dilated above the ring in 9 cases while in 3 specimens there was dilatation below the ring as well, a phenomenon which calls to mind the dilatation of an artery beyond a partial constriction. The stomach was moderately or markedly dilated in 4 cases and the pylorus was hypertrophied. Three cases presented pathological changes in the parenchyma of the pancreas which was definitely hard and indurated in 2 instances due to an interstitial pancreatitis, and in the other there was an acute pancreatitis secondary to a generalized sepsis. One patient was found to have two ulcers on the posterior wall of the hugely dilated stomach.

One case was unusual in that the ampulla of Vater opened 5 centimeters below the constricting ring. In 20 reported cases jaundice and interference with biliary outflow was lacking. Of the 20 reported cases 16 were first noted at autopsy or during anatomical dissection and no clinical history is available except in the report of Theken. His patient suffered from cardiac disease and the history indicated that there had been no gastric symptoms in spite of a hugely distended duodenum and stomach as disclosed at autopsy.

The cases of annular pancreas which were operated upon manifested symptoms of high acute intestinal obstruction or of pyloric occlusion and showed strikingly the variable extent of the constriction. In one instance acute symptoms occurred immediately after birth while in the remaining cases gastro intestinal disturbances were in abeyance from 10 to 47 years before the gradual dilatation and hypertrophy of the duodenum and stomach above the constriction or acute inflammatory changes in the pancreas itself resulted in marked disturbances of the function of the gastro intestinal tract.

CASE 1. Reported by Vidal. A child of 3 days had vomited since birth. Meconium had been passed and the abdomen was not distended but attempts at feeding provoked almost immediate vomiting of

Fig 4 This shows the mode of development of the annular pancreas The ventral pancreatic anlage becomes fixed at its free end and during its subsequent migration with the rotation of the duodenum the ventral anlage is drawn out and with the fusion of the two anlagen the pancreas comes to surround the duodenum (After Lecco)

the upper border of the pancreatic tissue and encircled the duodenum The pancreatic tissue was narrowed to an isthmus about 3 centimeters broad at the lateral anterior wall of the duodenum At this point a small vein left the vein described above and ran downward across the isthmus Above the ring of pancreatic tissue the duodenum was fully 6 centimeters in diameter, while below the ring it was narrowed to a diameter of about 4 centimeters The duodenum was exposed down to the inferior angle of the descending portion of the duodenum and no further abnormality was made out The duodenum was mobilized so that the ring of pancreas could be seen running laterally and posteriorly gradually enlarging from the isthmus till it joined the head of the pancreas posteriorly and enlarging also as it ran to the left anteriorly to join the head and body of the pancreas The common bile duct was not dilated and it was carefully palpated so that its position in relation to this anomaly could be fully appreciated As the patient strained under the anæsthetic the duodenum distended above the pancreatic ring and overlapped the constriction anteriorly and to the right thus forming the diverticulum seen in the roentgenogram (Fig 1)

The pancreatic tissue at the isthmus was freed from the underlying duodenum the vein clamped doubly and the isthmus incised A duct 2 or 3 millimeters in diameter which ran through the tissue of the isthmus was divided Several cubic centimeters of clear slightly green colored fluid was obtained This later became entirely clear colorless and issued from the right end of the incised duct A probe passed to the right upward and backward could be felt posterior to the common bile duct and duodenum When passed to the left anteriorly it could be felt as far as the pylorus in an upward and backward direction The isthmus was cut across a small artery running posterior to the duct was clamped

and tied, and the pancreatic tissue gently freed from the duodenum by blunt dissection This released the constriction in the duodenum, so that full two fingers could be inserted into the lumen of the bowel by invagination The divided ends of the duct were ligated and the stumps of pancreatic tissue covered with peritoneal folds The appendix was found to be fibrous and white and was removed The pelvic organs were normal except for a small cyst in the right ovary

The postoperative course was characterized by frequent vomiting of bile stained material, abdominal pain tenderness, and distention fever, and rapid pulse On the fourteenth postoperative day the patient's pulse increased to 140 her temperature was 38.2 degrees C, respiration, 24 blood pressure, 144 systolic 88 diastolic The white blood cells numbered 18,750 81 per cent of which were polymorphonuclears The direct Van den Berg reaction was positive in 6 minutes the indirect was three units positive and the icterus index was 16.6 Her skin and saliva had an icteric yellowish tinge The blood chlorides totalled 400.13 milligrams per 100 cubic centimeters The stool showed many moderate sized fat droplets and urobilin was present

On examination of the abdomen there was felt for the first time a tender mass in the right upper quadrant and epigastrium which did not move with respiration, and was dull to percussion The patient was in constant pain, markedly emaciated and dehydrated from frequent vomiting in spite of hypodermoclysis and fluid by rectum

When the incision was reopened free fluid was found in the abdominal cavity The fluid was clear and contained no fibrin Reaching from the liver edge to the level of the umbilicus was a firm mass enveloped in omentum When the omentum was separated a large amount of slightly yellow turbid fluid was evacuated After all the fluid was aspirated

Fig 2 The ventral pancreatic anlage *p v* migrates toward the dorsal pancreatic anlage *p d*, to fuse and enclose between them the ductus choledochus *dch*. The ducts of the ventral and dorsal anlagen anastomose as can be seen in the last figure. Duodenum *D*. (After Lecco)

was negative. The red blood cells numbered 3,690,000, hemoglobin, 80 per cent (Sahli); white blood cells 8,600, with a normal differential count. The urine examination was negative. Gastric analysis with the alcoholic test meal showed a free hydro-

chloric acid of 19 per cent and a total acidity of 31 per cent at the highest reading. The stomach contents varied in color from a slaty grey to a blue grey and contained a great deal of mucus. The stool examination was negative. A roentgenogram of the gastro-intestinal tract showed what appeared to be a diverticulum in the second portion of the duodenum.

The patient was transferred to the out-patient clinic for observation and treatment and given tincture of belladonna with some improvement. On May 9 she reported that she had an acute pain in the right upper quadrant and had vomited bile stained material five or six times. A roentgenogram of the gall bladder after the administration of colloidal tetraiodophthalein by mouth showed a normal gall bladder. She was admitted to the Surgical Service May 17, 1928, with physical findings and laboratory tests as noted above.

The patient was operated upon May 22, 1928, by Dr. Emile Holman. Through a right rectus incision the omentum was seen to run upward and to the right around the lateral border of the liver where it was adherent to the posterior abdominal wall. Dense adhesions between the gall bladder and omentum obscured the first part of the duodenum. These were gently separated and the gall bladder was seen to be moderately enlarged; the overlying peritoneum thickened and grey white in color but no stones were palpable. Releasing the adhesions to the lower border of the liver permitted palpation of the right kidney which was very freely movable with nodular apparently fetal lobulations. The pylorus and pyloric end of the stomach appeared normal. By separating the adhesions and the layers of the gastrocolic omentum from the first and upper portion of the second part of the duodenum no diverticulum could be found. Continuing the separation farther on the second portion of the duodenum and releasing it from its peritoneal coverings the duodenum appeared dilated flabby and bluish in color. The head of the pancreas completely encircled the duodenum at the midpart of the second portion of the duodenum. A large vein ran along

Fig 3 The upper figure illustrates the arrangement of ducts of the normal adult pancreas and their relationship to the ductus choledochus *dch*. The lower figure shows the arrangement of the ducts of the annular pancreas and their morphological identity to the corresponding parts of the upper figure. The lower horizontal duct shaded in black surrounds the duodenum. Both figures are viewed from behind. (After Lecco)

ligated, and the stump covered with pancreatic tissue and with peritoneum, with as little trauma as possible. Nevertheless, these precautions did not prevent the escape of pancreatic fluid and the formation of a pseudocyst with walls formed by the abdominal viscera and omentum, with a severe peritoneal irritation as shown by constant pain, tenderness, fever, very rapid pulse, and leucocytosis. This inflammatory process was evidently of a chemical nature as cultures of the fluid were negative. The absence of fat necrosis at the second operation is most interesting, doubly so since experiments with the fluid showed that it possessed active power to digest fat.

The pancreatic fistula through the stab wound of the second operation discharged an amazing amount of clear, odorless fluid as the patient's bed clothing was saturated with the fluid in spite of frequent changing of drain pads by the nurses. At the rate of 12 drops per minute from the catheter in the wound, as recorded in the progress notes, at least 1,100 cubic centimeters of fluid was lost a day, and to one seeing the seepage from the wound and the constant moisture of the dressing, this is a conservative estimate. The protection of the skin was found to be simple. Zinc oxide applied thick and warm, sprinkled with kaolin, was sufficient to prevent skin excoriation. Undoubtedly, the absence of intense skin ulceration was due to the absence of duodenal secretions, which activates the pancreatic trypsinogen. Trypsin activity was present in the fluid, however, as digestive tests showed complete digestion of 5 cubic centimeters of 1 per cent casein by 0.4 cubic centimeters of pancreatic fistula fluid in one-half hour at 37 degrees C. The amount and character of the fluid discharged warrants the assumption that the major portion of the pancreatic secretion escaped from the fistula by retrograde flow through the cut end of the duct and in the annular portion of the pancreas. It has been shown by Lecco that this duct is a main branch of the duct of Wirsung in the ring pancreas.

During the time that the fistula was draining the patient's symptoms are also of interest. Immediately after the second opera-

Fig. 6 Annular pancreas, ventral view. DPD, dorsal pancreatic duct; DPI, ventral pancreatic duct; Ch, choledochus. (After Cordes)

tion she felt much better, her appetite, which had been entirely lacking, returned and she took fluids readily. During the 8 days that the fistula was draining profusely, she began to lose flesh visibly, she was constantly thirsty, complained of feeling weak and tired and upon the tenth day she began to vomit, although her appetite was good. Improvement began at the time of the administration of large amounts of fluid containing salt, soda bicarbonate, and glucose, with the coincident diminished secretion from the fistula. Elman found that the total drainage of pancreatic secretion in dogs was accompanied by regurgitation of intestinal contents into the stomach, vomiting, rapid emaciation, and death. It is suggested that relief of dehydration with maintenance of the chlorides and alkali reserve of the body might prolong the survival period of such animals.

The relative infrequency of annular pancreas (Baldwin found 1 specimen in 99 adult human bodies examined with reference to the structure of the pancreas) prohibits any discussion of operative procedures, except to suggest that duodenojejunostomy, as advised by Huggins for chronic duodenal ileus, is the operation of choice, since it affords a more

Fig 5 The annular pancreas is seen from the dorsal aspect producing a marked constriction in the duodenum. The lower figure gives the arrangement of the ducts of this specimen. (After Lecco)

there remained a deep encysted cavity, between the liver and gastrohepatic omentum above and to the left, the lateral abdominal wall to the right and the transverse colon and omentum below. The head of the pancreas was seen as a greyish reddened mass indurated and with distinct lobulations on its surface. The duodenum was not constricted and there was no obstruction to the lumen of the bowel. The body and tail of the pancreas were palpated and found normal in consistency and extent. No fat necrosis was found. Drainage was established through a stab wound in the right lateral abdominal wall.

The fluid removed from the abdomen digested starches, fat and casein was strongly alkaline with a hydrogen ion concentration of 8.6 and was negative for bacterial growth on culture. It was unquestionably pancreatic secretion.

The day following operation the patient was brighter, felt better and was relieved of abdominal pain. There was continuous drainage of a clear, odorless, strongly alkaline fluid from the stab wound in the right side. The discharge was sufficient in

spite of frequent dressings, to wet the bed clothes and mattress. The skin surrounding the wound was covered with zinc oxide containing hydrochloric acid (10 per cent) and with kaolin but it was soon discovered that the acid dressing excoriated the skin, and thereafter zinc oxide and kaolin powder provided adequate protection. The amount of pancreatic secretion draining from the wound was estimated to be between 1,200 and 1,500 cubic centimeters for 24 hours.

On the eighth day when the discharge of pancreatic secretion was still profuse, her pulse rate had increased to 130 although her temperature remained normal. On the tenth day she thrice vomited large amounts of undigested food. The vomiting was repeated on the following day in spite of repeated gastric lavage. The patient felt hungry and had normal bowel movements; there was no distention nor tenderness in the abdomen and no masses were felt on palpation. The white cells numbered 17,450 with 86 per cent polymorphonuclears. Laboratory examination showed a blood urea of 59 milligrams per 100 cubic centimeters, a blood chloride of 396 milligrams per 100 cubic centimeters, and a carbon dioxide combining power of 40 cubic centimeters per 100 cubic centimeters of plasma. The patient was given per rectum 300 cubic centimeters of 5 per cent solution of bicarbonate every 4 hours, normal salt solution by hypodermoclysis and 10 per cent glucose in normal salt solution intravenously to compensate for the loss of chlorides and alkali through the draining fistula.

The intermittent vomiting ceased, the fistula stopped draining on the twentieth postoperative day, and the patient began to gain rapidly in weight and appearance.

The patient has been seen several times since her discharge from the hospital and 6 months after the first operation stated that she is markedly improved. She has no abdominal discomforts, has gained in weight and eats well and although the headaches persist they are much improved.

The case of annular pancreas here presented affords an opportunity for a number of interesting observations. The symptoms manifested first were those attributed by Higgins to chronic duodenal ileus, namely intense headaches and an irritable stomach followed later in the course by vomiting. As Higgins states, "The vomiting of large amounts of bile stained fluid with evidences of retention especially if associated with severe headaches, should arouse a suspicion of chronic duodenal ileus."

As shown by previous observers, a good sized duct always courses anterior to the duodenum in the ring of pancreatic tissue. In this case the duct was cut across, securely

THE MECHANISM CONTROLLING MIGRATION OF THE OMENTUM

C BRYANT SCHUTZ M D KANSAS CITY MISSOURI

THE most important function of the omentum is to localize foci of peritoneal irritation. In performing this function the efficiency of the omentum depends, to a large extent, upon its ability to migrate to, and surround such, foci.

Of the many attempts that have been made to explain the mechanism controlling this migration, few have anything but fancy upon which to base their assumptions. Adams's theory that migration is caused by gravity, though often quoted, has long since been discarded. Fisher believes that migration is brought about by intestinal peristalsis. It has been pointed out, however, that the greatest movement of the omentum occurs after it has become infiltrated, and it is then so rigid that intestinal movements slide beneath it without producing any change in its position.

Hertzler believes that the chemotactic attraction between the area of irritation and the leucocytes contained in the infiltrated omentum incidentally pulls the omentum to the irritant focus. Among other things, he made the interesting observation that small pieces of corn pith placed free in the abdominal cavity become covered with leucocytes and in a number of instances, are later found adherent to the abdominal wound—a phenomena difficult to explain unless one assumes that the leucocytes attracted to the area of irritation (the abdominal wound) incidentally pulled the corn pith along with them. The theory implies, however, an initial directional movement of the omentum, and such is not the case. Furthermore, in the experiments to be reported the omentum migrated in the absence of leucocytic infiltration. However, the theory probably does explain certain phases of the omentum's migration.

ANATOMY

Briefly, the omentum is a network of blood vessels, along the main branches of which varying amounts of fat are deposited. Sup-

porting the blood vessels is a thin, transparent, and somewhat elastic membrane formed by the union of two peritoneal plates and containing a delicate meshwork of connective tissue bearing minute blood vessels. These latter vessels are, in the resting omentum, practically empty. Only in the reacting omentum do they actually take on the function of blood vessels. They have been aptly called "potential" vessels.

The arterial blood supply arises from 6 to 8 fair sized branches of the gastro epiploic artery. Near their origin they give off very few branches and run a parallel and more or less straight course. As they approach the periphery of the omentum, their course becomes more tortuous and they give off many small anastomosing branches which divide into the small "potential" vessels afore mentioned.

Both the arteries and veins are but loosely attached to the omentum. The veins follow the course of the arteries and empty into the gastro epiploic vein.

In its so called normal position, the omentum extends from the transverse colon to the symphysis pubis below and to or over the colon on either side. Seldom, however, even in abdomens showing no evidence of disease, is it found occupying this position. Its peripheral portions are usually crumpled so that they do not reach much beyond the level of the umbilicus below and scarcely to the inner edge of the colon on either side. It thus occupies a smaller space than its size justifies. The tortuosity of the omental arteries is due to this latter fact rather than to any definite anatomical structure.

Above, the omentum is attached to the greater curvature of the stomach and to the transverse colon, to the left, to the phrenic and gastrosplenic ligaments, and on the right is continuous with the hepatic duodenal ligament. Not infrequently it is attached to the gall bladder, an attachment often erroneously considered pathologic.

complete relief of duodenal stasis than does gastro enterostomy. Furthermore, manipulation and trauma to the pancreas, which resulted in such distressing complications in this case, are thereby avoided. It may be suggested in passing that carcinoma of the head of the pancreas, if subjected to palliative operation, be treated by gastro enterostomy and cholecystogastrostomy, since the late stages of this hopeless condition are accompanied often by protracted nausea and vomiting. In one of our earlier cases there was complete gastric stasis with the accompanying vomiting and jaundice from pressure of a tumor of the head of the pancreas.

SUMMARY AND CONCLUSION

1 Twenty cases of annular pancreas have been reported in the literature. Four cases presented symptoms of high intestinal obstruction. Three were subjected to operation for relief of obstruction.

2 An instance of annular pancreas manifesting the symptoms of chronic duodenal ileus is reported.

3 The operation of releasing the pancreatic ring was followed by pseudocyst formation and drainage of the cyst resulted in a pancreatic fistula which healed spontaneously.

4 The metabolic disorders and symptoms accompanying the pancreatic fistula were relieved by the administration of soda bicarbonate by mouth and in rectal instillations, and by salt solution beneath the skin and intravenously.

5 This single experience with a very rare lesion indicates that rather than attempt a division of the abnormal ring of pancreatic tissue, it would be better to perform a duode-

nojejunostomy, avoiding thereby a possible pancreatic cyst or pancreatic fistula.

NOTE.—Smetaria Hans. *Beitr. z. path. Anat.* 1908 lxxix 231. reports 3 cases of annular pancreas from the Pathological Anatomical Institute of the University of Vienna. In addition he cites 8 cases from the literature not reported in this article.

suddenly advance for, as near as could be calculated one eighth to one quarter of an inch and then suddenly stop. In its advanced position it seemed to pull on adjacent portions so that in a short time they too moved forward. I got the impression that the omentum was lightly stuck to the surface of the intestines (perhaps by surface tension between the fluid on the surface of the omentum and that on the surface of the intestines) and that advancement was momentarily resisted by this factor. At the end of the experiment, when migration was no longer noted the omentum was thickened with edematous fluid and everywhere rested on the surface of the intestines. Its lateral edges covered the colon on either side and its lower edge had migrated into the pelvis.

Experiment 7 The omentum was removed from a woman who had just died from an extra abdominal disease. The left portion and all gastric branches of the gastro epiploic artery were carefully tied off. The omentum was floated on water and its edges crumpled as much as possible. Tap water was injected into the right gastro epiploic artery.

Following the injection the omentum spread out in all directions. The crumpled edges straightened and both lateral and lower edges advanced. As long as the pressure was maintained in the artery, the edges of the omentum retained their advanced positions but as soon as the pressure was released they receded with an abruptness suggestive of an elastic recoil.

This experiment was repeated once with a similar result.

Experiment 9 Through an upper abdominal incision the right gastro epiploic artery and all its omental branches were tied off so as to deprive the omentum of blood supply. Through a separate incision a pledget of gauze lightly soaked in turpentine was sewed into the peritoneum in the right lower quadrant. Twelve hours later the abdomen was opened.

In the region of the gauze pledget very marked inflammatory reaction was present. Peritoneal fluid was increased and peristalsis was hyperactive. The omentum however despite the hyperperistalsis had not changed its position.

In these experiments the omentum migrated when pressure in the omental arteries was increased. When the pressure was increased the arteries lost their tortuosity. As they straightened they advanced in the direction of their initial blood flow. The omentum migrated at the same time, in the same direction and to the same extent as the arteries. Its migration was independent of both leucocytic infiltration and intestinal peristalsis.

The straightening and advancement of the omental arteries which occurs when they

Fig 1 Diagrams showing mechanism controlling migration of the omentum

become hyperæmic is purely a mechanical phenomenon. As shown by Newton's second law of motion, change of motion (momentum) is proportionate to the force applied and takes place in the direction of a straight line, in which an applied force acts. It is the position of the moving force to continue to act in the direction in which it was initiated.

When the omental arteries, in the presence of peritoneal irritation, become hyperæmic the momentum, and, therefore, the force, of the blood increases. Since the omental arteries (Figure 1, first diagram) branch from the gastro epiploic artery, *ge*, at right angles and continue in a straight line for a considerable distance, the direction of this increased blood force is initially in the general direction of the pelvis. It is the tendency of this force to continue in this direction, regardless of any obstruction which it may meet.

When, therefore, the force of the blood strikes the first tortuosity, *a*, *a'*, in an omental

REACTION TO IRRITATION

In the presence of peritoneal irritation, the first change in the omentum is generalized active hyperæmia. This is followed by a serous and cellular exudate in its substance and on its surface. The vessels lose their tortuosity and the omentum gradually spreads out in all directions eventually extending over practically the entire lower abdominal cavity. When one portion of the omentum comes in contact with the focus of irritation, it adheres to it. After a variable time adjacent portions become adherent to and eventually surround the entire area. When localization has been completed much of the generalized reaction of the omentum subsides and only those portions in direct contact with the focus retain their high state of reaction. The exudate on the surface of the omentum fills up and effectually seals any spaces which have been left open. The end result is a thick, watertight wall which separates the irritant from the rest of the peritoneal cavity.

PURPOSE

In studying the reaction of the omentum to peritoneal irritation, I noted that as the arteries became hyperæmic much of their tortuosity was lost and that coincident with this the omentum began its migration. I was reminded of seeing a loosely curled garden hose tend to straighten and its distal end advance when an increased amount of water was caused to flow through it. It occurred to me that a similar mechanism might explain migration of the omentum. That is, as the arteries become hyperæmic the increased blood pressure causes them to straighten out. As they straighten all portions of the arteries necessarily advance in the general direction of the blood flow. The omentum, being loosely attached to the arteries is incidentally pulled by them to their advanced position.

EXPERIMENTS

To test the principle of this idea I sewed a two foot section of an eighth inch rubber tube to an ordinary towel. The towel was floated on water and crumpled up until the attached tube assumed a tortuous course. Water was then injected through the tube

Immediately following the injection the tube straightened and as it did so advanced in the direction of the initial water flow. As it advanced it carried the attached towel with it. The effect was increased, and much less pressure was needed, if the injection was done in a manner to simulate arterial pulsation.

Experiment 1. Under ether anesthesia a dog's omentum was exposed through a long midline incision. All the gastric branches and the left end of the gastro-epiploic artery were tied off. A solution of acacia (of approximately the same specific gravity as the dog's blood) was injected into the right gastro-epiploic artery.

When first exposed the omentum followed in an irregular fashion the undulations of the intestinal loops in some places resting on the surface of the intestines in others especially near its free margins, dipping into the spaces separating them. The free edges of the omentum were, as usual irregularly crumpled.

Following the injection the smaller as well as the larger arteries became definitely distended. Depressed portions of the omentum rose to the surface of the intestines and the whole organ seemed to flatten out. The free edges migrated in the general direction of their respective blood flow—the lateral edges advancing laterally, the lower edges moving toward the pelvis.

Using the tip of the xiphoid as a fixed measuring point the maximum longitudinal migration was slightly less than 3 inches. Estimated lateral migration was between one half to three quarters of an inch.

This experiment was repeated four times in different dogs. In each instance similar results were obtained.

Experiment 6. The omentum of a dog was exposed as before. The arteries to the omentum were tied off as in the previous experiments. In addition to this three of the omental veins were tied off near their entrance into the gastro-epiploic vein. The dog was kept under ether anesthesia.

When first exposed the omentum occupied approximately the same position and had the same general appearance as the omentum described. In half an hour hyperæmia of the omentum had become definite. As the hyperæmia increased the arteries and especially the small anastomosing branches began to lose their tortuosity. With abrupt movements the more central portions of the omentum began to spread or flatten out as in the previous experiments. Gradually this extended outward toward the periphery. The free edges the lateral as well as the lower then began an irregular advancement. This migration did not occur at the same time in all portions. Instead one area would

suddenly advance for, as near as could be calculated one-eighth to one quarter of an inch and then suddenly stop. In its advanced position it seemed to pull on adjacent portions so that in a short time they too moved forward. I got the impression that the omentum was lightly stuck to the surface of the intestines (perhaps by surface tension between the fluid on the surface of the omentum and that on the surface of the intestines) and that advancement was momentarily resisted by this factor. At the end of the experiment, when migration was no longer noted the omentum was thickened with edematous fluid and everywhere rested on the surface of the intestines. Its lateral edges covered the colon on either side and its lower edge had migrated into the pelvis.

Experiment 7 The omentum was removed from a woman who had just died from an extra abdominal disease. The left portion and all gastric branches of the gastro epiploic artery were carefully tied off. The omentum was floated on water and its edges crumpled as much as possible. Tap water was injected into the right gastro epiploic artery.

Following the injection the omentum spread out in all directions. The crumpled edges straightened and both lateral and lower edges advanced. As long as the pressure was maintained in the artery the edges of the omentum retained their advanced positions but as soon as the pressure was released they receded with an abruptness suggestive of an elastic recoil.

This experiment was repeated once with a similar result.

Experiment 9 Through an upper abdominal incision the right gastro epiploic artery and all its omental branches were tied off so as to deprive the omentum of blood supply. Through a separate incision a pledget of gauze lightly soaked in turpentine was sewed into the peritoneum in the right lower quadrant. Twelve hours later the abdomen was opened.

In the region of the gauze pledget very marked inflammatory reaction was present. Peritoneal fluid was increased and peristalsis was hyperactive. The omentum however despite the hyperperistalsis had not changed its position.

In these experiments the omentum migrated when pressure in the omental arteries was increased. When the pressure was increased the arteries lost their tortuosity. As they straightened they advanced in the direction of their initial blood flow. The omentum migrated at the same time, in the same direction and to the same extent as the arteries. Its migration was independent of both leucocytic infiltration and intestinal peristalsis.

The straightening and advancement of the omental arteries which occurs when they

Fig 1 Diagrams showing mechanism controlling migration of the omentum

become hyperæmic is purely a mechanical phenomenon. As shown by Newton's second law of motion, change of motion (momentum) is proportionate to the force applied and takes place in the direction, of a straight line, in which an applied force acts. It is the disposition of the moving force to continue to act in the direction in which it was initiated.

When the omental arteries, in the presence of peritoneal irritation, become hyperæmic, the momentum, and, therefore, the force of the blood increases. Since the omental arteries (Figure 1, first diagram) branch from the gastro epiploic artery, *ga*, at right angles and continue in a straight line for a considerable distance, the direction of this increased blood force is initially in the general direction of the pelvis. It is the tendency of this force to continue in this direction regardless of any obstruction which it may meet.

When therefore, the force of the blood strikes the first tortuosity *a, a'* in an omental

artery, it acts in the direction of the arrow, *f*. It has its greatest effect on the area *i*, which lies directly in its path. In the quiet omentum, since only a minimum amount of blood is flowing through the artery the force is not sufficient to affect the position of this portion of the artery. In the reacting omentum when hyperæmia causes an increase in the blood force area *i* is pushed forward. When advancement of *i* becomes limited by its attachment to the proximal portion of the artery it moves laterally—being as it were pushed aside by the force of the blood. These movements necessarily cause straightening and advancement of the tortuosity *a a*. Areas *j, k* are successively subject to the same changes with the result that *a a'* advances to assume the position shown in Figure 1 second diagram. Continuation of this process causes similar changes to occur at *b* and *c* so that eventually the artery assumes the position shown in third diagram.

This same mechanism controls changes in position of the branches of the main arterial trunks. For this reason arteries in all portions of the omentum share in the advancement of the larger longitudinal arteries.

The omentum, which is loosely attached to the arteries is pulled by them to their advanced position. Thus migration of the omentum is secondary to migration of its arteries.

THE MECHANISM OF THE MIGRATION OF THE OMENTUM

Migration of the omentum to the focus of peritoneal irritation is a blind mass movement of the entire organ. It occurs laterally as well as longitudinally regardless of the position of the irritant.

This blind generalized migration continues until one portion of the omentum comes in contact with the area of irritation. When this occurs generalized reaction and therefore, generalized migration ceases. Only those portions in direct contact with the area of irritation retain their state of reaction. The rest of the omentum gradually subsiding to a more or less normal state.

All activity now becomes centered about the area of irritation. Adjacent portions of the omentum begin to surround the focus of irritation by movements that differ from generalized migration in that they are definitely directional in character. This directional migration continues until all or practically all, of the area of irritation is surrounded.

A great deal of this local migration is caused by the same mechanism that controls generalized migration—the arteries in the locality retaining their hyperæmia and continuing their migration. There is reason to believe however that part of it may be explained by Hertzler's theory that the leucocytes embedded in the omentum pull it to the area of irritation as they move toward the latter in response to chemotaxis.

CONCLUSION

From the experiments reported the following conclusions seem justified.

1. Migration of the omentum is controlled and caused by migration of the omental arteries.

2. Migration of the omental arteries occurs in the direction of their respective blood flow and is caused by increase in the local blood force following hyperæmia of the omental arteries.

Examination of the anatomy of the omentum and observation of its changes during migration substantiates these conclusions. The question as to why the omentum the only function of which seems to be a mechanical one, i. e. walling off and localization of foci of peritoneal irritation should have such an exuberant blood supply may be answered by this theory. In this connection it is interesting to note the resemblance that the structure of the omentum bears to erectile tissue and to recall the fact that movements of erectile tissue are controlled by a mechanism similar to that described.

THE INJECTION TREATMENT OF VARICOSE VEINS¹

GEZA DE TAKATS M.D. M.S. F.A.C.S., AND HAROLD QUINT B.S. M.D. CHICAGO

WHILE it is true that Pravaz in 1813 was the inventor of the hypodermic syringe, as early as 1853 injected into varicose veins perchloride of iron and that others (1 and 18) have used for this purpose many coagulating substances such as alcohol, tincture of iodine, Lugol's solution, and carbolic acid, it is only in the past 10 years mainly through the efforts of Linser, Sicard and Nobl that hypertonic solutions of sodium chloride, sodium salicylate and sugar have replaced the coagulating substances and have become widely used in the treatment of varicose veins. The daily growing literature on this subject has been covered in the articles of McPheeters and in a previous paper by one of us (6). A wave of enthusiasm followed the introduction of this simple method and as is so often true we find that its use resulted at times in untoward reactions, necrosis, and even fatalities as summarized by McPheeters and Rise (15).

Since November 1, 1926, a clinic for the treatment of varicose veins has been conducted at Northwestern University. It has been our aim to select the safest and yet sufficiently effective solutions for injection to evaluate tests for arterial and venous circulation and finally to determine late results with the help of a follow up system. At the same time studies have been carried on to determine venous pressure and the dioxide and carbon dioxide content of the blood in varicose veins. These studies have been reported elsewhere (7).

In this paper we wish to present the method of management which has been gradually evolved during the course of 3 years—a method based on our experience in a series of 500 cases in which over three thousand injections were made.²

EXAMINATION OF THE PATIENT

In the history of the patient, a hereditary factor was elicited in 65 per cent. The lack

¹ In the compilation of this study made in 1930 patients have been treated with the method here described and discussed in the literature.

or diminution of elastic tissue as a dominant symptom of asthenic constitution has been frequently described since the pioneer contribution of Stiller. Flat feet and bunions have been noted in 58 per cent of all cases. Curtius has shown remarkable family trees indicating a dominant type of heredity in patients afflicted with a "varicose status." Such patients may present varicosities of the septum and consequent bleeding from the nose, small cutaneous nevi, and spiderlike telangiectases. Often a hypoplasia of the entire vascular system including the heart may be present. We were frequently impressed with the vascular fragility of young patients afflicted with varicose veins. Such patients would develop blue bumps at the slightest injury, yet routine determination of bleeding time, coagulation time, and platelet counts would fail to detect any changes, so that a vascular fragility with lack of elasticity as a constitutional factor, had to be accepted as a cause for the frequent rupture of small vessels. A developmental anomaly in the variation of the course and length of the short saphenous vein has also been given consideration (Figs. 1, 2, 3). Kosinski has pointed out that the short course of the small saphenous vein in man is probably an adaptation to posture and that the persistence of a long course of this vein, either emptying into the femoral vein or into the great saphenous on the thigh, may well explain some of the varicosities in the popliteal fossa and some abnormal configurations described by dilated veins. Sometimes conditions resembling a true phlebectasia with multiple cavernous sinuses and hypertrophied walls are produced (Figs. 4 and 5).

The first appearance of varicose veins was found to be at puberty in 26 per cent of our cases. The effect of menstruation on varicosities was elicited in almost every case. The effect of pregnancy on further increase in venous pressure is well known. Each subsequent pregnancy aggravates the existing dilatations

FIG. 1. Diagram of a short course of the short saphenous vein (After Kosinski)

A history of thrombophlebitis following pregnancy, pelvic operations or infectious diseases particularly typhoid fever and influenza has been elicited in 10 per cent of all cases coming to our clinic. Such a history immediately suggests the question of sufficient deep venous return. Trauma followed by dilated veins distal to the injury was found in 21 cases. Mechanical factors, such as prolonged standing as night watchman, as waiter and as laundress were found in 63 per cent. The effect of constricting garments was studied in a previous communication (7). A possible elimination of such factors seems desirable.

In the *physical examination* of the patient, the respiratory and vascular systems deserve most attention and in the general examination should be included a complete blood count, urinalysis, and Wassermann test. Diseases such as gastric ulcer, diabetes and hypertension to mention only the most frequent can be treated simultaneously with the veins while other conditions require immediate surgical attention and in their presence injection treatment should be postponed or not be undertaken. Hyperthyroidism should be treated before any other condition is dealt with. Basal metabolism rates should be determined if hyperthyroidism is suspected clinically. In our series 4 cases of hyperthyroidism were found and relieved before the treatment of the veins was started. In the presence of malignant growths or active

tuberculosis the injection treatment of varicose veins is not warranted. Acute infectious diseases, even acute colds, should be treated first. It is impossible to enumerate all possible co-existing diseases, but it should be stated that the treatment of the veins should never precede that of the more urgent conditions. This must be emphasized since the injection treatment of varicose veins has become a part of office practice and since as the technique is so simple many a practitioner has been misled to hasty and unwarranted injections.

Tests of arterial and venous circulation

In a previous communication (7), it has been pointed out that in beginning arterial occlusion of the lower extremities, as seen in senile and diabetic gangrene and in thromboangiitis obliterans the veins are frequently dilated and even inflamed. This is particularly true of Buerger's disease. In this series 6 cases were found in which injections had been made into the veins of such patients elsewhere. In these cases because of the nature of the disease the arterial occlusion will progress and possibly gangrene will develop, yet the patient will attribute the turn for the worse to the injections. Therefore, we have tried to eliminate such patients from the injection treatment although occasionally a well selected case may be benefited by an obstruction to the venous return (8). At all events patients must be told that their complaints—the intermittent claudication, the cramps in the sole of the foot so often attributed to flat feet—are due to poor arterial circulation.

The *arterial circulation* is estimated first by palpating the pulse of the dorsalis pedis of the tibialis postica and of the popliteal arteries. This estimation is especially important if other evidence of peripheral arteriosclerosis is or if diabetes is present. The pulsation of the arteries of the foot may not be palpable because of ankle oedema, induration, scars or ulcers. An X-ray picture of the leg may be taken to show calcification of the arteries. If the roentgenograms are taken with care and the proper technique the dilated veins will also show (Fig. 6). The constriction test of Moszkowicz which consists of the observation of the reactive hyperæmia following

Fig. 2 Diagram of a long course of the short saphenous vein (After Kosinski)

complete arterial obstruction is painful, not entirely harmless and not easily estimated. The angle of circulatory insufficiency as described by Buerger, can be tested only when there is rubor in the dependent position. In the response of the cutaneous vessels to histamine, we have found a simple clinical method for testing arterial circulation. Following Starr's brief communication on the subject, we have used this test routinely in all patients above 50 years of age and also in all patients in whom poor arterial circulation was suspected.

Histamine acid phosphate in a 1:1000 solution is used. The solvent is normal saline solution. The solution can be kept in the ice box for about 2 weeks without losing its potency or it can be kept in sterile ampoules in which it will probably remain stable for a long time. A drop of the sterile solution is placed on the skin, which has been previously gently swabbed with alcohol. The skin should not be rubbed too vigorously, otherwise the reactive hyperemia may simulate or cover the histamine reaction. With a fine hypodermic needle from 6 to 7 punctures are made through the drop of histamine. The needle should penetrate the cornified layers of the skin but should not cause any bleeding. Normally as described by Lewis a triple response ensues: a purple spot at the site of the puncture, a wheal superimposed on the purple spot, and a red flare around the wheal. The red flare is due to an active vasodilation of the

Fig. 3 The short saphenous vein empties into the long saphenous vein high up on the thigh.

minute vessels followed by an influx of arterial blood. It appears normally in $2\frac{1}{2}$ to 5 minutes and increases in intensity up to the fifteenth minute. We have discussed elsewhere (7) that the delayed appearance or absence of the flare means a lack of arterial inflow. A spasm or occlusion of the small vessels, which the histamine is unable to overcome, may equally be factors.

If such flares are elicited above the knee, below the knee, at the middle of the calf, and at the ankle, the level of impaired arterial inflow can be rapidly determined. The tested leg should be kept horizontal, otherwise the influx of arterial blood may be influenced by posture. A small delay at the ankle, particularly in older people, may not be called pathologic. The absence of a reaction is always a serious sign and patients in this condition may be considered to be in a stage of impending or at least potential, gangrene (Figs 7 and 8).

The venous circulation is tested mainly in regard to an adequate venous return in the deep veins. The "milk leg" following pregnancy, pelvic operations or infectious diseases together with a diffuse hard edema which appears to be due to lymphatic

obstruction makes the saphenous system invisible and in such instances injections are not only inadvisable but impossible. More difficult is the decision as to treatment when the swelling gradually diminishes after the use of elastic support or paste boots and the veins become visible and are dilated and tortuous. Often following a thrombosis of the iliac vein or the venæ cava an extensive collateral circulation develops on the anterior abdominal wall. These of course should be left alone. However if in spite of the tortuous veins on the thigh and calf the ankle is not oedematous in the ambulant patient we can be quite sure that the deep venous circulation is adequate. The superficial venous system with insufficient valves is not functioning anyway; the flow of blood is reversed in it as shown by the Trendelenburg test (Fig. 9) and by measurements of venous pressure in various positions (7).

A simple test of patent deep circulation is that of Perthes which we have slightly modified. A blood pressure cuff is thrown around the thigh in the standing position and is inflated just enough to compress the saphenous vein. Next the patient is asked to walk to and fro or to flex and to extend his knee about ten times. During this procedure the calf muscles contract, squeeze the blood out of the deep veins, and aspirate the blood from the vari-

cosities. The dilated veins must diminish in size, if the deep venous circulation is patent. To demonstrate better the loss of blood following this sucking action the blood pressure cuff is now deflated and we find that the blood rushes in from the saphenous vein and fills up the varix to its previous size. If there is no appreciable diminution in the size of the dilated veins when the patient walks an increased venous pressure must be present in the deep veins, a fact which signifies that obstruction is present somewhere between the veins of the calf and the venæ cava.

A similar test but one which requires a venous pressure apparatus is the measurement of venous pressure with patient in the horizontal position (7). The venous pressure which may be as high as 100-125 centimeters of water when the patient is in the standing position becomes normal when the patient assumes the horizontal position provided the deep circulation is unobstructed. In case of deep venous obstruction high readings are obtained with the patient in the horizontal position as the deep venous pressure is transmitted and prevents the emptying of the superficial veins. Such pressure determinations are not necessary in the general run of cases but do serve for a better understanding of faulty circulation. The lack of edema and in case of edema the test of Perthes is en-

Fig 7

Fig 8

Figs 7 and 8 Charts showing reaction in two patients. The reaction is considered positive when a red flare appears around a wheal at the site of the test. The reaction normally appears in 5 minutes. Figure 7 is the chart of a night watchman aged 47 years in whom no palpable pulsation could be felt in the left dorsalis pedis and posterior tibial arteries. Two weeks after this test the left fourth toe became cyanotic later turning black. Patient was sent to the hospital. In Figure 8 we have chart of a diabetic who had many varicosities of the right leg. Pulse was fair in the dorsalis pedis and posterior tibial arteries.

tirely sufficient for the estimation of the deep circulation

TECHNIQUE OF INJECTIONS

The patient's leg should be in the *hori* position. This position as particularly emphasized by Sicard is the one in which the blood is the most stationary and in which the relaxation of the calf muscles permits the injected fluid to stay in place for a longer period. As shown in a previous communication (7) the venous pressure with the leg in the standing position is so high in the varicose vein that the injected fluid is rapidly washed away to the periphery. Furthermore this position of the leg is preferable for it permits as little blood as possible in the vein thereby preventing unnecessary dilution of the hypertonic solution and insuring better contact of the irritant fluid with the intima. Usually two injections are made at one sitting, one at the highest palpable vein and the other at the lowest palpable dilatation of the same segment. We have never injected higher than the middle of the thigh, but we usually do not inject above the knee. After the selected site of injection is gently rubbed with alcohol an intravenous needle with short bevel and preferably of rustless steel and on a 10 cubic

centimeter Luer Lok syringe, is inserted into the vein. The syringe is filled with 10 cubic centimeters of a 50 per cent glucose solution. As soon as blood can be aspirated into the syringe the second and third fingers of the left hand gently strip the vein proximally and distally from the inserted needle and maintain compression on the segment to be injected. Thus the vein is emptied as much as possible, before the injection is made. The injection is made slowly and is perfectly painless, as long as the needle is free in the lumen. When the needle is withdrawn a dental pad or a small felt pad is placed on the site of injection and is pressed against the vein with a wide adhesive tape. The pressure should be considerable and its proper maintenance for at least 48 hours is very important. This pressure serves to keep the inflamed walls of the vein in the closest possible contact and thus favors obliteration.

The solution used most frequently is 50 per cent glucose. When the injection treatment was started in our clinic sodium chloride

¹ Since this article was submitted for publication we have adopted the usage of Kern and Angle (J. Am. Med. Ass. 99: 2845, 1930) and we are now using a mixture of 50 per cent dextrose and 50 per cent sodium chloride. The latter is thicker and the two solutions are kept in separate ampoules and are mixed in the syringe in equal parts. If less or more is necessary, the 10 cc. of dextrose is added to the sodium chloride ampoule. A total amount of 5 cubic centimeters is injected.

Fig 9 The negative positive and doubly positive Trendelenburg test. The patient's leg is elevated and the dilatations are emptied. Next pressure is made on the course of the long saphenous vein and the patient is asked to stand up. If the veins remain empty or slowly fill up from below and do not change in size after the pressure is relieved the test is negative. There is no reversed flow in the saphenous system. a If the veins remain empty so long as the pressure is maintained but fill up from above with a sudden gush when the pressure is relieved the test is positive. b If however the veins fill up suddenly on standing in spite of saphenous compression there is a reflux from the deep veins. Releasing the compression may produce a further filling of the veins thus making the test doubly positive. c This latter condition which indicates a valvular insufficiency of the anastomotic veins is not favorable to injection treatment and is a frequent cause of recurrence (Diagram from Homan)

sodium salicylate, quinine, and urethane were given a trial. Glucose proved to be the blandest, least irritant. There is no danger of necrosis if the solution is placed beside or leaks out of the vein. There is no or scarcely any cramping following the glucose injection. Glucose is non toxic and systemic reactions as seen with salicylates and quinine are absent. The action of glucose is not so prompt as that of the three other solutions but the reaction following its use is practically confined to the intima. Periphlebitis, an infiltration and subsequent pigmentation which has been described after the use of the other solutions, has not been observed. However it is true that large dilatations particularly if there is an appreciable reflux from the deep veins can not be obliterated with glucose. In such cases we have constantly felt the necessity of using more irritating solutions. Seventy five per

cent invert sugar proved to act more promptly than 50 per cent dextrose. The disadvantage of invert sugar lies in its great viscosity necessitating the use of large needles. A solution of 15 per cent sodium salicylate in 50 per cent dextrose has shown very prompt obliterating effect. However, while we were able to get large firm thrombi in patients who did not respond to dextrose, there was marked pallor, vertigo and cramps in some cases. Furthermore, the alkaline sodium salicylate will caramelize sugar and the injection of such a solution is not advisable. A 10 per cent solution of quinine and urethane, not exceeding 1 cubic centimeter at one injection and 2 cubic centimeters at one sitting gives satisfactory results in dextrose resistant cases. Here again, the injection should be given, if possible, with the patient in the horizontal or at least in the sitting position. Several patients have become dizzy when quinine was injected while they were in the standing position.

The use of dextrose in diabetics is not contra indicated, but one unit of insulin should be administered with every 3 grams of sugar or corresponding restrictions must be made in the glucose intake of the patient.

The amount of dextrose injected at one point is usually 10 cubic centimeters never more but frequently less, if the vein is small and the walls are thin. Of the quinine 1 cubic centimeter is injected with a fine hypodermic needle and a 2 cubic centimeter tightly closing syringe.

OUTLINE OF MANAGEMENT

It is almost impossible to foretell the necessary number of injections. This will depend on the site and extent of varicosities on the intensity of the backpressure on the presence of reflux from the deep veins and finally on the condition of the wall of the vein to be injected. Thickened walls with a shrunken scarry intima will not respond as readily as a thin walled vein. On the other hand the presence of latent infection in the wall may result in a sudden obliteration of a long segment with marked periphlebitis. There has been no complication even in such cases the temperature remains normal the tissue exudate is absorbed and there is no suppuration.

Fig 10 Drawing of a vein excised immediately after injection with 50 per cent dextrose. There is a small sub-intimal hemorrhage at the insertion of the needle. The intima was swollen hyperemic but no thrombus has as yet formed.

The patient is asked to wear an elastic bandage or stocking during the treatment. This helps to keep the veins collapsed and diminishes venous pressure. The patient goes about his or her daily work without any restrictions. Heavy manual labor is not excluded. However unusual exertion in patients not used to it is not permitted.

It is advisable to start injections simultaneously at the highest and lowest palpable point of the same segment, the highest point never exceeding the middle of the thigh. It is occasionally possible to obliterate with two such injections one entire segment. If this is not accomplished the following injections will be made between the two previous injections. If one segment is completely obliterated another one is selected for injection. If both legs are affected, one may treat them simultaneously although much will depend on the individual reaction of the patient.

If the veins are enlarged above the middle of the thigh, we ligate the long saphenous vein with a small transverse incision in the ambulatory patient and then follow with injections. Such ligations have also been made lower about a handwidth above the knee if the pressure seemed too great. Such ligations aid materially in obliterating the veins below, as they reduce the pressure when patient stands at least temporarily (?)

When all the visible and palpable dilations have been obliterated, we ask the patients to wear an elastic support for 3 weeks longer. At the end of that time they are permitted to go around without any bandage

Fig 11 Section of a vein one week after the injection of 50 per cent dextrose. The intima is destroyed and an obliterating thrombus has formed. There is a marked dilatation of the vasa vasorum.

but we ask them to return in 1 month. Not infrequently one or two more injections may be necessary to cure varicosities in veins that have not been completely obliterated in the first treatment. An exact follow up system is essential in evaluating the end result in each individual case.

PATHOLOGICAL STUDIES OF INJECTED VEINS

In a previous paper by one of us (5), the fact was stressed that the coagulation of the blood in the injected segment is only secondary to the endophlebitis due to physico-chemical irritation of the intima. If a vein is injected with 50 per cent dextrose solution and immediately excised, there is no thrombus formation visible (Fig 10). In performing our preliminary vein ligations we have frequently injected the vein before ligating it and were thus able to study the macroscopic appearance of the intima. The intima smooth, pale and glistening as it normally is, turns red and velvety, with occasional sub-intimal hemorrhages. This endophlebitis which corresponds to a catarrhal inflammation of any endothelial surface produces an exudate. The rationale of our method of localized compression consists first in producing stasis in the vein, an important factor in thrombosis, second in reducing the backpressure of the

Fig 12 Same section high power. Note the active organization of the clot as compared with Figure 13

column of blood and third in approximating the injured intimal surfaces. The organization of the thrombus which occurs slowly and gradually in the spontaneous clot will proceed so to speak simultaneously with the formation of the clot as the outpouring of fibrinous exudate will anchor the agglutinated corpuscular elements (Figs 11 12 13).

It is evident however that not all thrombi caused by injection treatment will show the same picture. A secondary clot, a true red thrombus, may form on top of the firmly adherent thrombus. This is all the more liable to happen when as a result of previous attacks of phlebitis known or unknown to the patient the intima is vulnerable, thickened (Fig 14). The importance of ligating the long saphenous vein if it is wide open and feels hard, lies not only in reducing the backpressure but in preventing such an ascending superimposed clot from reaching the saphenofemoral junction.

The result of well organized total thrombi is complete obliteration of the vein which turns into a fibrous cord. Such cords are well palpable even after months but gradually diminish in size and are not visible. However if the injection is followed by a marked periphlebitis, a brownish pigmentation may occur

along the course of the vein. We have not seen any such pigmentation after the use of glucose solution but have observed it after the use of salicylates, quinine, and urethane.

The organization of the clot may however follow a less fibrous and more vascular character. Small sinuses originating in newly formed capillaries form in the thrombus and contain circulating normal red cells. The walls of such intrathrombal canals are lined with endothelium so that they must originate from the capillary buds of the granulation tissue (Fig 15). Even more interesting is the dilatation of sinuses around the internal limiting membrane. These sinuses which may be seen to encircle the entire wall of the vein at the internal limiting membrane are also lined with endothelium and form a new circulation in the wall of the thrombosed vein (Fig 16). They must have afferent and efferent vessels otherwise normal red cells could not be seen in them. Cornil and Ranvier (17) have described a cavernous transformation of thrombosed veins. In our material one patient who had been injected elsewhere with hypertonic sodium chloride solution showed such cavernous transformation. Because of the multiple cavernous character of such a vein, it is difficult to get the needle into the lumen and the injection will be frustrated by a growing hematoma before the solution can be safely injected.

A real restoration of the obliterated lumen may also take place, either by a purulent softening of the thrombus with subsequent signs of pyæmia or embolism or by a gradual recanalization as a result of persistent increase in pressure. If the pressure from the saphenous distribution or from the deep veins is constantly high because of valvular insufficiency the recanalization will manifest itself in a true recurrence.

UNTOWARD SYMPTOMS FOLLOWING INJECTION

Untoward symptoms following injection can be grouped under immediate and late.

The immediate symptoms following the injection of 50 per cent dextrose are very slight but vary greatly. The reaction following the first injection is usually greater than after subsequent injections. This would indicate

Fig. 13. Static thrombus in the iliac vein. In spite of the age of the thrombus as shown by the intima scar there is no tendency to organize the clot.

Fig. 14. Chronic periphlebitis. The muscular layer has been replaced by fibrous tissue. The intima is thick and contains small areas of round cell infiltration. Injection of such a vein may result in acute phlebitis and periphlebitis.

that the patient's anxiety and the fear of the unknown lowers the threshold for pain stimuli. Also in women the complaints are more marked than in men. Most men receive the injection without any painful sensation. The cramping pain must be differentiated from the pain following a perivenous injection. If the needle is not in the vein, a blanching and ballooning out of the skin occurs. Simultaneously a sharp, localized burning pain is complained of which is a better danger signal than the visible infiltration of the subcutaneous tissue. The cramping pain which follows a correct intravenous injection occurs only after a minute or two, evidently at the time when the hypertonic solution reaches the nerve fibers in the adventitia either through the wall of the vein or through the capillaries. At the same time because of the stimulation of the sympathetic perivenous fibers an active contraction of the vein occurs, which may be so extensive and last so long that a second injection is not possible. This active venous contraction has been observed not only on the exposed vein but in a great many instances during the usual treatment. The veins empty, their walls become palpable and give the clinician a chance to estimate their thickness. Phlebotomies become palpable.

This cramp, which is described by patients as exactly the same sensation as they have experienced on stretching their limbs in bed or as occurs when the limbs are put in cold water, lasts only a few minutes. It is the most frequent symptom noted. The cramping is very much milder after injections of dextrose than after those of sodium chloride or sodium salicylate. With quinine and urethane, a moderate cramping is observed.

Other symptoms such as pallor, dizziness, nausea that may accompany any intravenous injection, sometimes occur. Of our entire series, one woman always became faint as long as she remained in the sitting position during the treatment, another had to lie down if the injection was given while she kept the standing position. This *postural hypotonia*, which occurs in individuals with an unstable vasomotor mechanism is probably exaggerated when hypertonic solutions are injected.

The injection with patient in the horizontal position then is desirable also from this standpoint. However, when the veins become partially obliterated by previous injections the sitting or standing position must be resumed. In our fairly large series of cases, only 2 could not stand the elevated posture.

Fig. 15 Varicose vein injected 3 months previously with 50 per cent dextrose. There was a marked reflux from the deep veins. There is an irregular sinus around a valve and another one in the middle of an old hyaline thrombus. There are narrow sinuses at the periphery of the thrombus. These are not artefacts as circulating red cells can be seen in them with higher magnification.

Fig. 16 Old hyaline thrombus. Vein has been injected with 50 per cent dextrose 2 months previous to excision. There was a marked backpressure from the long saphenous vein which had not been ligated in this patient. There are several sinuses within the thrombus. A large patent thrombus is seen in one of the sinuses that formed around the internal limiting membrane. These cavernous sinuses are very hard to reinject. The needle may not find the lumen and the response to the irritant solution is very poor. Such recurrences are the result of continuous pressure on the thrombus from above or from the deep veins.

In 2 cases in our series 10 cubic centimeters of the 15 per cent concentration of sodium salicylate produced violent abdominal pain, faintness, and dizziness followed by a chill. No further symptoms developed. Since these two instances we do not inject more than 3 cubic centimeters at the first sitting, although more than 50 patients tolerated the 10 cubic centimeter dose without any reaction.

Later symptoms—necrosis. In more than 3,000 injections of 50 per cent dextrose solution not one slough was encountered. The solution, a few drops to 2 cubic centimeters, was inadvertently several times deposited outside the vein but in 2 days when next seen such patients presented no sign of necrosis not even an induration. The safety of the dextrose solutions is a great advantage even if the action of the vein is not as prompt as with more irritant substances. Since we have used the dextrose solution combined with 15 per cent sodium salicylate we have not encountered any difficulties but we believe that increased caution when using such a solution is advisable. Following the use of quinine a marked fibrosis was observed in some instances but no slough was encountered. Three small sloughs were encountered since the use of the dextrose sodium chloride mixture by a younger member of our clinic.

Hæmorrhage. We have not observed any external hæmorrhage. Not infrequently, however, a hæmatoma develops around the punctured vein, due to leakage of blood from the injured vein. This is particularly seen in women with soft poorly contractile vessels who show 'blue bumps' at the slightest injury. These small hæmatomata have no further significance and disappear after the visible transformation of blood pigment into biliverdin and bilirubin. The compression pad applied after the injection, will prevent a large hæmatoma and helps in the absorption of the existing ones.

Embolism. Up to the present time, we have not observed any case of pulmonary embolism either fatal or non fatal. Our attitude in this question has been discussed in a previous paper (7). Not only is the danger of pulmonary embolism much less than after radical excision but it is probable that varicose veins untreated may give rise to a pulmonary embolism in a small percentage of cases. Phlebitis *per se* as shown in Brown's statistics from the Mayo Clinic carries hardly an incidence of embolism. On the other hand operations that require prolonged immobilization

Fig 17 Isolated varix running in a transverse direction slight back-pressure. One injection of 5 cubic centimeters of 50 per cent dextrose effected a perfect cosmetic and functional result. After 1 year result was still the same.

that prevent diaphragmatic and other muscular action, show the largest percentage of embolism. The fact that patients are ambulatory and that the thrombus is firmly attached and not loose as is a spontaneous thrombosis add a certain safety to the injection method. However, no such procedure can ever be entirely devoid of this danger. If one were to condemn a method for a possible incidence of embolism, fractures could not be reduced and splinted hernias could not be repaired.

INDICATIONS AND CONTRA INDICATIONS

As has been mentioned, injections are advised only if the varices are below the knee and if the reflux from the deep veins is not appreciable. If the long saphenous vein is distinctly palpable above the knee or if distinct dilatations are palpable the vein is tied at the highest palpable point. In case of very extensive varicosities both below and above the knee and particularly if there is a marked venous reflux, a radical operation is advised.

These indications have been followed in our clinic for the past 3 years. They are of course subject to change and are the result of our analyses of failures.

The injection treatment is contra indicated when the history or the test for deep venous return reveals an obstruction of the deep veins.

Fig 18 Varicose ulcer with marked involvement of the long saphenous vein. Injections and three applications of Unna's boot resulted in a firm healing of the ulcer. Such healed ulcers must be protected for several months from injury and carefully bandaged.

It may be quite possible and in *one case* we have definite evidence of it, that the deep thrombosis which brings on the superficial dilatations became compensated or otherwise overcome, so that the superficial veins could be removed without the slightest disturbance. Generally speaking the diffuse, hard oedema which is claimed by some authors to be of lymphatic origin (10-16) either prevents the injection of the superficial veins, or at least makes it unnecessary, as the oedema will not be benefited and the veins will refill from the deep circulation. Occasionally, an injection into a superficial vein may flare up an old deep phlebitis and result in oedema.

A superficial phlebitis, acute or subacute, contra indicates the injection treatment. If the infection still slumbers in the wall of the vein an injection may flare up the process. We had the opportunity to observe such a reaction in two instances, while the sudden flare up successfully obliterated the veins,

FIG. 19 Large varicose ulcer treated with pasteboots for 2 years previous to admission. The vein was radically excised because of the extent of varicosities and a full thickness graft was applied. Prompt healing took place.

such reactions are painful and alarming to the patient. If the patient is up and around and if the saphenous vein is ligated, no propagation of the clot must be feared.

In order to avoid such reactions, the rule should be followed that we observe in repairing a ventral hernia due to abdominal suppurative. For 6 months but preferably for a year, varicose veins should not be injected if there is a history of acute redness, swelling, and induration of the superficial veins. A chronic induration, however, even in the presence of an open ulcer is not a contraindication. We have injected veins above varicose ulcers in 75 instances without any reaction.

Pregnancy and injection treatment. Venous pressure in the lower extremities rises with the advance of pregnancy. Existing varicose veins are aggravated. They do not recede after childbirth but get progressively worse with each pregnancy. The question arises whether it is advisable to treat the veins during pregnancy or whether it is better to wait until after childbirth. Based on a small experience with pregnant women (6 cases) we found that the injection treatment gave them subjective relief and that if the main saphenous trunk was obliterated or ligated, the progress of the disease could be stopped. This,

FIG. 20 Extensive varicosities both below and above the knee with marked reflux from the deep veins. Pressure is applied on the long saphenous vein above in place of which marked tilting of the veins has taken place.

of course, is true only of the true varicose vein. If the deep circulation is obstructed and if the co-existing lymphatic block produces oedema, the injection treatment is obviously not indicated and will not influence a post-partum phlegmasia. This important held-pregnancy and varicose veins—needs further investigation and study.

RESULTS

The figures given include the first 160 cases which were reported in a previous article (6). The total number of cases reported in this paper is 500. Of these 389 have received the entire course of treatment.

The average number of injections in any one patient is astonishingly low due to the fact that several young women, especially in our private work, presented themselves early and were relieved very readily after a few treatments (Fig. 17). In these early cases the number of required injections varied between one and six and averaged roughly four. The more advanced the condition was and the more incompetent the communications between the long and short saphenous veins and between the superficial and deep veins, the higher the number of injections became. In a group of 100 such cases the average number of injections was 22. If ulcers were present the injection treatment was supplemented with pasteboot treatments of Linn.

Fig. 22. Bilateral elephantiasis with necrotic spreading ulcers. The ulcers were infected. She refused hospitalization after a while and could not be followed.

Fig. 21. Marked edema, cyanosis, and multiple livid ulcers following deep thrombophlebitis. The limbs were suspended almost vertically for 10 days. The ulcers on the right leg were excised, grafted, and an extensive removal of subcutaneous tissue and fascia was performed. The ulcer on the left side healed during rest in bed. The leg was not operated upon. Six months after operation the induration and edema were far less marked on right side.

While the degree of involvement to a certain extent will enable us to determine the necessary number of treatments, other factors such as the prevailing backpressure in the varicose vein, the degree of stagnation, the condition of the wall of the vessel should be considered. So it is impossible to tell the patient even approximately the necessary number of injections. It is also true that different patients respond differently to this treatment. In one patient every single injection produces prompt obliteration in a segment of several centimeters while in another patient seemingly in the same identical condition only repeated injections into the same segment will bring results. We have learned recently not to inject glucose into a partially obliterated vein as the parietal thrombi in such previously injected veins do not respond to glucose as readily as in a thin walled vein. For such cases glucose sodium chloride has proved to be effective.

The length of time for cure varied not only according to the degree of involvement but according to the number of visits made in a week and the number of injections during one visit. Therefore the average time required for cure, namely 2.94 months, roughly 3 months, cannot be evaluated without further analysis. Injections of glucose can be made every second day, two or three segments being treated at a time. However, most patients prefer not to come more often than twice a week and because of social reasons, the dispensary patient can hardly come more often than once a week. Also the number of injections given at one visit seldom exceeds two. The length of time for cure varies from 2 weeks to 9 months, the average is 3 months. The large number of ulcers treated makes the time unduly long.

An unusual opportunity was offered to compare these results with those obtained in 19 patients previous to the institution of the injection treatment. These patients had visited the surgical dispensary at earlier periods and had continued their visits after our clinic had started. The length of previous treatment varied from 1 year to 35 years, an average of 8.6 years. The average time required for cure under our management was 3½ months (Fig. 18).

With the reservations mentioned, we submit the immediate results of the injection treatment as follows

Total number of cases injected	389
Number of injections in a single case	1-35
Average number of injections in a single case	6.2
Length of time required for cure	2 weeks to 9 months
Average length of time required for cure	3 months

FAILURES

The failures must be classified into immediate and late the late failures being the recurrences. Every case in which a permanent obliteration had not been obtained was classified as a failure. Recurrences could be observed as early as 6 weeks and as late as 1 year. While it was impossible to re-examine all discharged patients they were routinely asked to return every 3 months. It is probable that a comparatively larger number of patients with failures returned than of those cured.

The total number of failures in this series was 41.106 per cent, in 389 cases. The analysis of these failures was far more instructive to us than was an analysis of our favorable results. The cases which resulted in failures could be readily classified into the three groups, namely

1. Those with long saphenous veins wide open with incompetent valves so that the back pressure caused canalization of the thrombus (Fig. 16)

2. Those with large saccular dilatations with intima not intact and with extensive scar formation. In these cases the intima would not react to a bland stimulus (Fig. 14)

3. Those in which the Trendelenburg test was doubly positive indicating a reflux from the deep circulation as a result of incompetent valves in the anastomoses between the superficial and deep venous system (Fig. 15)

The logical means of overcoming failures in the first group is the ligation of the long saphenous vein at the highest palpable point. Under local infiltration anesthesia with one half per cent novocain adrenalin a short transverse line of incision is infiltrated with great care not to inject into the vein. The vein is exposed and cut between two No. 1 chromic catgut ligatures. To avoid damage to

the intima no artery clamps are applied on the vein. In this manner we believe it is possible to reduce to a minimum the possibility of the occurrence of a thrombus at the proximal stump of the vein. The skin incision is closed with a few stitches of interrupted dermal sutures on a straight skin needle. A compression bandage is applied with adhesive tape. The patient is allowed to go home immediately or if conditions would so indicate, is hospitalized for 24 hours.

Such ligations have been carried out in 61 instances, with no infection or bleeding in any of them. A thrombus of the proximal stump was palpable in 3 cases. A thrombus was found in the distal stump in almost every case. In two cases following the ligation a massive thrombus of the entire long saphenous vein occurred distal to the ligation. One patient suffered an extensive periphlebitis followed by a brawny induration, but the temperature remained normal. These patients were not hospitalized. The massive thrombosis resulted in a complete obliteration of the varicose veins. A latent infection must have been present in the wall of the vein at the time of operation.

Further experience is essential to determine how often massive thrombosis will follow ambulatory vein ligations. While such a reaction is not aimed at it may lead to a rapid cure of such varices as have been observed after trauma or after an acute superficial phlebitis.

As to the second group, invert sugar 75 per cent was the first of the stronger solutions used. The solution is thick which necessitates the use of large needles. This is an evident disadvantage. However the action of invert sugar is noticeably stronger than that of the 50 per cent dextrose solution and the reaction of the patient to it hardly any greater. Solutions of 60 and 50 per cent invert sugar have been tried and discontinued as no particular advantage over the 50 per cent dextrose could be observed.

A 10 per cent solution of quinine urethane produced rapid and satisfactory obliteration.

A solution of 50 per cent dextrose and 15 per cent sodium salicylate combined produces good effects while injected separately they

have been known to sclerose the veins. It is possible that the corroding effect of sodium salicylate, which is used in the combined solution in a comparatively weak concentration, is buffered by the thick sugar solution, which attracts a great deal of fluid and thus further dilutes the caustic agent. Clinically the solution causes a marked cramping, but a thrombus is promptly formed and there is much perivenous exudate. We reserve the use of this solution for large sclerotic veins that do not respond to treatment with sugar solutions. When used in large varicosities, it should be easier to avoid the danger of a perivenous injection. Because of the caramelization of the sugar in the alkaline sodium salicylate we have given up the use of this mixture and have substituted glucose sodium chloride.

In the third group, those with incompetent anastomotic valves, there is either an increased deep venous pressure or at least a continuous reflux from the deep circulation (Fig. 20). Clinically, these veins respond readily to injection, but the varices reappear very shortly, and can be obliterated only with great difficulty. The pressure in such veins is high even in the horizontal position, and they do not disappear when the patient lies down. However, there may not be an obstruction to the deep circulation—a fact which can be ruled out by the test of Perthes described.

In these cases with incompetent anastomotic valves, radical excision of the main trunk, with the lifting up of the tributaries from the fascia thus breaking the connections between the deep and superficial system, has given us the best results. In this series 16 such operations were done. Spinal anæsthesia is preferable. Patients are not immobilized in bed and are allowed to get out of bed on the fifth day. Thus instead of trying to prevent embolism by the usual prolonged immobilization, we try to prevent thrombosis by early movements.

The use of thyroid extract to prevent pulmonary embolism has been suggested by Walters. In an obese woman with low blood pressure, the type of patient in whom embolism is to be feared, a very extensive Kondoleon operation was performed. She developed

a pulmonary embolism on the twenty first postoperative day which, however, did not end fatally. She received 6 grains of potent thyroid extract during the entire postoperative convalescence but could not be allowed to get up, because of the necessary elevation

COMMENT

The injection treatment of varicose veins has proved to be a valuable addition to our therapeutic armamentarium. If the cases are properly selected, the percentage of cures will certainly exceed those following radical surgery. Our oldest cure is now of 3 years' duration. However, judging from the end results following radical operations, the greatest percentage of recurrences takes place within the first 5 years after operation. The follow up records of the discharged cases are naturally of great interest, and for this reason every effort is being used to establish an accurate follow up system.

The advantages of the injection treatment are evident: the patient is not hospitalized, does not have to discontinue work, and suffers very little discomfort during the treatment. The danger of the injection treatment lies in the fact that it is easy to perform. However, if the cases are not scrupulously selected, the treatment will be discredited and again discarded, as has happened before in the past.

The ideal solution for the injection treatment has not yet been found. We believe that most of the solutions used are too irritant. Sodium chloride, sodium salicylate, quinine and urethane, all cause a great deal of cramping and the possibility of necrosis is always present. Fifty per cent dextrose is the least irritant and works very well in the non-inflamed, thin walled vein. By the addition of 15 per cent sodium salicylate, the efficiency of dextrose has been increased and yet we have reason to believe that the presence of the hypertonic dextrose buffers the sodium salicylate and the danger of necrosis is thereby diminished. Viscosity is another problem. If the solution were thinner, finer needles could be used.

The combination of preliminary ligations followed by injections has been very satisfac-

tory This method diminishes backpressure and prevents an ascending thrombosis We are aware of the objection—that the proximal stump itself may give rise to an embolism We have carefully palpated the site of ligatures in every case While the distal stump has very often shown a thrombosis and while in 2 cases a massive thrombosis distal to the ligation followed, the proximal stump showed a palpable thrombus in 2 out of 61 cases The patients are not immobilized, not hospitalized Most of them have lost but one day of work after ligation

We believe that the radical operation also has a very definite place in the treatment of varicose veins The reflux from the deep veins can be logically attacked only by interrupting the communications between the deep and superficial venous system If radical surgery is resorted to, it should really be radical The ligation of the saphenous vein should be done as high as possible, with an incision about two fingerwidths below and parallel to Poupart's ligament The stump of the ligated saphenous vein should be as short as possible The long saphenous vein can be stripped above the knee, but below the knee the main object of the operation is to interrupt all perforating veins This is far more important than the removal of an isolated dilated segment The operation is preferably done under spinal anesthesia, the patient is not immobilized longer than 4 to 5 days after the operation

Such operations are not frequently indicated In close to 400 cases it was performed 16 times an incidence of 4 per cent of the total number

Discrimination in the selection of cases for the injection treatment will bring the highest percentage of results

No mention has been made in this paper of the treatment of deep thrombophlebitis and of the thrombophlebitic ulcer, as the injection treatment of them obviously is not indicated The history of a sudden painful swelling following operations, infectious diseases or childbirth, and later of a persisting œdema and quite frequently of ulceration suggests such a diagnosis even without circulatory tests Collateral circulation, developing after deep venous block, may appear on the ab-

dominal wall or in the lumbar region and helps to diagnose the level of venous block

The prognosis as regards these disfiguring and painful swellings is not entirely hopeless The leg must be kept as free as possible from œdema by the prolonged use of an elastic support Six months after the initial attack careful massage and baking may be started We have seen slight rises in temperature and malaise even as late as 6 years after treatment and therefore advise massage which should be gradually increased in intensity If the limb has been allowed to remain water logged for a long period of time, the skin and subcutaneous tissue become so fibrous that even when the œdema has been removed the leg will not be able to regain its normal shape and size In extreme cases which may justly be called elephantiasis, a modified Kondoleon operation has been tried with encouraging results (Fig 21) In one patient, large, almost circular ulcers developed on the base of an old thrombophlebitis (Fig 22) Treatment consisting of vertical suspension sterilization of the ulcer, and full thickness grafts resulted in great improvement but the patient left the hospital before completion of the treatment and could not be traced

Some thrombophlebitic ulcers, if not too far advanced, may be treated with paste boots Such treatment results in a slow but firm healing and 6 months to a year later careful baking and massage may be started to loosen up the fibrosis

Patches of hyperkeratosis which develop on old ulcers must be treated with dermatological measures Itching eczematous skin responds very well to crude coal tar Shiny bright red weeping areas of eczema, which give the impression that the epidermis has simply been pulled off the surface are very painful and occur around varicose ulcers Paste boots are a most soothing dressing for them

Differentiation between the varicose ulcer from the thrombophlebitic traumatic luetic trophic ulcers and arteriosclerotic and diabetic gangrene is important not only from a prognostic standpoint but because the use of injections in varicose ulcers is not indicated, even if a few varices above the ulcers are present

Considerable use has been made of skin grafts. If the granulations show a healthy red appearance and if smears show a relative sterility they are shaved off with a flat razor and the graft is applied. Full thickness grafts and pinch grafts seemed to give better permanent results, although the percentage of takes was not so high as with Thiersch grafts. It is essential, however, to get rid of the œdema as much as possible before the grafting is undertaken.

SUMMARY

1 The management of 500 cases of varicose veins and their sequelæ is described. A thorough examination of the patient, ruling out conditions which contra indicate injections, is discussed.

2 Tests of arterial and venous circulation are described. Patients with beginning arterial occlusion or with obstructed deep venous circulation are excluded from treatment. The test for reflux from the deep veins is also significant.

3 The technique of injections and the solutions used are described together with the selection of the site and number of injections.

4 The histology of injected veins is briefly discussed.

5 The perusal of follow up records showed recurrences in 10.8 per cent of the cases. In such cases the persistence of increased pressure usually indicated surgical procedures such as ligation or radical excision.

6 The radical operation for varicose veins has been carried out in 4 per cent of the total number of treated cases. It is believed to have a limited but definite place in the treatment of varicose veins.

BACTERIOLOGY AND PATHOGENESIS OF APPENDICITIS¹

ANNA H E DORSEY, B S M S ROCHESTER MINNESOTA

Fellow in Bacteriology The Mayo Foundation

ROSENOW, Barga, Nickel, Haden, and Bumpus and Meisser have shown that when streptococci freshly isolated from foci in patients who have certain diseases, are injected intravenously into animals, it is possible to produce, in a large percentage of the animals, the same disease as that from which the patient is suffering. The bacteriology of appendicitis and the elective localization of bacteria isolated from the appendix have been studied by Rosenow. He isolated streptococci and colon bacilli from patients with acute and with chronic appendicitis, and by injection of these cultures into rabbits he produced lesions in the appendices of a considerable percentage of the rabbits. In a second series of experiments, he was able to produce lesions in 70 per cent of animals which received injections with strains of organisms obtained from human beings with appendicitis. Rosenow and Dunlap found that cultures made from the tonsils of persons who had had appendicitis, caused appendicitis in 47 per cent of the animals which received injections of the cultures. This work of Rosenow and Dunlap was done during an outbreak of appendicitis in a military academy. Evans studied 236 cases of acute appendicitis in more than 16,000 students, and found that infection in the respiratory tract preceded the acute appendiceal attack by, on an average, 16 days. It was noted also that appendicitis most frequently followed the subsidence of acute infections of the nose or throat. Of the total number of students who had acute infection of the upper part of the respiratory tract acute appendicitis developed in only 1.5 per cent whereas an acute infection of the appendix developed in 3 or 3.5 per cent of the students who had this type of infection of the respiratory tract during periods when there were outbreaks of appendicitis.

Organisms other than streptococci have been recovered from the appendix removed at

operation. Thus, Dudgeon and Mitchner isolated bacillus welchii from material removed from the interior of the appendix. Cultured aerobically, it yielded either pure cultures of colon bacilli, mixed cultures of colon bacilli and streptococci, or staphylococcus albus and streptococci. More recently, Hatzieganu and Irimoiu were able to isolate the bacillus mucosus capsulatus enterogenes from 8.4 of 105 appendices from cases of appendicitis.

In view of the reported variation in the results of cultures in acute appendicitis it becomes apparent that in order to establish an etiological relationship of the organism to the disease, one must determine the results of inoculation of experimental animals with these bacteria. The work of Rosenow on the elective localization of bacteria in various pathological conditions, including his own studies on appendicitis suggested the present additional study of the bacterial flora isolated from the diseased appendix and from the throats of patients during acute attacks. In the attempt to throw light on the source of infection in the appendix, I studied the cultural characteristics of bacteria isolated from the appendices of patients who had undergone appendectomy and from the nasopharynges of patients with appendicitis. Next, I studied the localizing power in animals of these bacteria. As a control, I made a similar study of bacteria obtained from the tonsils in patients who had arthritis. The part of the study that had to do with culturing of the original material will be related first. Cultures were not always taken from the appendix and the nasopharynx of the same patient, for the reason that the appendix was not available for culture in each case. The technique employed was similar to that used by Rosenow.

The material for cultures from the nasopharynges of patients with appendicitis was obtained by swabbing the nasopharynges

with sterile cotton swabs, at the time of, or within 24 hours after, appendectomy. The material on the swabs was suspended in 2 cubic centimeters of gelatin Locke solution and this suspension was introduced into tall tubes of glucose brain broth and glucose brain agar.

The tubes previously had been heated to boiling for 10 minutes to drive off the oxygen and subsequently were cooled to 40 degrees C. The tubes then were rotated vigorously to mix the contents thoroughly.

The tubes were sealed with sterile vaseline, all cultures were incubated for from 18 to 24 hours, and the primary, often mixed, culture was used for inoculation of animals.

The use of tall tubes of glucose brain broth and agar was suggested by Rosenow to obtain a wide range of oxygen tension in order to fulfill the oxygen requirements of various bacteria. It has been found that at the bottom of the tubes, adjacent to the piece of brain, methylene blue is decolorized and that the media are sufficiently anaerobic to grow tetanus bacilli. Also, the bacteria from the nasopharynx were planted on plates of horse blood agar.

The cultures from the appendices were made in a similar manner. As soon as the appendix was removed by the surgeon it was placed in sterile gauze and taken to the laboratory. If the appendix appeared acutely inflamed, some of the material from the interior was drawn into a sterile Pasteur pipette and introduced into tall tubes of glucose brain broth and glucose brain agar.

Usually one tube of agar and one tube of broth were sealed with vaseline to insure anaerobic conditions.

Further cultures were made directly from tissue of the appendices. Under sterile precautions, a portion of the wall of the appendix was cut off and placed in a tube containing 10 cubic centimeters of sterile physiological solution of sodium chloride, and this was shaken thoroughly. The tissue then was transferred into another tube containing sterile physiological solution of sodium chloride and this was repeated until the tissue had been washed three times. Under sterile precautions an emulsion was made of this

thoroughly washed tissue by grinding it in a mortar with sand and about 4 cubic centimeters of glucose brain broth. Approximately 1 to 1.5 cubic centimeters of this emulsion then was inoculated into tall tubes of glucose brain broth and glucose brain agar.

Since most of the cultures from the appendix yielded mixtures of streptococci and colon bacilli, since pure cultures of the streptococcus obtained by plating methods failed to produce lesions in the appendices of experimental animals, and since colon bacilli, if present in large numbers, usually killed rabbits from overwhelming infection before lesions of the appendix had time to develop, it was attempted to kill the colon bacilli by heating the inoculated tubes of glucose brain broth and glucose brain agar to 55 degrees C for 45 minutes in a water bath. Most often (and this is the preferable method) they were heated before they had been incubated, although in some cases the cultures were incubated from 18 to 24 hours and if a mixed culture of streptococci and colon bacilli was obtained, they then were heated. The culture then was plated to determine its purity or the relative number of colon bacilli that remained.

In the control cases of chronic arthritis, the cultures for injection of animals were obtained either from extirpated tonsils or from material expressed from tonsils *in situ*, by inserting a small laryngeal mirror between the tonsil and the anterior pillar and by applying pressure toward the base of the tonsil. By this means, material was expressed and by means of the mirror it was transferred to gelatin Locke solution. In the laboratory, the gelatin Locke solution was introduced into tubes of glucose brain broth and glucose brain agar and on blood agar plates. The 18 to 24 hour primary growth in the glucose brain broth was injected into animals.

RESULTS OF CULTURES

Strains of streptococci were isolated from the nasopharynxes of 13 patients suffering from acute, subacute, and chronic appendicitis. Of these cultures 9 were of nonhemolytic streptococci, and one was of a hemolytic streptococcus. In three instances the strep-

TABLE I.—RESULTS OF CULTURES FROM THE APPENDICES AND NASOPHARYNGES OF PATIENTS WITH APPENDICITIS AND FROM THE TONSILS OF PATIENTS WITH ARTHRITIS

Source of culture	Cases	Organisms isolated
Appendices from 28 patients with acute appendicitis	23 2 3	Green producing streptococcus and colon bacilli (small non wall) Streptococcus staphylococcus and colon bacilli Green producing streptococcus (lumen of the appendix)
Appendices from 28 patients with subacute and chronic appendicitis	16 2 1 4	Streptococcus and colon bacilli Streptococcus and staphylococcus Pure cultures of streptococci Colon bacilli No growth
Nasopharyngeal swabs from 23 patients with appendicitis	9 3 1	Non hemolytic streptococcus Green producing streptococcus and gram negative coccus Hemolytic streptococcus
Tonsils from 22 patients with arthritis	12 5 3 1 1	Green producing streptococcus Green producing streptococcus and gram negative coccus Hemolytic streptococcus Streptococcus and staphylococcus Hemolytic and green producing streptococcus

tococcus was associated with micrococcus catarrhalis

Up to this point the cases of appendicitis have been mentioned as a group, without subgroups. In considering results of cultures and inoculation of animals, acute and chronic cases will be separated. The cultures obtained from the appendices in 28 cases of acute appendicitis consisted chiefly of streptococci and colon bacilli. The former were present in predominating numbers and were morphologically typical diplostreptococci and streptococci in short chains which grew readily in ordinary media after the primary growth had occurred under reduced oxygen tension in tall tubes of glucose brain broth. These streptococci produced green pigmentation or indifferent colonies on blood agar. Twenty five of these cultures were from emulsions of the wall of the appendix, and of these 23 consisted of mixed cultures of streptococci and colon bacilli, and 2 cases yielded streptococci, staphylococci, and colon bacilli. The 3 remaining cases which yielded pure cultures of green producing streptococci were obtained from material from the lumen of the appendix.

Emulsions of the walls of 28 appendices in the cases of subacute and chronic appendicitis yielded the following results streptococci

and colon bacilli were cultured from 16 appendices, streptococci and staphylococci from 2, pure cultures of streptococci from 3, and pure cultures of colon bacilli from 4. The three remaining cultures were negative. *Oryzis vermicularis* was found in one appendix from which a pure culture of green producing streptococci was obtained. The indifferent streptococci were morphologically identical with the green producing streptococci.

The results of cultures of material from the tonsils of 22 patients with arthritis are mentioned in general in the section on results of inoculation of animals and are given in detail in Table I.

RESULTS OF INOCULATION OF ANIMALS

The number of strains and animals used in the inoculation experiments, the mortality rate, the incidence of lesions in, and the isolation of the streptococcus from the different organs following intravenous injection of the organisms that had been isolated in the different groups of cases are summarized in Table II.

Throughout this study, rabbits weighing 1,500 to 1,800 grams were given from 3 to 6 cubic centimeters of the original glucose brain broth culture by way of the marginal vein of the ear. Subcultures in glucose brain broth in a dosage of 7 to 12 cubic centimeters, were used for the two subsequent injections given on successive days to those animals that survived. The animals that withstood the effects of the injection were chloroformed usually at the end of 7 to 10 days after the first injection.

At necropsy, the organs were carefully investigated for gross lesions, and specimens of the heart's blood as well as material aspirated from the lumen of the appendix, mesenteric lymph nodes, kidneys, and joints, were introduced into glucose brain broth and spread on the surface of blood agar plates. Appendices in which there were gross pathological changes were placed in 10 per cent formalin to prepare them for microscopic section. These were stained for cellular changes by hematoxylin and eosin. Also they were stained for bacteria by the Rosenow modification of the Gram method which con-

First, elective localization of organisms from the appendix of patients with appendicitis was studied. Material from the lumens of these appendices was found to be unsuitable for this work. Therefore the organisms which were cultured for the purpose of obtaining a growth for injection were obtained from the walls of the removed appendices.

The elective localization in rabbits of organisms isolated from the appendix in 20 cases of acute appendicitis was studied in 35 rabbits. Pure cultures of streptococci were injected into 10 rabbits, mixed cultures of streptococci and colon bacilli were injected into 24 rabbits, and in 1 case a mixed culture of streptococci, staphylococci, and colon bacilli was used.

Streptococci were recovered from the appendices in 21 (60 per cent) and lesions in the form of gross hæmorrhages were found in 17 (49 per cent) of the appendices of these animals. The streptococci were obtained in pure culture in 7 instances and in association with colon bacilli in the remaining 14 positive appendiceal cultures. In 15 (43 per cent)

of the rabbits, there were marked hæmorrhages in the mesenteric lymph nodes and in 7 (20 per cent) the mesenteric lymph nodes contained streptococci. In contrast to the predominating tendency of these strains of streptococci to become localized in the appendix of rabbits, is the strikingly less frequent localization of them in other organs. Streptococci were cultured from the heart's blood in 31 per cent, and in 37 per cent from the kidney. Thus, in only 4 of the 35 rabbits were there hæmorrhages in the stomach and in 2, gastric ulcers, a total of 17 per cent of lesions in the stomach. Gross lesions occurred in the heart in 5 (14 per cent), and in 2 (6 per cent) in the kidney.

There was localization of streptococci in the joints of 3 (9 per cent) of the 35 rabbits which received injections. Included in this group is one rabbit which received intravenous injection with the emulsion of the appendix from a case of acute appendicitis. This animal lived 48 hours. At necropsy, performed shortly after death, hæmorrhages were found in the appendix and mesenteric lymph nodes. Streptococci were obtained in cultures of the mesenteric lymph nodes, but cultures from the appendix, joints, and heart's blood did not yield streptococci.

Organisms obtained from the appendices in 20 of the cases of subacute and chronic appendicitis were injected into 30 rabbits. Pure cultures of streptococci were injected into 9 of these 30 rabbits. Mixed cultures of streptococci and colon bacilli were injected into 18 rabbits and in 3 instances only colon bacilli were injected. Streptococci were cultured from 19 of the 30 appendices (63 per cent). Gross lesions in the form of hæmorrhages were found in 12 (40 per cent) of the appendices. A pure culture of streptococci was obtained from 7 of the appendices, a mixed culture in 11, and only colon bacilli in 6. Hæmorrhages were observed and streptococci cultured in glucose brain broth from 6 (20 per cent) of the mesenteric lymph nodes. There were hæmorrhages in the mucous membrane of the stomach in 2 (7 per cent) and petechial ulcers in 2 (7 per cent). Three (10 per cent) of the animals had gross lesions of the heart and kidneys. Streptococci were cultured from the heart's blood in 6 (20 per cent), from the kidney in 9 (30 per cent), and from the knee joints in 4 (13 per cent).

The original cultures obtained from the nasopharynx in cases of acute and subacute and chronic appendicitis were injected intravenously into 17 rabbits. Of the cultures from the appendices 9 (53 per cent) yielded streptococci and there were hæmorrhages in 7 (41 per cent) of the appendices. Streptococci were obtained in pure culture from the mesenteric lymph nodes and in 5 (29 per cent) of these nodes there were hæmorrhages. Petechial hæmorrhages and ulcers were observed in the stomach in 7 (41 per cent). Streptococci were obtained from 9 (53 per cent) of the kidneys and in 9 cases from the heart's blood. Five (29 per cent) of the animals had slight hæmorrhages in the myocardium and in one there were gross lesions in the kidney. Swelling of the joints was noted in two rabbits and positive cultures of streptococci were obtained from the turbid fluid in 5 (29 per cent).

Cultures were made from the tonsils of 22 arthritic patients, and the primary cultures in glucose brain broth were injected intravenously into 31 rabbits. The material obtained directly from the tonsils, when

streaked on blood agar was found to consist, chiefly, of green producing streptococci, associated with smaller numbers of hæmolytic streptococci, *Micrococcus catarhalis*, and staphylococci. Blood agar plate cultures, made from the primary culture of this material in glucose brain broth, when injected, yielded green producing streptococci only or green producing streptococci together with a few staphylococci.

Of these 31 rabbits, hæmorrhages of the joint developed in 16 (51 per cent) and there was swelling of one or more joints, or turbid fluid, in one or both knee joints. In 14 (45 per cent) of the rabbits, streptococci identical morphologically with those injected, were isolated in cultures of the joint fluid. Hæmorrhages were seen in 5 (10 per cent) of the appendices of 3 rabbits and streptococci were obtained from the appendices of 5 of them (16 per cent). There were gross lesions of the mesenteric lymph nodes in 2 (6 per cent), and from both streptococci were obtained in culture. Five (16 per cent) had hæmorrhages of the stomach but none had gastric ulcer. Streptococci were found in the heart's blood in 8 (26 per cent) and subendocardial petechial hæmorrhages in 6 (19 per cent). There were no gross lesions in the kidneys but the streptococci injected were recovered in culture of the kidneys in 9 (29 per cent).

Eight strains of streptococci from the appendices of patients who had appendicitis had been filed in meat infusion broth. That they had produced lesions in the appendices of rabbits was known. After a period of 10 to 12 months subcultures of these 8 strains in glucose brain broth were injected intravenously into 8 rabbits. Two of the animals were found dead at the end of 48 hours; the remainder were chloroformed, within from 2 to 5 days. Cultures made from the heart's blood contained streptococci in 2 cases and cultures made from the kidneys contained streptococci in 5 of the 8 animals. Growth was not obtained from the fluid from the knee joints or the mesenteric lymph nodes. Streptococci in association with colon bacilli were cultured from 2 of the appendices but these appendices were without lesions. Pe

Fig 1 Section of the appendix in a case of acute gangrenous appendicitis removed 24 hours after onset of symptoms. There are marked leucocytic infiltration beginning sloughing of the mucous membrane and oedema of the lymph follicle in the submucosa (Haematoxylin and eosin $\times 60$)

technical hemorrhages were found in the heart and stomach of one rabbit and in the mesenteric lymph nodes of another. Lesions were not observed in the joints or the kidneys of any of these rabbits.

SUMMARY OF RESULTS OF EXAMINATION OF TISSUE

Although changes in tissue have been mentioned earlier in this paper it seems advisable to amplify this aspect of the work. The appendices were removed at operation early in the attack in nearly all cases of acute appendicitis. They presented the usual gross picture of marked congestion, with swelling of the wall and fibrinous exudation. In sections, marked leucocytic infiltration was found, usually, throughout the different coats and sometimes beyond the peritoneum. The mucous membrane often was necrotic and partly sloughed away (Fig 1). Search for bacteria was made in 13 sections. All of

Fig 2 Diplococci in the tissues in 2 cases of acute appendicitis in man: a and b from lesions of the submucosa shown in Figure 1 c, from the serosa of another case of acute gangrenous appendicitis (Modified Gram's stain $\times 800$)

these, stained by the modified Gram Weigert method, contained diplococci or streptococci in short chains, in the peritoneal coat, the mucosa, or the submucosa (Fig 2). Gram

Fig 3 Section of the appendix of a rabbit in which there was marked evidence of hemorrhage of the appendix and mesenteric lymph nodes 24 hours after an intravenous injection of a culture containing a marked preponderance of streptococci and a few colon bacilli. The source of the organisms was the wall of the appendix in a case of acute appendicitis. There were necrosis sloughing and cellular infiltration of the mucosa and submucosa (Haematoxylin and eosin $\times 20$)

Fig 4 Higher magnification of an area in the submucosa of the appendix from which Figure 3 was made. Polymorphonuclear leucocytes and large and small round cells in varying states of disintegration (Hematoxylin and eosin $\times 400$)

Marked edema, necrosis and cellular infiltration are present in the large lymph follicles. edema and cellular infiltration in the serosa and submucosa (Hematoxylin and eosin $\times 45$)

negative bacilli, presumably colon bacilli, were found chiefly on the surface and in the superficial layers of the mucosa. They were never found in the peritoneal coat. Large gram positive bacilli, associated with fusiform bacilli and diplococci were seen in the peritoneal coat of two appendices. In many instances only individual cocci or single pairs of diplococci were seen (Fig 2 a and c). In other instances clusters of diplococci (Fig 2 b) were seen usually within large collections of lymphocytes.

In those animals in which there were lesions in the appendix the organ usually was found on macroscopic examination to be diffusely congested, swollen and edematous. However, there were no evidences of hemorrhages or purulent exudation in the serosa nor were there adhesions to the surrounding structures. The lumen usually contained mucoid or mucopurulent material, especially in the distal end which often was distended with exudate. Only occasionally was fecal material found in the proximal end of the appendices in which there were lesions, whereas in the ap-

pendices in which there was neither mucus nor lesions fecal material usually was found throughout the whole length of the lumen. Fecal concretions similar to those seen in the appendices in human beings were not found in a single instance.

Hemorrhages of the appendices of the rabbits were found chiefly in mucosa, submucosa and immediately beneath the peritoneal coat. The number of hemorrhages varied from a few in one or more sharply circumscribed areas and mostly in the distal end to large numbers scattered throughout the entire appendix.

Studies were made of sections of the appendices of 22 rabbits in which gross lesions of the appendix appeared following injection of cultures made from the appendices or nasopharynxes of patients with acute, subacute, and chronic appendicitis. Microscopically,

Fig 6 Large numbers of gram positive diplococci and a few bacilli in the area of necrosis shown in Figure 5 (Modified Gram's stain $\times 1000$)

Fig 7 Section of the appendix of a rabbit which 24 hours before had received an injection of the primary culture of streptococci made from material swabbed from the throat in a case of acute appendicitis (Edema necrosis and leucocytic and round cell infiltration extending especially throughout the mucosa submucosa lymph follicles and serosa (Hematoxylin and eosin $\times 60$)

the lesions consisted, chiefly, of edema, hemorrhage, and superficial necrosis of the mucous membrane (Fig 3), and necrosis in the centers of lymph follicles associated with relatively slight leucocytic infiltration (Figs 4, 5, and 6). Edema and leucocytic infiltration (Fig 4) often consisting chiefly of eosinophiles were especially marked in the mucosa, in lymphoid follicles and beneath the peritoneal coat (Fig 7). The Gram stain revealed a variety of organisms: gram positive diplococci or streptococci resembling those injected intravenously (Figs 6, 8, and 9); gram negative bacilli resembling *Escherichia coli*, and large gram positive bacilli resembling *Bacillus subtilis* and *Clostridium welchii*. With one exception, only the gram positive diplococci or streptococci seemed to bear a causal relationship to the lesions found. At times masses of these were found in the centers of large regions of necrosis and of leucocytic infiltration (Figs 5 and 6). The gram positive and gram negative bacilli were especially numerous and diffusely distributed without regard to lesions in those animals that suc-

cumbed some time previous to necropsy. Diplococci or streptococci in short chains were found in lesions of the appendix in all but one instance, and this section was made from a region remote from the lesions noted at necropsy. The diplococci were found free in the mucopurulent material in the lumen and in the tissues where there was evidence of edema, necrosis, or hemorrhage. They almost never were found in the normal tissues remote from lesions. They were present in large numbers in most of the sections although they were hard to find in others. They were successfully demonstrated in animals that were chloroformed or died from the effects of the injection and in which cultures from the blood, joints, and kidneys did not afford growth. Frequently, they occurred in nests especially within the lymph follicles in the lymphatic channels beneath the peritoneum of the wall of the appendix. They were found in sections as early as 24 hours and as long as 10 days after injection.

Sections were made and studied of hemorrhagic or edematous mesenteric lymph nodes in 16 of the rabbits that showed evidence of

Fig 8 Diplococci in the tissues of the appendices of rabbits a and b from section shown in Figure 7 c from the appendix of a rabbit in which lesions in the appendix developed following intravenous injection with an emulsion of the wall of an acutely inflamed appendix of a human being (Modified Gram's stain $\times 1000$)

Fig 9 Diplococci in the hemorrhagic necrotic lymph nodes of two rabbits in which appendicitis developed following intravenous injection of streptococci from patients with appendicitis a and b from the rabbit referred to in Figure 7 c from a rabbit injected intravenously with streptococci isolated from the appendix in a case of acute gangrenous appendicitis (Modified Gram's stain $\times 1000$)

lesions in the appendix. The abnormalities found were similar to those found in the appendix. Diplococci or streptococci in short chains (Fig 9, a, b, and c) were demonstrated in all but two of these.

Examination of the appendix and mesenteric lymph nodes of 4 rabbits that received intravenous injections of cultures from the tonsils in cases of arthritis disclosed diplococci in only 1 appendix.

SUMMARY AND CONCLUSIONS

Streptococci isolated from diseased appendices removed at operation on human beings have a most striking resemblance morphologically and culturally to the streptococci isolated from the nasopharynges of patients suffering from appendicitis and to those obtained from tonsils of patients with arthritis. It would have been impossible, therefore, to determine the relation of streptococci isolated from either of these sources to the disease from which the patient was suffering unless animal experiments had been carried out. From my data it becomes clear that despite the morphological and cultural similarity of these streptococci their localizing power varied greatly. Thus a glance at the figures in Table II shows that the proportion of lesions in the appendices of rabbits and in the joints of rabbits varied with the

source of the material injected. When material derived from the nasopharynges or from the appendices of patients who had appendicitis was injected into animals the incidence of localization in the appendices of the animals was high. In these same animals the incidence of localization in the joints was low. On the other hand when material from the tonsils of patients with arthritis was injected into animals the incidence of localization in the joints of the animals was high and the incidence of the localization in the appendices low. This is entirely in accord with the observations of Rosenow in his studies on appendicitis and incidentally adds further support to the large mass of data which has been accumulated to substantiate the theory of elective localization.

It should be emphasized that the use of original cultures, either pure or mixed is an important factor in the success of studies such as this. This is brought out by the fact that cultures which had previously produced appendicitis lost their elective localizing power for the appendix after cultivation on artificial media for several months.

Diplococci and streptococci in short chains were successfully demonstrated by the modified gram stain in sections of appendices from human beings and in the appendices and mesenteric lymph nodes of rabbits.

The relation of focal infection to appendicitis is definitely shown by the marked contrast between the degree of localization in the appendices, of streptococci found in the nasopharynges of patients who had appendicitis and those who had arthritis. It seems, then, that streptococci more often than colon bacilli or other bacteria which are isolated from the diseased appendix have definite etiological significance in appendicitis that the nasopharynx may be the source of the streptococcus having this localizing power, and that appendicitis is commonly an hæmatogenous intramural streptococcal infection.

SUMMARY AND CONCLUSIONS

Streptococci isolated from diseased appendices removed at operation on human beings have a most striking resemblance morphologically and culturally, to the streptococci isolated from the nasopharynges of patients suffering from appendicitis and to those obtained from tonsils of patients with arthritis. It would have been impossible, therefore, to determine the relation of streptococci isolated from either of these sources to the disease from which the patient was suffering unless animal experiments had been carried out. From my data it becomes clear that despite the morphological and cultural similarity of these streptococci their localizing power varied greatly. Thus a glance at the figures in Table II shows that the proportion of lesions in the appendices of rabbits and in the joints of rabbits varied with the

source of the material injected. When material derived from the nasopharynges or from the appendices of patients who had appendicitis was injected into animals, the incidence of localization in the appendices of the animals was high. In these same animals the incidence of localization in the joints was low. On the other hand when material from the tonsils of patients with arthritis was injected into animals, the incidence of localization in the joints of the animals was high and the incidence of the localization in the appendices, low. This is entirely in accord with the observations of Rosenow in his studies on appendicitis and incidentally adds further support to the large mass of data which has been accumulated to substantiate the theory of elective localization.

It should be emphasized that the use of original cultures either pure or mixed is an important factor in the success of studies such as this. This is brought out by the fact that cultures which had previously produced appendicitis lost their elective localizing power for the appendix after cultivation on artificial media for several months.

Diplococci and streptococci in short chains were successfully demonstrated by the modified gram stain in sections of appendices from human beings and in the appendices and mesenteric lymph nodes of rabbits.

Muehsam (1900) ligated the appendiceal vessels of rabbits and obtained gangrene of the peripheral parts of the appendix. After ligation of the appendiceal vessels, appendicitis was produced by intravenous and intraperitoneal injections.

Adrian (1901) injected the streptococcus, staphylococcus, pneumococcus, bacillus coli, bacillus typhosus, bacillus tuberculosis, and bacillus anthracis into the blood stream and obtained follicular appendicitis. He concluded that the appendix was a particularly vulnerable part of the body.

Van Zwalenburg (1904) occluded the appendices of dogs by a ligature and injected fluid under high pressure into the appendix. He states "Experiments in dogs show that hydraulic pressure equal to the arterial tension maintained within the lumen of the appendix for a short time is promptly followed by typical appendicitis."

Richet and Saint Givans (1911) injected bacteria into the blood stream of rabbits and produced lesions in the appendix. The lesions were covered up by other lesions produced by secondary infection from the intestinal tract.

Heyde (1911) thought that anaerobic organisms played a very important role in the production of acute appendicitis.

Boit and Heyde (1912) and Sprengel (1912) considered stagnation as the most important factor in the production of acute appendicitis.

Heile (9) found changes in 6 of 100 appendices removed from apparently healthy dogs which resembled those found in man with acute appendicitis. He found that simple ligation of the appendix was followed by a restoration of the lumen, but he was able to produce what he considered complete occlusion of the lumen by the injection of paraffin into the wall of the appendix distal to a ligature which was tied very loosely. Complete occlusion produced in this manner never led to peritonitis or death but to localized abscesses at the sites of the injection. However if normal intestinal contents were placed in the appendix and the lumen occluded death followed in 1 to 5 days. Bacteria alone never caused destructive inflammation. Heile (10) was unable to confirm the work of the investigators who found that the infection of organisms in

Fig 1 The relative positions of the initial incision and of the exteriorized appendix are shown in this drawing. In most instances a slightly greater length of the ileum and caecum were left attached to the appendix. In some experiments the wall of the intestine was not cut across just at the base of the appendix as is shown here.

to the blood stream led to severe inflammation. He was very careful not to traumatize the appendix. The injection of sausage into the ligated appendix led to destructive inflammation of its wall.

Rosenow (1915) injected into rabbits isolated strains of organisms which were obtained from human appendices and tonsils. He states "The results of the observations and experiments indicate that appendicitis, in the absence of foreign bodies, commonly is a hematogenous infection secondary to some distant focus, that it develops when, for some reason or other, the organisms in the focus, usually streptococci, have acquired an elective affinity for the appendix and at the same time gain entrance into the circulation."

Heile (12) as a result of experiments on more than 80 dogs could not confirm the origin of appendicitis by way of the blood stream. He believed that the neighboring colon with its varied bacterial flora made the origin of appendicitis from intestinal contents more probable. A normal appendix restored its lumen after ligation alone. A retention of bacteria in the appendix has never led to a

OBSERVATIONS UPON THE EXTERIORIZED APPENDIX OF THE DOG¹

P. N. HARRIS BENTLEY COX M.D. AND ALFRED BLOCK M.D. NASHVILLE, TENNESSEE

SINCE the description of appendicitis by Fitz in the latter part of the nineteenth century much experimental work has been performed in an effort to determine the etiology of acute appendicitis. Studies have also been made upon the secretion of the appendix with particular reference to the enzymes which are present. In all of these studies, the appendix has either been left entirely in the peritoneal cavity or it has had its tip anchored to the anterior abdominal wall.

Dr Florey, of the Department of Pathology of Cambridge University, was kind enough to demonstrate to one of us (A. B.) a method by which he exteriorized a small piece of the colon with its mesenteric attachment intact for the purpose of studying the changes in color of the mucous membrane during excitement. This together with experience with the exteriorized spleen as described by Barcroft and Stephens suggested to us the possibility of exteriorizing the appendix together with a small part of the ileum and cæcum. It was thought that this would afford an opportunity for making frequent observations after the various procedures had been carried out and that the secretion from the appendix could be collected without danger of intermixing with that from the small and large intestines.

HISTORY

Rabbits have been used in most of the experimental work which has been done on the appendix. Ribbert (1885) tied off the appendix at the base and injected a culture of staphylococcus aureus into the tip. The animals were sacrificed after 5¹ hours and staphylococci were found in the follicles.

Roger and Josue (18) working on rabbits found that a wax ball would not remain in the appendix when placed there. Ligation of the appendix without including the appendiceal vessels produced no noteworthy lesion while if the vessels were included in the liga-

ture death followed after a shorter or longer time. Ligation of the appendix and the injection of a culture of bacillus coli resulted in death of the animals from suppurative appendicitis.

Beaussenat (1897) studied the effects on the appendices of rabbits of simple ligation of partial occlusion of the introduction of septic and aseptic foreign bodies with and without injury of the mucosa of intra appendicular and intra intestinal injections with and without injury of the mucosa, of infection introduced into the circulation with and without injury to the mucosa, of interfering with the circulation of the appendix with and without the injection of organisms into the vessels of the appendix of the intraparietal introduction of infection of the production of intestinal irritation by the feeding of badly infected meat and of the production of a blood stream infection when there had previously been inflammation of the intestinal tract. He came to the conclusion that appendicitis could be produced by blood or lymph stream infection but that more commonly it resulted from infection of the intestinal tract. Bacillus coli was the prevailing organism. He believed that the pathogenicity of the organisms was increased greatly by injury to the mucous membrane. He was not able to keep foreign bodies in the appendix and they were expelled.

Josue (1897) injected 'strepto bacilli' intravenously in rabbits and obtained appendicitis without having traumatized the mucosa of the appendix. The same results were obtained after the injection of intestinal contents.

Anghel (1897) was unable to maintain for eign bodies in the lumen of the appendix of rabbits.

Gouget (1899) injected contaminated urine subcutaneously and as a result abscesses appeared at the site of the injection in the mesenteric lymph nodes in the spleen and in the appendix.

employed was not suitable for the detection of other enzymes, hence Heile digested the mucous membrane of the human appendix and found trypsin, amylase, and invertase. Lactase and maltase were absent.

METHOD

All of the experiments were performed upon dogs. Females were used because of the greater ease with which the dressings could be kept clean. The operation which was necessary for the exteriorization of the appendix was carried out as follows. An incision was made in the midline of the abdomen with the center of the incision at the level of the umbilicus. The appendix was then located and it was delivered through the incision together with the terminal ileum and proximal cæcum. After the intestinal clamps were applied the ileum was cut across about 4 centimeters proximal to the appendix and the cæcum was divided at an equal distance distal to the appendix. The mesentery was not disturbed. Either an end-to-end or a side to side anastomosis was then made between the ileum and cæcum, thereby restoring the continuity of the intestine. A stab incision was made in the right side of the abdomen at the level of the umbilicus. Care was taken to see that the stab incision was very near to the ileocecal region in order to avoid any tension on the mesentery. The appendix with the attached ileum and cæcum was pushed through the stab incision. The original midline incision was closed. In most of the experiments a longitudinal incision was then made through the walls of the exteriorized ileum and cæcum and the free edges were sutured to the surrounding skin. This left all of the mucous membrane exposed. In several instances, the wall of the intestine was left intact for a short distance just at the base of the appendix. The opening of the appendix into the ileocecal region was easily visible. Bleeding from the mucous membrane of the intestine was controlled by the sutures which held it to the skin. A large amount of sterile vaseline was placed over the mucous membrane and the appendix in order to avoid irritation by the dressing. A roll of gauze was then applied around the abdomen in a circular direction. A jacket which was made of cotton

cloth with perforations for the legs of the animal was then placed on and this was held in position by safety pins. Daily dressings were performed during the first week following the operation. The appearance of the preparation at the completion of the operation is illustrated in Figure 1.

The movements of the appendix and the reactions of the mucous membrane of the small and large intestine following stimulation were observed. Many attempts were made to block the lumen of the appendix by placing foreign bodies in it. The foreign bodies which were employed included balls of paraffin, cork, rubber balloons, and solid glass covered by rubber. Attempts were made to occlude the lumen of the appendix at its base by freeing one edge of the mucous membrane in this area and suturing it across the opening. In other instances, ligatures of catgut were placed around the base of the appendix without occluding its blood supply. In several experiments, the base of the appendix was occluded by a broad piece of tape which did not include the appendiceal blood vessels.

The secretion from the appendix was obtained by inserting the tip of a syringe into the lumen of the appendix at its base and making suction. The secretion was tested for the presence of invertase, maltase, crepsin, amylase, lipase, pepsin, trypsin, and lactase.

RESULTS

The peritoneum covering the appendix became quite reddened as a result of placing it outside the peritoneal cavity. There was very little alteration in the color of the mucous membrane. Approximately 2 weeks after an appendix had been exteriorized, it began to diminish in size slowly. The decrease in size was probably due to a constricting effect exerted by scar tissue which formed around the pedicle. In one appendix which had been exteriorized for 40 days and in another which had been exteriorized for 100 days, a perforation appeared in the tip. This again was probably due to a poor blood supply and the tip was the most vulnerable point. The microscopic appearance of an appendix which had been exteriorized for 40 days is shown in Figure 2. A ligature of catgut or silk, when

Fig. 2 An appendix which had had its lumen occluded by a ligature of tape for 48 hours is shown in this photograph. The appendix was very much enlarged due to its being tightly filled with fluid and the peritoneal covering was quite red.

destructive inflammation of the wall with progressive peritonitis but at most to a local abscess formation in the lumen. However, if intestinal contents were imprisoned, a severe destructive inflammation of the walls with perforation took place and this resulted in peritonitis and death. The course of the inflammatory process was found to depend upon the amount of material present which was capable of being split down. The more of enzymes and unsplit proteins that were in the appendix the more rapid the inflammatory process, so that even 2 to 4 hours after beginning the experiment great alterations were found in the appendix. He further noted that if food which was fully digested was occluded in the appendix together with the usual intestinal flora no significant inflammation with tissue destruction resulted. Heile made the interesting comment that ordinary faces at the junction of the small and large intestine did not lead to severe inflammation but that in diarrhoea and overeating more of the food passed undigested into the ileocaecal region. This was true of the protein in particular. He considered enteroliths dangerous only in that they contained unsplit proteins. However, he believed that occlusion was necessary, otherwise the peristaltic waves would carry away the toxins. He produced occlusion by placing strips of fascia around the appendix as well as

Fig. 3 A photomicrograph showing an appendix which had been exteriorized for 40 days. The low magnification was used in order to show the entire thickness of the wall. The appendix appears essentially normal except for the thick layer of fibrin on its peritoneal surface.

by injecting paraffin into the wall of the appendix. Microscopic examination of the appendices showed changes similar to those in acute appendicitis in man.

The studies upon the secretions of the appendix have not been numerous. Roger and Josue (19) demonstrated the presence of amylase in the appendices of rabbits by ligating the base and opening the tip. Strazesco (1904) made caecal fistulae in two dogs and found in the secretion in small amounts erepsin, amylase, maltase and invertase. He did not attempt to determine the secretions of the appendix alone. These secretions were found to be entirely independent of feeding as well as the composition of the food. Heile (11), working on dogs, performed an appendicostomy and so altered the base of the appendix that intestinal contents could not enter into it. Bags of gauze containing fibrin and cooked egg white were introduced into the appendix. Digestion took place indicating the presence of trypsin. The most active digestion took place 2 to 3 hours after meals. The method

employed was not suitable for the detection of other enzymes, hence Heile digested the mucous membrane of the human appendix and found trypsin, amylase, and invertase. Lactase and maltase were absent.

METHOD

All of the experiments were performed upon dogs. Females were used because of the greater ease with which the dressings could be kept clean. The operation which was necessary for the exteriorization of the appendix was carried out as follows. An incision was made in the midline of the abdomen with the center of the incision at the level of the umbilicus. The appendix was then located and it was delivered through the incision together with the terminal ileum and proximal cæcum. After the intestinal clamps were applied the ileum was cut across about 4 centimeters proximal to the appendix and the cæcum was divided at an equal distance distal to the appendix. The mesentery was not disturbed. Either an end-to-end or a side-to-side anastomosis was then made between the ileum and cæcum, thereby restoring the continuity of the intestine. A stab incision was made in the right side of the abdomen at the level of the umbilicus. Care was taken to see that the stab incision was very near to the ileocecal region in order to avoid any tension on the mesentery. The appendix with the attached ileum and cæcum was pushed through the stab incision. The original midline incision was closed. In most of the experiments a longitudinal incision was then made through the walls of the exteriorized ileum and cæcum and the free edges were sutured to the surrounding skin. This left all of the mucous membrane exposed. In several instances, the wall of the intestine was left intact for a short distance just at the base of the appendix. The opening of the appendix into the ileocecal region was easily visible. Bleeding from the mucous membrane of the intestine was controlled by the sutures which held it to the skin. A large amount of sterile vaseline was placed over the mucous membrane and the appendix in order to avoid irritation by the dressing. A roll of gauze was then applied around the abdomen in a circular direction. A jacket which was made of cotton

cloth with perforations for the legs of the animal was then placed on and this was held in position by safety pins. Daily dressings were performed during the first week following the operation. The appearance of the preparation at the completion of the operation is illustrated in Figure 1.

The movements of the appendix and the reactions of the mucous membrane of the small and large intestine following stimulation were observed. Many attempts were made to block the lumen of the appendix by placing foreign bodies in it. The foreign bodies which were employed included balls of paraffin, cork, rubber balloons, and solid glass covered by rubber. Attempts were made to occlude the lumen of the appendix at its base by freeing one edge of the mucous membrane in this area and suturing it across the opening. In other instances, ligatures of catgut were placed around the base of the appendix without occluding its blood supply. In several experiments, the base of the appendix was occluded by a broad piece of tape which did not include the appendiceal blood vessels.

The secretion from the appendix was obtained by inserting the tip of a syringe into the lumen of the appendix at its base and making suction. The secretion was tested for the presence of invertase, maltase, erepsin, amylase, lipase, pepsin, trypsin, and lactase.

RESULTS

The peritoneum covering the appendix became quite reddened as a result of placing it outside the peritoneal cavity. There was very little alteration in the color of the mucous membrane. Approximately 2 weeks after an appendix had been exteriorized, it began to diminish in size slowly. The decrease in size was probably due to a constricting effect exerted by scar tissue which formed around the pedicle. In one appendix which had been exteriorized for 40 days and in another which had been exteriorized for 100 days, a perforation appeared in the tip. This again was probably due to a poor blood supply and the tip was the most vulnerable point. The microscopic appearance of an appendix which had been exteriorized for 40 days is shown in Figure 2. A ligature of catgut or silk, when

placed around the base of the appendix with out occluding the blood supply, cut through after 1 or 2 days and the contents of the appendix were discharged through the perforation.

Every effort directed toward maintaining foreign bodies in the lumen of the appendix was unsuccessful. The peristaltic waves were extremely vigorous. The contractile power of the sphincter at the base of the appendix was very strong and it was only with difficulty that foreign bodies could be inserted past it. The secretion of the appendix was usually expelled in a spurt at the end of a peristaltic wave.

In another series of experiments the lumen of the appendix at its base was occluded by a broad piece of tape. The tape was so placed that it did not cause occlusion of the blood supply. A marked distention of the appendix followed in less than 24 hours as a result of the inability of the secretion of the appendix to escape. The appearance of the appendix was similar to that seen in hydrops of the gall bladder. A photograph of an appendix which had had its lumen occluded for 48 hours by a ligature of tape is shown in Figure 3. After 2 to 4 days a perforation appeared in the wall of the appendix. The site of the perforation in all instances was slightly distal to the tape which had been placed around the base. In order to be sure that the extraperitoneal location of the appendix did not alter the results, several experiments were performed in which the appendix was left in the peritoneal cavity after a ligature of tape had been placed around its base. Alterations in the location of the appendix did not seem to change the results. An appendix which had had its base occluded by tape for from 2 to 4 days showed on microscopic examination the presence of fibrin on its peritoneal surface and leucocytes in the muscular coats.

The enzymes which were found in the secretion from the appendix were amylase, invertase, trypsin, and erepsin. Pepsin, lactase, maltase, and lipase were tested for but not demonstrated. The secretion consisted in the main of mucus. A few white blood cells and a few epithelial cells were usually found on microscopic examination.

DISCUSSION

The method of studying the appendix which is described here has both advantages and disadvantages. Chief among the disadvantages is the fact that an intraperitoneal structure is placed on the outside where it is subjected to irritation by the dressing. It also has the objection that there is a slowly progressive occlusion of the blood supply by the scar tissue which forms around the mesenteric attachment. It has the advantage that the appendix can be observed constantly in the essentially normal, non-narcotized dog. It allows one to collect the secretions from the appendix without danger of contamination by those from the remainder of the intestinal tract. It offers the opportunity for a study of the mucous membrane of both the large and small intestines in the unanesthetized dog.

Many investigators have failed in the attempt to block the lumen of the appendix of the rabbit or dog by placing foreign bodies in it. We were also unsuccessful in our efforts even though the appendix had been placed outside the peritoneal cavity.

The experiments of Van Zwalenburg in which he produced acute appendicitis in dogs have been mentioned previously. He injected fluid under very high pressure into the lumen of the appendix distal to a ligature which had been placed around its base. The experiments which are reported here in which a ligature of tape was placed around the base of the appendix produced a condition very similar to that reported by him. The inability of the secretion of the mucous membrane to escape produced a marked distention of the appendix with some evidence of acute inflammation.

If the appendix of man has as vigorous peristaltic waves as does that of the dog it is difficult to believe that acute appendicitis is produced simply by the lodging of a concretion in its lumen. It is possible that the escape of a foreign body which happens to be in the appendix is prevented by a concurrent swelling and oedema of the mucous membrane. Here again if the contractions of the appendix of the human approach at all closely in strength those of the dog it is difficult to understand how the swelling could take place

quickly enough to prevent the escape of a foreign body. It is possible that a difference in the strength of contractions may explain the frequency of appendicitis in man and the infrequency in dogs. The fact that the appendix of the dog is usually larger than that of man may also be a factor.

In summary, it is not certain whether appendicitis in man is or is not frequently the result of simple blockage of the lumen of the appendix. However, since a condition which simulates acute appendicitis can be produced in dogs by occluding the lumen by a ligature of tape and since the appendix of the dog is larger and probably has more forceful contractions, it is believed that some instances of appendicitis in man result from simple blockage of the lumen.

The enzymes which were found in the secretions from the appendix of the dog were amylase, invertase, trypsin, and erepsin. These enzymes have to do respectively with the splitting of starch to dextrin and maltose, with the changing of sucrose to glucose and fructose, with the conversion of the higher proteins to peptones and proteoses, and with the formation of amino acids from the peptones and proteoses. Heile (11) digested the mucous membrane of the human appendix and demonstrated the presence of amylase, invertase, and trypsin. The fact that three of the four enzymes which were found in the dog's appendix have been demonstrated in the human appendix suggest that the functions of the appendix in man and dog are quite similar. The copious secretion and the presence of the various enzymes lead one to think that the dog's appendix has to do with the digestion of food and not with the absorption of fluids.

SUMMARY

- 1. An operation has been described by which the appendix of the dog can be placed outside the peritoneal cavity.
- 2. Various attempts which were made in an effort to block the lumen of the appendix by placing foreign bodies in it were unsuccessful.
- 3. The occlusion of the lumen of the appendix at its base by a ligature of heavy tape results in a great increase in the size of the appendix with evidences of acute inflammation.
- 4. Amylase, invertase, trypsin, and erepsin were found in the secretions of the appendix.

TRAUMATIC ASPHYXIA

WITH REPORT OF FIVE ADDITIONAL CASES

WILLIAM K. LAIRD, M.D., F.A.C.S. AND MILTON C. FORMAN, M.D., F.A.C.P. MONTGOMERY, WEST VIRGINIA
From the Montgomery Clinic

TRAUMATIC asphyxia or traumatic cyanosis was probably first described by Ollivier of Anvers in 1837 and later by Tardeu in 1870. In discussing the history of the study of this condition, Burrell and Crandon state:

'Classic and horrible examples of this are to be found in the rush of the mob at the Champ de Mars June 14, 1837, where 23 persons were crushed, the Pont de la Concorde panic in Paris August 15, 1866, where a mob crowded 9 of its number to death, the Vienna Ring Theater fire December 8, 1881, with nearly 1,000 fatalities, the panic at Victoria Hall, Sunderland, June 16, 1883, where nearly 700 children rushed into a closed corridor and were asphyxiated by crushing, and most recently at the Charity Bazaar fire in Paris May 4, 1897.'

In the panic occurring in a ball park May 19, 1929, in New York City, two deaths occurred (Kennard). In each the evidence of asphyxia was pronounced. One was believed to have died from the asphyxiation incident to the pressure of the feet of the crowd upon the chest. The other had in addition fractured ribs.

Besides accidents that produce terror in large numbers of people with resulting panic, the industrial age has begun to claim traumatic asphyxia victims. Compression by elevators, cranes, steam shovels, street cars, cow catchers, and wagon wheels may be mentioned. Mine accidents such as slate falls, compression between mine cars or between the mine top or side and a moving car have caused several cases. Perhaps the most unusual report we found was that of two sailors accidentally rolled as by a mangle into a ship's sail (Story).

It is interesting to note that since Heuer reported his case in 1923, 6 of the 11 cases of traumatic asphyxia described in the literature were caused by automobile accidents. One

of the 5 cases we are herein reporting was produced in an auto truck accident. The 4 remaining were coal mine injuries.

INCIDENCE

Since first noted in 1837, many cases of traumatic asphyxia have appeared in the literature. Heuer in 1923 collected 127 cases including one of his own. We have found 11 more cases, a brief summary of each of which we include in this article. We have added 5 new cases observed by us in the past 23½ years in a series of over 37,000 hospital and clinic patients in an industrial field. Five other physicians in industrial practices in Southern West Virginia recalled out of approximately 75,000 major accident cases only 2 of traumatic asphyxia. These 2 cases have not been reported. This suggests that the condition is relatively rare or not always recognized. Modern textbooks on surgery refer to the subject very briefly, or make no mention whatever of it.

CLINICAL SUMMARY

Although in his paper published in 1923 Heuer referred more particularly to the visual disturbances associated with traumatic asphyxia, he has given the best clinical summary we have found in the literature. These patients present themselves with a history of immediately preceding severe compression of the thorax, abdomen or both with complete or partial cessation of respiration for varying periods of time. The brilliant purple discoloration of the skin of the face, neck, and upper chest and the vivid blood red conjunctivæ present a truly startling clinical appearance. The characteristic lesion from which the condition receives its name is the skin discoloration which may be reddish violet or even black and covers the face, neck, upper chest to the level of the nipples, the upper arms to the insertion of the deltoid

muscles, and the back to the angles of the scapula producing the so called "double trapezius triangles" On close examination, the discoloration is seen to be due to minute ecchymotic spots so numerous as to appear confluent. The subconjunctival hæmorrhage may be extensive, and is usually lozenge (Robertson) or wedge shaped occupying the area of the exposed portions of the bulbar conjunctiva covering the sclera. There may be a marked bulbar and palpebral conjunctival œdema so that the patient is unable to close his eyes, which have the appearance of exophthalmos. There may be hæmorrhages from all mucous membranes. Unconsciousness occurs frequently. Convulsions and milder mental disturbances due to cortical irritation occur less frequently. The respiratory and cardiac functions may be markedly depressed. Ettinger noted cardiac dilatation and hæmaturia. Pulmonary congestion and œdema with other evidence of intrathoracic damage are revealed by hæmoptysis, blood tinged frothy expectoration, and bubbling rales, with elevation of temperature on the third or fourth day suggesting a "contusion pneumonia." This condition usually promptly clears up. Ecchymosis of the soft tissues about the site of compression, and fractured bones, especially the ribs and pelvis are noted. Hæmothorax, pneumonia, empyema multiple pulmonary abscesses, pleural effusion followed by empyema, open thoracic wounds, and subcutaneous emphysema have occurred. Associated abdominal lesions have been clinically rather uncommon. Contusions and lacerations of the soft tissues of the trunk, extremities, cord, peripheral nerves and fractured spines have been observed. Numerous eye changes have been reported including the subconjunctival hæmorrhage hereinbefore described, exophthalmos, proptosis oculi, pupillary changes, temporary and complete vision loss, retinal œdema, hæmorrhage into practically all portions of the eye, and optic atrophy. Death is usually the result of the more serious associated lesions.

PATHOLOGICAL PHYSIOLOGY

Green states that in addition to cessation of respiration in this condition, the venous

blood in the large veins of the thorax, neck, and head are forced backward into the capillaries of the skin. Perthes believed that the cause of discoloration is extravasation of blood, either minute or more extensive subcutaneous effusions or hæmorrhages. The peculiar limitation of the cyanosis he explained by the absence of functioning valves in the innominate and internal jugular veins except a pair where the jugular enters the innominate. These are irregular and incompetent. There are two pairs in the external jugular one at its junction with the subclavian and the other just above the clavicle. Both sets of valves are incompetent. We have noted in one of our cases that the cyanosis was less pronounced in the left face and neck than in the right. Huerter mentions the probable vasomotor paralysis with vascular distention as a factor in the production of cyanosis. Beach and Cobb removed two pieces of cyanosed skin under local anæsthesia, and sectioning revealed no extravasation of blood into the tissues. This is corroborated, they believe, by the blanching on pressure and the rapid disappearance without passing through the various stages of discoloration as shown where blood is extravasated into the tissues. These histological findings were corroborated by Winslow and also in our study of one patient.

We have noted that in addition to its being the last to clear up the discoloration of the sclera passes through the various color stages of extravasated blood. We have attempted to shrink the vessels by applying 1:1000 dilution of adrenalin hydrochloride which has caused contraction only of the vessels at the margin of the discoloration. Pressure has produced no change. In 3 of our patients who recovered, we observed that the scleral discoloration was definitely wedge shaped, with the apices pointing toward the canthi. The remaining portions of the sclera above and below the iris were white and later became icteroid in color. We are unable to explain the wedge shaped discoloration upon anatomical arrangement of blood supply. We have noted the most intensely discolored portions of the sclera were those exposed to light and air, not being

covered by the eyelids. This is the same site in which pinguiculae are found. It is our belief that the eyelids help support the vessels and prevent their rupture in that portion of the sclera normally covered by the palpebrae. This opinion is strengthened by the collar like band of almost normally colored skin around the necks of traumatic asphyxia patients described by Conwell and Coullie due no doubt to the skin being supported by the external pressure of the collar bands worn by the patients at the time of the injury. Similarly the skin beneath suspenders and hat bands has been reported normal. It is our belief that in traumatic asphyxia there is actual subconjunctival hemorrhage partially due to the lack of supporting tissue. Such hemorrhage is seen in old persons after straining or violent coughing and in children during whooping cough.

Normally a negative pressure exists in each intrapleural cavity. The elevation of the ribs and the pulling down of the diaphragm in inspiration increase the size of the intrapleural cavities and the pressure drops from minus 5 to minus 10 millimeters of mercury. This drop in pressure pulls apart the elastic structures in the thorax for example the lungs and the large veins thus exerting a sucking action on the blood flowing into the thorax through the large veins. In expiration the opposite obtains. The intrapleural space is made smaller and pressure rises. If further pressure is applied externally to the thorax as when a heavy weight such as falling slate in a mine is applied to the thorax, or if the chest is caught between two opposing forces and a squeezing action exerted, as when a miner is caught between two cars, the intrapleural space is made smaller and the pressure therein becomes positive. The degree to which this pressure may be raised must be tremendous. Macleod states that when 'the respiratory passages are blocked and a forced expiration is made, as for example in the first stage of coughing or during such acts as defecation and parturition, the thoracic cage is compressed upon the viscera with the result that the air in the lungs assumes a positive pressure, amounting to 100 millimeters mercury."

How much greater must be the positive pressure when the acting forces are not the patient's muscles, but the sudden vise like compression exerted by a ton of falling slate on one side and the unyielding rock floor of a mine on the other. It is easy to see how sudden reflux of the blood occurs with possible actual rupture of delicate vessels.

Concerning the production of this condition, Crile states that compression of the trunk produces traumatic asphyxia. Von Morian reports the case of a coal miner pinned across the thighs by a loaded car and held for 90 minutes, in whom the left leg for its entire length from a hand's breadth below the inguinal fold down to the malleoli was bluish in color due to innumerable small ecchymoses. The cyanosis extended above the zone of compression in the mid thigh, but at the zone of compression and in the foot the skin was not discolored. That the condition reported by von Morian is one of "traumatic cyanosis" there is no doubt. This suggests the advisability of using the term "traumatic asphyxia" to connote the cyanosis of the face, head, neck, and upper chest associated with compression of the chest and the upper abdomen when breathing is suspended for an abnormal length of time. The term 'traumatic cyanosis' could then readily be applied to a condition as described by von Morian. It is further advised that we use the term 'epileptic cyanosis' to describe the condition occasionally noted following a severe attack of grand mal epilepsy.

Coullie has recently reported a case of a white male, aged 18 years, subject to occasional epileptic seizures, who consulted his physician because of his deeply cyanosed face and bilateral subconjunctival hemorrhages. Seven months before, the patient had had a similar, but milder attack. There was a sharp line of demarcation at the level of the collar band. The case is described as one of traumatic asphyxia, the strangulating agent being the unyielding collar band operating during the congestion and partial asphyxiation of the epileptic fit. An account of the case was sent to the late Professor Harvey Littlejohn, of Edinburgh, who expressed the opinion that it was undoubtedly "a case of

so called traumatic asphyxia caused by the collar band compressing the jugulars, together with the partial asphyxia, high blood pressure, and fixation of the chest caused by the epileptic fit." The author further states that "so far as I can ascertain, my case is the only one on record which did not originate in compression of the chest and abdomen by external violence." Alexander, in 1909, reported a case of "stasis cyanosis" following an epileptic seizure, simulating traumatic asphyxia. This patient also wore a collar which was described as being tight, below which the skin was of normal color. Alexander quotes several other writers on the subject of hæmorrhage and cyanosis in epilepsy, stating further "I am inclined to believe that factors producing this condition are similar to those causing traumatic asphyxia, namely, a fixed thorax, a closed glottis, and increased intrathoracic pressure, a lack of aeration of the blood, and the incompetent and absent valves of the jugular, subclavian, and facial veins." In this connection, one of the authors has recently examined the body of an epileptic who had hung himself. There was a moderate degree of cyanosis of the face and neck. Above the skin compressed by the noose, the color was a faint violet. A section of tissue from the cyanosed area was examined histologically, and no evidence of change was noted except for probable dilatation of the capillaries.

Goldschmidt and Light have recently described "a cyanosis unrelated to oxygen unsaturation produced by increased peripheral venous pressure." They noted that when the arm is allowed to hang vertically from the shoulder and kept stationary, a greater or less degree of engorgement of the veins of the forearm and hand occurs. The skin of the hand, wrist, and lower part of the forearm takes on a bluish color of varying intensity. They present evidence showing that no marked increase in oxygen saturation of the venous blood occurs under these conditions. On the contrary, in the majority of cases it was either decreased or remained the same as the value obtained from blood drawn under conditions where the blue color of the skin was not present. They conclude that when

the arm is allowed to hang down and kept stationary the resulting engorgement of the capillaries and the venules may be a primary cause of blueness of the skin in the absence of an increase in oxygen unsaturation of the blood in these vessels that the immediate cause of dilatation of the capillaries and the subcapillary venules when the arm is hanging down is the increased hydrostatic pressure imposed upon the blood in the veins. There results in consequence an opening up and engorgement of the venules and at least a portion of the loop of the capillaries in the papillæ of the skin.

NECROPSY FINDINGS

Subdural hæmorrhage has been found by Ollivier in a single case. Others have found no other cerebral change except congestion. The brain singularly escapes injury. The pulmonary changes noted have been œdema, congestion, apoplexy, hæmothorax, ruptured lung, multiple abscesses, thrombosis, and bronchopneumonia. Increased fluidity of the blood, and subserous hæmorrhages occur. These hæmorrhages are customary findings in asphyxiated patients. Among the abdominal lesions noted have been hæmoperitoneum, herniæ, and rupture of various abdominal viscera. Bones are frequently broken especially the ribs, clavicles, extremities, jaw, pelvis, and vertebrae.

PROGNOSIS

The prognosis in this type of injury is exceedingly grave. Of the 5 cases we have seen, 2 died soon after admission to this hospital. The 3 others recovered and are living today. Unreported cases, no doubt, occur, intervening death or inability to recognize the condition precluding their report. Beach and Cobb state that the patients who live without the immediate aid of artificial respiration and oxygen will always be extraordinarily rare. Only 1 of the 3 patients who recovered in our cases had oxygen, and only 1 of them had artificial respiration immediately following the injury. Of the 143 cases included in this report, 27 were dead or died a few minutes after being seen. Of the 116 cases surviving the initial injury, 104

recovered and 12 died. Death is due to associated extensive injuries to important structures or to infectious complications.

SUMMARIES OF CASES IN THE LITERATURE

The following are brief summaries of cases reported in the literature since Heuer's collected series of 177 cases appeared in May 1913.

Davidson in 1922 reports the case of a boy aged 12 years who ran headlong into the radiator of an automobile. The youth was almost in *extremis* in a profound state of shock. There was cyanosis of the scalp, face, lips and neck. There was bilateral subconjunctival hemorrhage. The sputum was frothy, blood stained and the patient developed a cough. A cellular emphysema of the neck and chest was noted. The right lung had collapsed and there was a forward dislocation of the sternal end of the left clavicle. Recovery was practically complete in 4 weeks.

Lawrence in February 1923 reports the case of a patient who in a wreck was pinned beneath the back of the front seat of an automobile. The patient regained consciousness 30 minutes after being removed from the wreck. The eyeballs were puffy and red. The pupils reacted to light and accommodation. The forehead, face, neck to the shoulder points down to the sternal notch and in the trapezius muscle areas behind were of a peculiar bluish red cyanotic color with pale spots between. Other petechial areas resembled minute subcutaneous hemorrhages. The discoloration disappeared on pressure. Patient was discharged in good condition 12 days after admission.

Travers in March 1923 reported the case of a white male 47 years old who was squeezed for 20 minutes between the top of an overturned automobile weighing 3,000 pounds and the ground, the car resting on the lower part of his chest. The following were noted: cyanosis of the face and neck, protruding eyeballs, bulging conjunctive, subconjunctival hemorrhages and epistaxis. Patient was pulseless and unable to see light until 12 hours after the accident. The blindness was believed to be due to hemorrhage surrounding the ocular nerve. There were fractures of the 1st transverse processes of the seventh, eighth and ninth vertebrae. About 3 months later vision of the right eye was 20/15 fundus clear left eye 20/15 slight change in both arteries and veins. Field of vision was contracted. Small central scotoma was present in the left eye. The disk was white.

Bager on April 15 1924 reported a patient whose chest was crushed between two cars and held for 1 minute. There was no loss of consciousness. Bager discusses the reasons for the retention of consciousness why blindness is common early with complete vision recovery as in his case in 2 weeks. He believes that the pre-existing pressure in the rigid skull and orbit evidently protect against the influx of blood during the compression.

Kunz in May 1924 reports that the trunk of a previously healthy man was squeezed down by an elevator. Severe and profuse stasis hemorrhage followed which developed evidently inside the skull as well as in the skin. This was relieved by lumbar puncture. The last trace of paralysis subsided by the end of the third month.

Conant in April 1926 reported that a male aged 41 years was pinned between an automobile and the ground. When examined 90 minutes later he was still unconscious. His head and neck were swollen and discolored a bluish black. Very soon the upper chest assumed the same color. There

were many striations of varying lengths on the anterior surface of the chest. The blue tint was due to stasis in the venules and to numerous punctiform hemorrhages or extensive ecchymoses. Tenderness was noted over the fourth and fifth ribs but fluoroscopy was negative. Normal color was regained in 10 days. The author observes that we must take into account both the passive agent and the active voluntary or reflex movements.

Conwell in January 1927 reports 4 cases. A male aged 22 years was pinned beneath a truck and suffered a fractured pelvis involving the superior ramus and the third pulis. He remained unconscious for several minutes. There was a definite strip of normal tissue at the base of the neck where the collar had been buttoned. The face and neck were cyanotic and severe bilateral subconjunctival hemorrhage was present impairing vision. The symptoms had disappeared in 2 weeks. The second was a white male aged 16 years injured in a similar manner. In addition to traumatic asphyxia he suffered an extensive skull fracture. He died 16 hours after the accident. The third a white male aged 22 years had the chest and abdomen crushed between a crane and a wall. He died 8 1/2 hours after injury. The fourth patient a female aged 22 years was injured in an automobile accident. She had marked subconjunctival hemorrhage in the left eye. There was a chip fracture of the right ulna in its upper third. The cyanosis had cleared up 12 days later except for the subconjunctival hemorrhage which had practically disappeared on the nineteenth day. Conwell states that convulsions are seldom present that the subconjunctival hemorrhage is invariable that death was probably never due directly to the asphyxia but to associated injuries.

Kosenblatt in June 1927 reported the case of a single white Polish laborer aged 30 years who was compressed against a stone wall by a steam shovel. He suffered great pain and shock. An indigo blue color appeared on the skin of the face neck and upper portion of the shoulders. There was extensive bilateral subconjunctival hemorrhage. A double fracture line was present in the inferior ramus of the pelvis with displacement of the fragments with fracture of the superior ramus the second rib and with dislocation of the left clavicle. Patient was discharged 63 days after the accident and was well 2 months thereafter.

Von Monan in January 1926 reports an interesting case which we suggest should be called traumatic cyanosis. The patient a coal miner of 33 years was pinned across the thighs by a loaded car and held for 90 minutes. Neither wound nor fracture was found but there was complete paralysis of the right leg which disappeared in a few days. The left leg for its entire length was a bluish color due to unnumerable small ecchymoses beginning a hand's breadth below the inguinal fold and running to the malleoli hence above the zone of compression which was the mid thigh. At the point of pressure and in the foot no discoloration was noted. The cyanosis faded away in a fortnight.

Because of the absence of chest pressure and upper abdominal pressure with resulting circulatory disturbances within the thorax we prefer to call this a case of "traumatic cyanosis" rather than "traumatic asphyxia" and therefore have omitted it in this series.

The appearance of cyanosis of the face with bilateral subconjunctival hemorrhage in the male epileptic patient referred to

FIG. 1. Traumatic cyanosis in patient 3 days after accident showing, 1 blood red sclerae cyanosis of head, neck, and chest with superficial abrasions of face and lower chest. The greater intensity of the cyanosis of the right face, neck, and chest is shown (a c c 2 No. B11 802).

Traumatic Isoplexy:—William R. T. and Milton C. Brown

previously as reported by Couillie in September, 1928, might be considered also as a case of traumatic asphyxia. We prefer to call this condition "epileptic cyanosis."

The 5 following traumatic cases were observed in a hospital service during the past 2½ years. This may appear to be a large group of cases for individual authors to report especially when it is known that the cases occurred singly. M. Ollivier, in 1837, reported a large series with 23 deaths occurring in the rush of a mob. Tardieu studied 30 victims of a panic of whom 9 died, as well as several cases of Professor Hardy's injured by a stampede produced by a falling wall. Ench Lange, in 1913, reported 7 cases. L. E. Robertson, in 1914, reported 6 cases. The next largest numbers reported are 4 by F. Voelcker in 1900, 4 by E. R. Ruppner, in 1904, and 4 by H. E. Conwell, in 1927.

CASE 1. No B9393. C. E. T. A white male mining engineer aged 5½ years while riding on a mine motor was caught between the top of the mine and the car. He was not believed to have been rendered unconscious although there was practically complete cessation of breathing for several minutes. When rescued from his pinched position he presented an extremely dark, purplish discoloration of the face, neck, and upper chest and marked bilateral ocular conjunctival hemorrhage. He was markedly dyspnoeic and had a brassy cough. He complained of severe pain in his chest. He was admitted to the hospital 2 hours after the accident. The cyanosis was still present. There were several superficial abrasions over the chest wall and upper abdomen. Despite rest, elevation, and the administration of morphine sulphate and digitalis the patient died 6 hours after admission. Necropsy was not performed.

CASE 2. No B1802. R. H. A white male 18 years old was caught in a slate fall in a coal mine. His body and extremities remained covered by a pile of slate during the 20 minutes required by 10 workers to recover his body. He was alive but unconscious when admitted to the hospital 45 minutes after the accident occurred. He remained unconscious for 5 hours after admission. On admission his temperature was 98.2 degrees F, pulse rate 110, respiratory rate 22, blood pressure 104-60. There was marked cyanosis of the right half of the head, neck, and chest. The cyanosis was a diffuse bright purple. The sclerae were a brilliant blood red. The palpebrae were purple, the right being more intensely colored than the left and moderately oedematous. The right ramus of the maxilla in its mid portion was completely fractured. There was a comminuted fracture in the upper third of the right femur. The cardiac action was unduly prominent.

the precordium heaving. The cardiac apex was visible and palpable in the fourth interspace 6 centimeters to the left of the midsternal line. There was a loud slapping systolic murmur, heard best over the apex. A crackling sound was heard over the fourth interspace to the left of the sternum. The second heart sound over the lower sternum was pistol shot, clear and ringing in quality. During the height of inspiration breath being held the crackling sounds practically disappeared. When the breath was held at the end of expiration the sounds were intensified. Oxygen was given and external heat applied. Morphine sulphate hypodermically followed by elixir bromides and chloral hydrate in drachm doses were used thereafter to keep patient quiet and comfortable. The right lower extremity was placed in Buck's extension. Patient remained at rest for 2 months. On the third day after admission the discoloration of the skin became a dusky purple and at its margin on the chest there were small red punctate areas in the skin (See Fig. 1). One month after admission the cyanosis had completely cleared up except for the hemorrhage in the right sclera which was wedge shaped with the apices pointing toward the canthi. The labored cardiac action subsided at the end of the first week and the crackling sounds heard over the sternum disappeared at the end of the second week. Patient's urine contained large amounts of urobilin. The icterus index studied at repeated intervals during the 2 months of hospitalization revealed normal figures. The blood Wassermann was 2 plus the Meinicke was negative. The ophthalmoscopic examination was negative. X-ray of the spine revealed a compression fracture of the third and fourth lumbar vertebrae. Eighteen months after the injury when he returned he was still walking on crutches with paresis of the left lower extremity and left toe drop.

This case should teach a valuable lesson. Multiple bone fractures and especially fractures of the vertebrae should be suspected in every patient with traumatic asphyxia.

CASE 3. No B13480. L. J. Patient was a colored male aged 28 years a coal loader in the mines. While at work he was pinned beneath a large slate fall which his foreman stated weighed about 2 tons. Patient was completely buried beneath this slate which was estimated as varying from 1 to 2 feet in thickness. After about 20 minutes he was finally extricated when the slate had been elevated with jacks. He was unconscious and occasionally took a deep gasping breath. He was given one half grain morphine sulphate hypodermically. No artificial respiration was practiced or oxygen administered. It was believed that the patient would expire in a few minutes. There was marked cyanosis of the face, neck, and upper chest. During the day the patient gradually improved. His pulse became stronger, the respirations became relatively normal.

and about 10 hours after the accident he was removed to the hospital. He was still unconscious. There was apparent exophthalmos with edema and hemorrhage in the conjunctiva and sclera. There was a dark purple discoloration extending over the upper half of the chest neck and right face. The blood pressure was 120/84, the cardiac rate 130, the heart sounds were subnormal in intensity but normal in duration and rhythm. Ophthalmoscopic examination revealed normal eye grounds. Patient rapidly improved and was discharged from the hospital 8 days after admission. X ray revealed no evidence of fractured ribs. Patient's blood Wassermann and Meinicke tests were both 3 plus. He gave a history of an apparently initial laceration. Ten weeks after the accident patient had not returned to work. He occasionally spat up blood streaked sputum. His general physical condition however was excellent. The discoloration of the sclera had completely disappeared. Another ophthalmoscopic examination revealed normal retinal disks and retinal vessels. Patient is living and well 5 months after the injury. X ray of the lumbar and lower thoracic spine revealed no evidence of fracture.

CASE 4. No B13 728 R F H. The patient a white male 36 years old was driving a truck when its right front wheel collapsed and the truck turned over three times. No information could be secured as to whether or not patient was squeezed or unconscious. At the hospital 2 hours after injury examination revealed a mottled dusky purple discoloration over the face and ears extending to the lower margin of the jaw. The eyelids were edematous and purple and the sclera were blood red in color. There was a punctate red mottling extending down the neck to a level about 2 inches below the clavicle. Ophthalmoscopic examination revealed normal fundi. Patient gradually became stuporous and died 3 days after admission.

Necropsy performed 2 hours after death revealed fractures of the first five right ribs in the right anterior axillary line with partial hemothorax. Emphysema of the subcutaneous tissues was present over the right pectoral and axillary regions. There was a right pneumothorax with bronchiolitis atelectasis of the right lung compensatory emphysema of the left lung a bronchopneumonia and passive hepatic congestion with pericholecystic adhesions. Each cusp of the aortic valve showed a normal free margin but an incomplete leaflet each leaflet giving the appearance of being perforated beneath its free margin. The left kidney weighed only 76 grams while its fellow weighed 220 grams. Histologically there was a bilateral renal congestion but no other change in either kidney. The spleen showed lymphoid hyperplasia.

CASE 5. No B13 777 A H. Patient was a colored male coal miner 21 years old. Eleven hours before admission to the hospital he was wedged between a moving mine car and top of a mine. The motor was reversed and patient withdrawn. Artificial respiration was given. It was 20 minutes be-

fore patient breathed properly. He was unconscious for one half hour. On admission to the hospital the skin of the face and neck and upper chest down almost to the nipple line was dark purple in color. The sclera were a bright blood red in color. Although there was considerable chest pain no fractured ribs could be demonstrated by physical examination or X ray and no other evidences of abnormality were found. Five days after admission the optic disks and the retina were examined and reported normal. One week after admission the only evidences of injury were the slightly discolored palpebrae and the blood red sclera. Iressure applied to the sclera produced no change. Adrenalin hydrochloride in 1:1000 dilution produced apparent contraction of the vessels only at the margin of the scleral discoloration which in its mid portion was dark purple in color. This discoloration was wedge shaped on each side of the pupil with the apex of the wedge pointing toward the canthi. Above and below the pupils the sclera were clear except for a definite lateroid tinge. Ophthalmoscopic examination was negative. Patient is alive and well 3 months after injury.

SUMMARY

In the foregoing paper on traumatic asphyxia we have presented a brief citation of various panics and public calamities resulting in traumatic asphyxia the different situations in our social and economic life reported as producing the condition, the incidence symptoms pathogenesis pathological physiology necropsy findings, and prognosis of traumatic asphyxia. The literature has been reviewed and the cases collected and briefly described since the date of Heuer's summary in May 1923. Five additional cases coming under our own observation during the past 2½ years are added making a total of 143 reported cases.

CONCLUSIONS

1. Although only 138 cases of traumatic asphyxia have been reported heretofore in medical literature it is probable that the condition is more frequently found than the literature would indicate.

2. Among the factors responsible for the morbidity of this condition are the occurrence of panics in large crowds the collapse of structures seating or housing large collections of people human negligence our desire for speed, and the consequent use of machinery in industry and vehicles for rapid transportation.

3. The invariable subconjunctival hemorrhage noted in this condition has a peculiar

lozenge or wedge shaped distribution due probably to lack of supporting tissues

4 Unsuspected multiple bone fractures, especially fractured vertebræ, may be associated with the condition and may remain undetected in patients who recover unless thorough X ray study of the bony framework is performed

5 The probabilities of associated injuries to the abdominal and intrathoracic viscera must be remembered

6 The cyanosis noted in this condition is probably essentially due to capillary and venous dilatation and engorgement as revealed by histological studies and the recently reported studies of Goldschmidt and Light who have shown that cyanosis may be produced without change in the oxygen content of the blood

7 For the sake of accuracy and clarity, we suggest that the term "traumatic asphyxia" be applied to patients in whom there has been squeezing compression of the chest and upper abdomen with cessation of respiration for an abnormal length of time, with resulting cyanosis, subconjunctival hemorrhage, and the typical syndrome hereinbefore described, that local cyanosis, occurring for example in an extremity following local trauma or pressure be called "traumatic cyanosis", and that the rarely observed cyanosis developing in the face, neck, and upper chest during an attack of grand mal epilepsy be termed "epileptic cyanosis"

THE INCREASED TOLERANCE OF PREGNANT RABBITS FOR INSULIN¹

GEORGE VAN S. SMITH, M.D. AND GEORGE A. MARKS, M.D. BROOKLINE, MASSACHUSETTS

THE following work represents part of an experiment that was instigated by the papers of Itus and his associates in which low blood sugar values and rapid fluctuations of the blood sugar level in eclampsia were reported. It was thought that the administration of insulin to rabbits during pregnancy by generally lowering the blood sugar level and by causing fluctuations in that level would result in diminished liver reserve and increased susceptibility to the strain of pregnancy. It was hoped that an upset in carbohydrate metabolism would lead to a syndrome in rabbits that would give a lead in the investigation of eclampsia or at least give some information concerning the carbohydrate changes in pregnancy.

During this experiment which was begun in December 1925 the rabbits were fed on a weighed diet consisting of 100 grams of oats 100 grams of greens (lettuce cauliflower leaves and celery) 100 grams of carrots and about 60 grams of alfalfa hay daily. Water was given *ad lib*. Insulin was administered subcutaneously.

The urine was tested for albumin by the nitric acid method. Frequently the heat and acetic acid method was used as well.

Blood sugars were determined by the micro method of Folin. The reagents were frequently checked and Folin's modifications and improvements were followed constantly.

Experiment 1. On the fifteenth day after being served doe rabbit No. 3 (weight 4.110 kilograms) received 10 units of insulin in two doses of 5 units each morning and evening. On the sixteenth day it received 12 units in the same way. The dose of insulin was thus increased daily so that on the thirty first day the animal received 42 units. It showed no evidence of any upset. By the nitric acid test the urine was consistently negative for albumin. The doe kindled normally the litter was normal. After kindling the doe weighed 4.135 kilograms.

Seven weeks later the experiment was repeated in exactly the same fashion the animal (weight 4.205 kilograms) not being pregnant. On the fifteenth day after it had received 39 units in the

previous 24 hours convulsions occurred. It died despite the administration of pituitrin and glucose. At autopsy the gross findings were negative. The microscopic examination of tissues was negative with the exception of the thyroid which showed considerable atrophy. The liver was apparently normal.

Experiment 2. Rabbit No. 4 (weight 4.812 kilograms) not pregnant received insulin in increasing doses starting with 12 units (6 units morning and evening). It had convulsions on the tenth day having had 31 units in the previous 24 hours.

Experiment 3. Rabbit No. 6 (weight 2.7 kilograms) 22 days pregnant having fasted 16 hours was given 15 units. Twelve blood sugar tests during the next 6 hours were as follows:

(a) 90.9	(d) 63.0	(g) 45.8	(j) 55.3
(b) 56.3	(e) 50.5	(h) 42.5	(k) trace
(c) 60.0	(f) 49.7	(i) 30.0	(l) 31.5

There were no convulsions. It kindled normally the litter was normal. Five months later it received 16 units of insulin having fasted 16 hours. It was not pregnant and weighed 0.5 kilograms. Convulsions occurred in 3 hours and 8 minutes.

Experiment 4. Doe rabbit No. 13 (weight 3.125 kilograms) received 10 units on the tenth day of pregnancy, 20 units on the eleventh day and 4 units on the twelfth, thirteenth, fourteenth and fifteenth days. On the twentieth, twenty first, twenty second and twenty third days it received 24, 6, 5 and 35 units respectively. On the twenty fourth day having fasted 12 hours it received 16 units. Blood sugars during the following 6 hours were:

(a) 11.5	(d) 58.0	(e) 115.0
(b) 61.5	(f) 61.0	(f) 75.5

It received 16 more units that evening. The next morning (twenty fifth day weight 3.555 kilograms) food was withheld and 0 units were given. Mild convulsions occurred 1 hour and 34 minutes later. It delivered itself of a dead litter 80 hours and 19 minutes later after which it weighed 3.360 kilograms. At no time did the urine give a positive test for albumin.

Experiment 5. Doe rabbit No. 14 (weight 2.97 kilograms) received 10 units on the fifteenth day of pregnancy, 16 units on the sixteenth day (in two doses of 8 units), 18 units on the seventeenth day etc. until the thirtieth day when the dose was 44 units. Blood sugars taken 3 to 3.5 hours after morning insulin were:

(a) 1st day 83.72.8	(d) 4th day 75.61.5
(b) 2d day 60.70	(e) 5th day 53
(c) 23d day 67.65	(f) 30th day 78

On the morning of the thirty first day the animal

¹The bearing of any vestige of insulin tolerance in pregnancy reported by Mrs. William Lowell Putnam, M.D., F.R.C.P., Research Laboratory, Free Hospital for Women, Brookline, Massachusetts.

was found dead. The first fetus that had passed into the vagina was firmly wedged in the pelvis. There was no evidence of convulsions. At autopsy the gross and microscopic examinations were all negative.

Experiment 6. On May 31, 1929, doe rabbits No. 4, No. 8 and No. 18 not pregnant (weights 5.135, 4.515 and 3.545 kilograms respectively) and rabbits No. 12 and No. 17 (weights 3.605 and 3.520 kilograms) 19 and 26 days pregnant respectively, all received 16 units of insulin, no food having been placed in their cages since the previous morning. All three non-pregnant animals went into convulsions; the pregnant animals were apparently unaffected despite the fact that they were smaller.

Since doe rabbit No. 3 had been receiving 10 to 18 units of insulin daily for 19 days before the actual start of the experiment and had had convulsions during that period, its increased tolerance during the latter half of pregnancy seemed especially impressive. Rabbit No. 4, though larger and heavier, did not tolerate as much insulin as No. 3 under the same experimental conditions. In a number of other instances it was found that greater weight and size did not give one rabbit more tolerance for insulin than another. This fact makes definite conclusions almost impossible unless the reactions of the same rabbit while pregnant be compared to those while not pregnant.

In doe No. 6 the convulsive blood sugar level was remarkably low while pregnant; its blood sugar following insulin hovered around 30, the usual convulsive level in rabbits, and no convulsions occurred, while not pregnant its blood sugar 38 minutes before convulsions supervened was 31, at which time the level must have been considerably lower.

Although it was not determined exactly how much insulin would throw rabbits No. 3, No. 6, and No. 14 into convulsions during the latter part of pregnancy, it is probable that

they could have tolerated at least two or three units more which would have made the contrast more marked.

SUMMARY

Since the original plan in this experiment was to determine the effect of various methods of insulin administration on pregnant rabbits, no carefully organized effort was made to compare their tolerance for insulin with that of non-pregnant rabbits, and the above protocols are given more as suggestive evidence than as proof. At the start it was more or less assumed that pregnant rabbits would be more susceptible to insulin. Contrary to expectation they seemed to thrive during the experiment as did also the non-pregnant rabbits. Apparently in the latter third of pregnancy they can mobilize their glycogen more rapidly and completely or, what is more probable, can call upon their fetuses for glycogen in an emergency or depend upon them to utilize the extra insulin.

CONCLUSION

From the evidence at hand it is concluded that

1. Insulin cannot be related to the production of a toxemia of pregnancy in rabbits under the experimental conditions herein outlined.
2. Pregnant rabbits in the latter third of their gestation period have a greater tolerance for insulin than do non-pregnant rabbits.

PRECONCEPTION OVARIAN IRRADIATION ITS INFLUENCE UPON THE DESCENDANTS OF THE ALBINO RAT (*MUS NORVEGICUS*)

DOUGLAS I. MURPHY, M.D., F.A.C.S., PHILADELPHIA
 Gynecological Fellow of the University of Pennsylvania

It is a well known fact that the ovaries and especially their follicular elements are peculiarly sensitive to radium and roentgen irradiation.¹ Furthermore a few defective and unhealthy children have been born after relatively prolonged exposures of the mothers to these two agents. The question has therefore naturally arisen as to whether the maternal irradiation has in any way been responsible for these disturbances of health and growth in the children.

Recent clinical studies by the author have summarized our knowledge regarding the health of the first generation of descendants from women receiving therapeutic ovarian radium or roentgen irradiation prior to conception (1946). On the basis of these studies it was concluded that such maternal treatment does not injure the health or growth of any subsequent children.

It could not be determined however whether or not the preconception irradiation caused any latent condition in the children—any damage which might be passed on to a succeeding generation and there appear for the first time. Information to this end was lacking because none of the children whose health was studied had as yet reached mature age. Since many heritable traits are known to skip one generation a further investigation was considered necessary especially in view of the importance of irradiation in gynecological practice and also because of certain conflicting observations which are the result of animal experimentation.²

EXPERIMENTS

A group of virgin albino rats was selected and each animal subjected to a single radium

exposure of each ovary, prior to being mated. Those which remained fertile in spite of the treatment and their offspring form the basis for the present report. The investigation was concerned, mainly, with the health of the descendants of these animals and especially that of the second generation.

In planning the experiment the circumstances met with in practice, when women of child bearing age are exposed to sterilizing amounts of therapeutic pelvic irradiation were duplicated as closely as possible. Mating was permitted only with non irradiated males and was delayed for a short time (14 days) following treatment. This postponement of mating was carried out in order that no ova which were in the oviducts at the time of irradiation should have an opportunity of becoming fertilized. It was desired that an ovum later to become fertilized should be in the ovaries at the time of the treatment. Furthermore according to Donaldson the life cycle of the rat passes with a speed which is 30 times more rapid than that of man. Therefore, a 14 day interval between treatment and mating of the former would be equivalent to 14 months in the case of the human.

For a number of reasons, the rat was selected for study. As it is a mammal, it structurally resembles man. Furthermore, it is small, reproduces frequently, and gives birth to many young at one time. In addition it is one of the best standardized of the smaller laboratory animals and—through the courtesy of the Wistar Institute of Anatomy and Biology—rats with a pedigree of many generations could be secured. This last feature was, perhaps, the most valuable for our purpose.

Virgin animals 120 days old were employed. It was desired that the first litters after irradiation should be the first born of the irradiated animals and, according to Duhning, the 120 day old rat is at its optimum breeding age.

¹When referring to an animal treatment the term "irradiation" applies to the use of radium. When referring to human treatment it applies to radium and the roentgen ray. By the expression "roentgen irradiation" is meant the therapeutic exposure—not the degree of exposure commonly employed for diagnostic purposes.

²The literature dealing with ovarian irradiation before fertilization was recently reviewed by the author (1951).

Note that the litters of the irradiated animals were smaller in size than were those of the control animals and that a single young was the most common litter size for the irradiated animals.

The minimum sterilizing radium exposure was first determined (5), in order to secure a standard by which a substerilizing exposure might be measured. When this had been accomplished, 50 animals were exposed to three-fourths of this sterilizing dose. Since some of them apparently were sterilized, even by this amount of treatment, other irradiated but fertile animals (used in the sterilization experiment) were included for study, in order to increase the total and because it was not known how any of the various dosages of radium used might affect the offspring.

Radium was employed because of its frequent use in gynecological practice and because a relatively large supply of this agent (2 grams) was available through the courtesy of the Cancer Research Committee of the medical staff of the Philadelphia General Hospital. The treatments were given in the Radium Research Laboratories of the hospital.

The radium was employed in the form of emanation now commonly termed "radon"

Its preparation and measurement and the calculation of dosages were carried out with the generous co-operation and assistance of Mr. Charles Robb, assistant physicist of the Philadelphia General Hospital.

Each animal received a bilateral ovarian irradiation, one exposure over each lumbar region, one ovary treated immediately after the other. The irradiation of the entire series of animals extended over a period of 6 months. The radium was measured before and after each group of animals was treated, as a check against the accidental breakage of the glass tubes containing radon during the course of the experiment.

The radium applicator was made in the form of a two piece brass capsule (Fig. 1), 2 centimeters in length and 8 millimeters in diameter, with a wall thickness of 2 millimeters, held to the animal's back by means of a bakelite holder and adhesive plaster (Fig. 2). Further details of the technique are described in the paper on sterilization (5).

The subsequent offspring were examined and weighed the day of birth. The litter at that time was weighed as a whole. A similar weighing was made on the fifteenth day. Individual weighings were made on the

PRECONCEPTION OVARIAN IRRADIATION ITS INFLUENCE UPON THE DESCENDANTS OF THE ALBINO RAT (*MUS NORVEGICUS*)

DOUGLAS E. MUKHY, M.D., F.A.C.S., PHILADELPHIA
 Cytologist and Director of Cancer Research of the University of Pennsylvania

It is a well known fact that the ovaries and especially their follicular elements are peculiarly sensitive to radium and roentgen irradiation.¹ Furthermore a few defective and unhealthy children have been born after relatively prolonged exposures of the mothers to these two agents. The question has therefore naturally arisen as to whether the maternal irradiation has in any way been responsible for these disturbances of health and growth in the children.

Recent clinical studies by the author have summarized our knowledge regarding the health of the first generation of descendants from women receiving therapeutic ovarian radium or roentgen irradiation prior to conception (1, 4-6). On the basis of these studies it was concluded that such maternal treatment does not injure the health or growth of any subsequent children.

It could not be determined however whether or not the preconception irradiation caused any latent condition in the children—any damage which might be passed on to a succeeding generation and there appear for the first time. Information to this end was lacking because none of the children whose health was studied had as yet reached mature age. Since many heritable traits are known to skip one generation a further investigation was considered necessary especially in view of the importance of irradiation in gynecological practice and also because of certain conflicting observations which are the result of animal experimentation.²

EXPERIMENTS

A group of virgin albino rats was selected and each animal subjected to a single radium

exposure of each ovary, prior to being mated. Those which remained fertile in spite of the treatment and their offspring form the basis for the present report. The investigation was concerned, mainly, with the health of the descendants of these animals and especially that of the second generation.

In planning the experiment the circumstances met with in practice, when women of child bearing age are exposed to sub-sterilizing amounts of therapeutic pelvic irradiation were duplicated as closely as possible. Mating was permitted only with non-irradiated males and was delayed for a short time (14 days) following treatment. This postponement of mating was carried out in order that no ova which were in the oviducts at the time of irradiation should have an opportunity of becoming fertilized. It was desired that an ovum later to become fertilized should be in the ovaries at the time of the treatment. Furthermore according to Donaldson the life cycle of the rat passes with a speed which is 30 times more rapid than that of man. Therefore a 14-day interval between treatment and mating of the former would be equivalent to 14 months in the case of the human.

For a number of reasons the rat was selected for study. As it is a mammal it structurally resembles man. Furthermore it is small reproduces frequently and gives birth to many young at one time. In addition it is one of the best standardized of the smaller laboratory animals and—through the courtesy of the Wistar Institute of Anatomy and Biology—rats with a pedigree of many generations could be secured. This last feature was perhaps the most valuable for our purpose.

Virgin animals 120 days old were employed. It was desired that the first litters after irradiation should be the first born of the irradiated animals and according to Dühring the 120 day old rat is at its optimum breeding age.

¹ When referring to normal treatment, the term "irradiation" applies to the use of radium. When referring to human treatment, it applies to radium and the roentgen ray. By the expression "roentgen irradiation" is meant the therapeutic exposure—not the degree of exposure commonly employed for diagnostic purposes.

² The literature dealing with ovarian irradiation before fertilization was recently reviewed by the author (1).

120 days of age	94	92	104

thirtieth, sixtieth, ninetieth, and one hundred and twentieth days. On the thirtieth day the young were weaned and the sexes separated. On the one hundred and twentieth day the sexes, brothers and sisters when possible, in order to accentuate any inherited defect which might have resulted from the treatment were brought together again.

EFFECT OF TREATMENT UPON IRRADIATED ANIMALS

All of the irradiated animals exhibited marked local and general reaction to the severe treatment which they all received. The local reaction consisted of loss of hair over the treated area and this was followed in every case by severe ulceration of the body wall varying in extent and depth with the amount of exposure. In most instances the ulcerations finally healed although in some cases thick crusts persisted in the ulcerated regions and in several animals paralysis of the lower limbs was noted. The general reaction was manifested by a loss of weight in many instances amounting to as much as one fourth of the weight before treatment. In spite of the severity of the treatment none of the animals appeared to suffer in respect to their ability to reproduce. On the other hand the reaction to irradiation no doubt played an important role in affecting the health of the young prior to birth and the ability of their mothers properly to nurse them.

EFFECT ON FERTILITY

Length of pregnancy. Full term litters were cast by all of the 51 fertile animals (Table I)

TABLE VII—SUMMARY OF OBSERVATIONS

First generation of female young mated	31
Males mated with the albinos	41
Female deaths during experiment	3
Under 30 days	2
Dying female, one litter before death	1

Number of first generation in females casting litters	11
Number of litters cast by these animals	17
Intervals between mating and first litter casting for the first litters of these 11 animals	
Longest interval (in days)	218
Shortest interval (in days)	23
Average interval (in days)	10
Average interval for 17 control animals	37
Number of young cast by the first generation (17 litters)	91
Number of these 91 presenting gross abnormalities	1

Although abortion does occur very rarely in the albino rat, no instance was observed in the more than 100 litters cast after irradiation.

One litter sterility. Of the 51 fertile animals only 23 cast two or more litters. The irradiation appears to have been the most likely cause of the subsequent sterility in the remaining 28 animals. This high frequency of one litter sterility indicates the degree of irradiation to which these animals were subjected.

Irradiation effect on the reproductive cycle. The intervals between mating and the casting of the first litters of 51 irradiated and 17 control animals are presented graphically in Figure 3. Pregnancy in the rat lasts 21 or 23 days while insemination is possible once every 3-4 days (the length of the estrus cycle). The observations recorded in Figure 3 indicate that the greater number of the first litters of the 51 irradiated animals were conceived very shortly after mating. From this observation it appears that the estrus cycle when not completely inhibited by irradiation (as when permanent sterility is immediately produced) suffers no disturbance whatever. It further suggests that even heavy irradiation probably does not injure the ova which it does not destroy.

A similar study of the intervals between the births of the first and second litters of 33 irradiated animals leads to the same conclusions. In this group the interval between litters was longer than in the control animals (Table II).

Fig 1 Showing bakelite holders with hinged covers and brass radon-containing capsule *in situ*

Fig 2 Showing pair of bakelite holders in position for bilateral ovarian radium exposure. Note the partially concealed brass radon containing capsule under the hinged cover on the animal's right side

Two or more litters were cast by the 23 animals just mentioned. In Figure 4 the intervals between mating and the casting of the first litters of these animals are contrasted with the intervals between the casting of the first and second litters. It will be observed here that the young of both groups of litters were practically all cast within 35 days of the mating or of the previous litter casting dates as the case might be.

FIRST GENERATION OFFSPRING

Litter size. A study of the litter size of the first generation young of the irradiated animals shows (Table III) that the irradiation decreased the number of offspring per litter. One young was the rule in the first litters of the 51 irradiated animals, while 7 young was the common litter in 25 control animals. The second litters of the 23 animals casting more than one (Table IV) were still smaller than the second litters of the control animals.

From a study of the litter sizes as influenced by the amount of the maternal treatment (Table V) it will be seen that in general the larger the amount of maternal treatment the smaller the size of the first litters.

Mortality. The 51 irradiated animals cast from 1 to 5 litters apiece more than 100 litters in all gave birth to 402 young. Of these, 39 were dead at the time of first observation while the death rate during the first month of life was very high among the remainder.

Many of the young animals were killed or eaten by their mothers shortly after birth. This was attributed to the ill health of the mothers which was the result of the local and general radium reaction, and also to the necessity of disturbing the newborn litters for examination and weighing.

Bodily structure. Of all the young live and dead, only one was deformed. It exhibited a clear cut case of hydrocephalus and was killed by the mother on the fifteenth day. Since this condition is not extremely rare in the experimental colony of the Wistar Institute the irradiation is not believed to have played an important role, if any, in its production. It may therefore be stated that, as far as could be determined by our study, no gross disturbances of bodily structure were observed which might be attributed to preconception irradiation of the subsequently fertilized ova.

Fig 3 Two polygon curves demonstrating the relative speeds with which first litters were cast by 51 irradiated animals (uninterrupted line) and by 17 control animals (broken line). The vertical line indicates the number of animals while the base line records the intervals (in 5-day periods) between mating and litter casting. Note that the greater number of the litters of both groups were cast within 35 days of mating.

Although abortion does occur very rarely in the albino rat no instance was observed in the more than 100 litters cast after irradiation.

One litter sterility. Of the 51 fertile animals only 3 cast two or more litters. The irradiation appears to have been the most likely cause of the subsequent sterility in the remaining 28 animals. This high frequency of one litter sterility indicates the degree of irradiation to which these animals were subjected.

Irradiation effect on the reproductive cycle. The intervals between mating and the casting of the first litters of 51 irradiated and 1, control animals are presented graphically in Figure 3. Pregnancy in the rat lasts 22 or 23 days while insemination is possible once every 3, 5 days (the length of the oestrus cycle). The observations recorded in Figure 3 indicate that the greater number of the first litters of the 51 irradiated animals were conceived very shortly after mating. From this observation it appears that the oestrus cycle when not completely inhibited by irradiation (as when permanent sterility is immediately produced) suffers no disturbance whatever. It further suggests that even heavy irradiation probably does not injure the ova which it does not destroy.

A similar study of the intervals between the births of the first and second litters of 23 irradiated animals leads to the same conclusions. In this group the interval between litters was longer than in the control animals (Table II).

the 91 young exhibited any developmental defects, nor did the living ones, while under observation, present any evidence of injury which might have been attributed to the ovarian irradiation of their grandmothers. These second generation young were observed for a period of 4 months after birth.

RESULTS OF STUDY

In order more properly to evaluate the results of this experimental study, certain characteristics of the rat must be borne in mind. According to Donaldson the rat is approximately seven times more resistant to the ordinary poisons than is man. Also it normally presents few morphological abnormalities. These two characteristics indicate that we are dealing with an animal with a high degree of natural resistance.

From the local and general effects of the treatment and the relatively high frequency of one litter sterility, it is apparent that the ovaries of the irradiated animals were definitely affected. That no gross structural abnormalities were seen in any of the subsequent offspring is in accord with the clinical observations recently reported (2). Further, it was seen that the oestrus cycles and reproductive powers of the fertile animals seemed to be uninjured by the irradiation received. The truth of these observations seems to be substantiated by histological studies made upon the ovaries of these animals, which will be reported at a later date.

The disturbances in health and fertility observed in the offspring of the irradiated stock must be attributed, it is believed, to the systemic influence of the treatment upon the mother rather than to any specific influence upon the unfertilized ovum—at least until further experimentation shows this standpoint to be fallacious.

SUMMARY

1 A group of 51 albino rats was exposed to heavy ovarian radium treatments, before they were mated. Each of these animals later cast one or more litters.

2 The total first generation young amounted to 402. Of these, 17 females gave birth to 91 offspring (second generation), after mating

with brothers or with males born of other irradiated mothers.

3 No instance of abortion was observed in either generation.

4 In the irradiated animals either sterilization resulted or else the treatment did not materially alter the frequency with which subsequent conceptions followed one another.

5 Litter size was diminished by maternal ovarian irradiation, the earliest litters being the smallest.

6 The first generation young exhibited a delay in growth and fertility but presented no gross abnormalities which could reasonably be ascribed to the effect of the maternal irradiation.

7 Likewise the second generation of offspring showed no evidence of ill health or underdevelopment which might be attributed to the grandmaternal irradiation.

CONCLUSION

From this study no definite conclusion can be drawn in regard to the influence of preconception ovarian irradiation upon the health and development of the subsequent offspring of the albino rat. It is significant, however, that no gross structural abnormalities attributable to maternal ovarian irradiation were observed among 493 first and second generation descendants of a group of animals which received preconception ovarian radium irradiation.

Fig. 4. Polygon curves indicating the interval in days before the casting of the first litters (uninterrupted line) and the interval in days between the casting of the first and second litters (dotted line) for 25 animals which had received preconception ovarian irradiation. The vertical line indicates the number of animals while the base line records the intervals (in 5 day periods) between mating and the casting of the first litter in the one case and between the casting of the first and second litters in the other case the animals having been constantly mated throughout this period.

Note that the casting of these 2 groups of litters occurred with relatively equal promptness.

Growth rate. The average weights of young of irradiated and of control animals as recorded at birth and during the succeeding 120 days are shown in Table VI. These have been graphically depicted in the 2 curves in Figure 5. It will be seen that the young of irradiated and of control animals grew with approximately the same degree of speed and that only during the last month of observation did there seem to be any appreciable degree of retardation in the growth of the young of the irradiated animals. It is believed that this retardation of growth was most likely the result of the general poor health of the mother due to the severity of her irradiation rather than to any specific effect of the irradiation upon the unfertilized ovum.

Fertility. At 120 days of age all female young were mated, with their brothers, if possible, but, if impossible then with other young from irradiated females. The summary (Table VII) of observations shows that 51 female young of irradiated parents, when mated for an average of 111.9 days, cast only 11 litters (21.6 per cent of fertility). Furthermore, the first litters of these young were cast on the average, 107 days after mating, while 17 control animals cast their first litters on the average, only 37.4 days after mating. These figures reveal that the first generation young of the irradiated stock were less fertile

Fig. 5. Growth curves for 355 young born of irradiated mothers (dotted line) and for 234 young of control animals (uninterrupted line), based on weightings as recorded in Table VI. The vertical line shows the average weights in grams, while the base line records the intervals in days after birth at which times the various weightings were made.

than they should have been and that there was a considerable delay in the casting of litters.

A subsequent mating of these animals with males born of non irradiated stock was followed by a comparatively higher frequency of litter casting. However since the females in this later mating were older and larger than when first mated, this comparison is not very valuable. It suggests, however, that the young of the irradiated stock probably exhibited only a latent sterility, due to causes which are not very well understood. The delayed fertility may have been due to lack of early and proper nourishment, the result of the influence of the irradiation upon the mother, especially upon her mammary glands. That this delay in fertility may have been entirely due to the somewhat delayed growth of the young of the irradiated animals is suggested by the findings of Dr. Helen Dean King of the Wistar Institute. She has found that conception is rarely possible in female rats which, at 120 days of age, weighed less than 100 grams.

SECOND GENERATION OFFSPRING

The 17 litters cast by 11 of the offspring of the irradiated animals comprised a total of 91 young of the second generation, 67 of which were alive at the first observation. None of

Fig 1 Abdominal incision exposing carcinoma of the sigmoid

Fig 2 Beginning mobilization of neoplasm. Incision in the lateral peritoneum which frees the growth and allows its rotation medially. There are no blood vessels in this peritoneal layer.

After the employment of a type of pre operative treatment in all cases of lesions of the colon which resulted, in most instances in emptying the obstructed bowel to such a degree that it approached normal size, I began to perform a type of resection, similar to the procedure in which the first two steps of the exteriorization are performed in one step, but far more radical. It enabled me to remove not only all of the mesentery desirable but the tissues in immediate juxtaposition to the growth, to peritonize the raw surfaces to insure the blood supply to the two ends of the bowel and to leave the bowel obstructed for 48 to 72 hours with impunity. All this was possible because of the thorough pre operative cleansing and concomitant reduction of local infection. The technique of such obstructive resection I believe employs the admirable principles of the procedure of exteriorization and at the same time, obviates undesirable features and a high rate of mortality. Although it has not been noted so far as I know the Mikulicz procedure carries a higher operative mortality than any other type of resection. This obstructive type of resection I have employed as a routine in the last year as the operation of choice for all lesions in mobile segments of the large bowel. From January 10, 1929, to November 22, 1931 I performed 31 obstructive resections of the colon with a single fatality. The man who died was aged 64 years, he was of short and heavy build so that the operation was technically difficult. He died 36 hours after the operation from a pulmonary embolus.

The indications for obstructive resection are the same as those for the Mikulicz operation, and I believe they may be extended considerably. The pre operative preparation that is made as a routine has lessened the infection of growths of the colon and has left the colon itself free from obstruction or only slightly obstructed, and thus has promoted extension of the operative attack to conditions which otherwise would have been approached by different technical steps. The indications for this operation are the presence of a mobile growth in any segment of the bowel and one which on the basis of experience and clinical judgment, is deemed not too infected or too much attached to surrounding tissues to prevent its resection. The contra indications to procedures of exteriorization, as laid down by Sistrunk at a recent meeting of the American Surgical Society, are as follows: (1) cases of adherent growths associated with infection of the wall of the bowel and adjacent tissues, (2) large growths associated with infection, (3) growths associated with obstruction and (4) growths in the sigmoid colon with a short mesentery in obese patients, with thick abdominal walls. I heartily concur in these contra indications. My feeling is that the original type of Mikulicz procedure is most aptly applied to a small annular, scirrhous growth in a mobile segment of colon in an elderly patient, who is unable to withstand any extensive opera-

CLINICAL SURGERY

FROM THE MAYO CLINIC

RESECTION AND OBSTRUCTION OF THE COLON (OBSTRUCTIVE RESECTION)¹

Division of Surgery, The Mayo Clinic

INTESTINAL resection in multiple stages as an emergency measure had been performed by surgeons for many years before Block in 1892 first suggested the employment of this method as a deliberate maneuver in the eradication of a malignant neoplasm of the large bowel. Shortly thereafter the operation of exteriorization became popularized by Mikulicz and Bruns and was hailed as a radical advance in surgery of the colon. The operation as performed by these men and as described in a system of practical surgery by Bergmann, Bruns and Mikulicz differs somewhat from the modifications which have been introduced in this country, but the principles of bringing the bowel to the outside without opening its lumen and of subsequently removing the offending segment remain the predominant features.

This procedure was uniformly acceptable because of the theoretic possibilities it offered. Unquestionably the underlying fundamental principle of resection in multiple stages without incision of the bowel at the initial step was admirable. The theory of lack of peritoneal contamination from exteriorization, although ideal, failed to take into account the contamination from exploration and mobilization of the growth which subsequent endeavors so frequently have proved to take place. My experience is that contamination comes not so much from the open operation as from the handling of the growth during its mobilization or during the necessary exploration of the abdominal cavity. Infection is spread because of the thinness of the wall of the bowel under manipulation and the already existing contamination in the pericolic tissues and adjacent lymphatic channels as frequently has been demonstrated by numerous observers.

Experience has proved that this procedure as originally described had certain definite drawbacks, the most prominent of which was the

likelihood of direct transplantation of malignant cells into a cut wound when the growth was brought out in the original incision. This actually occurred in 1 per cent of the cases in which operation was performed by this method in The Mayo Clinic despite the fact that numerous and various attempts were made to preclude its occurrence.

Another disadvantage was the limitation of application of the principle unless extensive mobilization were effected and the frequent necessity of ligating the blood supply in order to render the tumefaction extraperitoneal. After the blood supply had been ligated one not infrequently was confronted with a serious problem, namely the development of necrosis and gangrene in the exteriorized growth with subsequent contamination from direct extension. Furthermore resection of the loop was frequently demanded in the first 48 hours after the primary stage of the operation and contamination took place by direct extension because of poor healing power, and the attendant dehydration and desiccation from which many of these patients suffered. Occasionally as an emergency measure the first two stages of the operation were performed at one step, clamps being left on the ends of the bowel thus obstructing it until peritoneal coaptation had taken place when the proximal end could be opened safely. This I found on looking up the records however was a step which was accompanied by higher mortality than the other type of procedures employed, evidently because of the type of case in which it had been undertaken. However it occurred to me that any operation in which recurrence of the malignant condition in the abdominal wall took place in 1 per cent of cases either should be abandoned or modified to correct this defect and yet the admirable features of the Mikulicz operation were theoretically and fundamentally sound.

Fig. 1 Abdominal incision exposing carcinoma of the sigmoid

After the employment of a type of pre operative treatment in all cases of lesions of the colon which resulted, in most instances, in emptying the obstructed bowel to such a degree that it approached normal size, I began to perform a type of resection, similar to the procedure in which the first two steps of the exteriorization are performed in one step, but far more radical. It enabled me to remove not only all of the mesentery desirable but the tissues in immediate juxtaposition to the growth, to peritonize the raw surfaces to insure the blood supply to the two ends of the bowel, and to leave the bowel obstructed for 48 to 72 hours with impunity. All this was possible because of the thorough pre-operative cleansing and concomitant reduction of local infection. The technique of such 'obstructive resection' I believe, employs the admirable principles of the procedure of exteriorization and at the same time obviates undesirable features and a high rate of mortality. Although it has not been noted, so far as I know, the Mikulicz procedure carries a higher operative mortality than any other type of resection. This obstructive type of resection I have employed as a routine in the last year as the operation of choice for all lesions in mobile segments of the large bowel. From January 10, 1929 to November 22, 1931, I performed 31 obstructive resections of the colon with a single fatality. The man who died was aged 64 years, he was of short and heavy build so that the operation was technically difficult. He died 36 hours after the operation from a pulmonary embolus.

Fig. 2 Beginning mobilization of neoplasm. Incision in the lateral parietal peritoneum which frees the growth and allows its rotation mesally. There are no blood vessels in this peritoneal layer.

The indications for obstructive resection are the same as those for the Mikulicz operation, and I believe they may be extended considerably. The pre-operative preparation that is made as a routine has lessened the infection of growths of the colon and has left the colon itself free from obstruction or only slightly obstructed, and thus has promoted extension of the operative attack to conditions which otherwise would have been approached by different technical steps. The indications for this operation are the presence of a mobile growth in any segment of the bowel and one which, on the basis of experience and clinical judgment, is deemed not too infected or too much attached to surrounding tissues to prevent its resection. The contra indications to procedures of exteriorization, as laid down by Sistrunk at a recent meeting of the American Surgical Society, are as follows: (1) cases of adherent growths associated with infection of the wall of the bowel and adjacent tissues, (2) large growths associated with infection, (3) growths associated with obstruction, and (4) growths in the sigmoid colon with a short mesentery, in obese patients, with thick abdominal walls. I heartily concur in these contra indications. My feeling is that the original type of Mikulicz procedure is most aptly applied to a small annular scirrhous growth, in a mobile segment of colon in an elderly patient, who is unable to withstand any extensive opera-

CLINICAL SURGERY

FROM THE MAYO CLINIC

RESECTION AND OBSTRUCTION OF THE COLON (OBSTRUCTIVE RESECTION)¹

EDWARD W. HANKIN, M.D., ROCHESTER, MINN. (TA)

Department of Surgery, The Mayo Clinic

INTESTINAL resection in multiple stages as an emergency measure had been performed by surgeons for many years before Block in 1892, first suggested the employment of this method as a deliberate maneuver in the eradication of a malignant neoplasm of the large bowel. Shortly thereafter the operation of exteriorization became popularized by Mikulicz and Bruns and was hailed as a radical advance in surgery of the colon. The operation as performed by these men and as described in a system of practical surgery by Bergmann, Bruns and Mikulicz, differs somewhat from the modifications which have been introduced in this country, but the principles of bringing the bowel to the outside without opening its lumen and of subsequently removing the offending segment remain the predominant features.

This procedure was uniformly acceptable because of the theoretic possibilities it offered. Unquestionably, the underlying fundamental principle of resection in multiple stages without incision of the bowel at the initial step was admirable. The theory of lack of peritoneal contamination from exteriorization although ideal failed to take into account the contamination from exploration and mobilization of the growth which subsequent endeavors so frequently have proved to take place. My experience is that contamination comes not so much from the open operation as from the handling of the growth during its mobilization or during the necessary exploration of the abdominal cavity. Infection is spread because of the thinness of the wall of the bowel under manipulation and the already existing contamination in the pericolonial tissues and adjacent lymphatic channels as frequently has been demonstrated by numerous observers.

Experience has proved that this procedure as originally described, had certain definite drawbacks, the most prominent of which was the

likelihood of direct transplantation of malignant cells into a cut wound when the growth was brought out in the original incision. This actually occurred in 12 per cent of the cases in which operation was performed by this method in The Mayo Clinic despite the fact that numerous and various attempts were made to preclude its occurrence.

Another disadvantage was the limitation of application of the principle unless extensive mobilization were effected and the frequent necessity of ligating the blood supply in order to render the tumefaction extraperitoneal. After the blood supply had been ligated one not infrequently was confronted with a serious problem, namely, the development of necrosis and gangrene in the exteriorized growth with subsequent contamination from direct extension. Furthermore, resection of the loop was frequently demanded in the first 48 hours after the primary stage of the operation and contamination took place by direct extension because of poor healing power and the attendant dehydration and desiccation from which many of these patients suffered. Occasionally as an emergency measure the first two stages of the operation were performed at one step, clamps being left on the ends of the bowel thus obstructing it until peritoneal coaptation had taken place when the proximal end could be opened safely. This, I found on looking up the records, however, was a step which was accompanied by higher mortality than the other type of procedures employed, evidently because of the type of case in which it had been undertaken. However it occurred to me that any operation in which recurrence of the malignant condition in the abdominal wall took place in 12 per cent of cases either should be abandoned or modified to correct this defect and yet the admirable features of the Mikulicz operation were theoretically and fundamentally sound.

¹Submitted for publication January 24, 1930.

FIG. 1. Abdominal incision exposing carcinoma of the sigmoid.

After the employment of a type of pre operative treatment in all cases of lesions of the colon which resulted, in most instances, in emptying the obstructed bowel to such a degree that it approached normal size, I began to perform a type of resection similar to the procedure in which the first two steps of the exteriorization are performed in one step, but far more radical. It enabled me to remove not only all of the mesentery desirable but the tissues in immediate juxtaposition to the growth, to peritonize the raw surfaces to insure the blood supply to the two ends of the bowel and to leave the bowel obstructed for 48 to 72 hours with impunity. All this was possible because of the thorough pre operative cleansing and concomitant reduction of local infection. The technique of such obstructive resection I believe employs the admirable principles of the procedure of exteriorization and at the same time, obviates undesirable features and a high rate of mortality. Although it has not been noted so far as I know, the Mikulicz procedure carries a higher operative mortality than any other type of resection. This obstructive type of resection I have employed as a routine in the last year as the operation of choice for all lesions in mobile segments of the large bowel. From January 10, 1929 to November 22, 1931, I performed 31 obstructive resections of the colon with a single fatality. The man who died was aged 64 years, he was of short and heavy build so that the operation was technically difficult. He died 36 hours after the operation from a pulmonary embolus.

FIG. 2. Beginning mobilization of neoplasm. Incision in the lateral parietal peritoneum which frees the growth and allows its rotation mesially. There are no blood vessels in this peritoneal layer.

The indications for obstructive resection are the same as those for the Mikulicz operation, and I believe they may be extended considerably. The pre operative preparation that is made as a routine has lessened the infection of growths of the colon and has left the colon itself free from obstruction, or only slightly obstructed, and thus has promoted extension of the operative attack to conditions which otherwise would have been approached by different technical steps. The indications for this operation are the presence of a mobile growth in any segment of the bowel, and one which, on the basis of experience and clinical judgment, is deemed not too infected or too much attached to surrounding tissues to prevent its resection. The contra indications to procedures of exteriorization, as laid down by Sistrunk at a recent meeting of the American Surgical Society, are as follows: (1) cases of adherent growths associated with infection of the wall of the bowel and adjacent tissues; (2) large growths associated with infection; (3) growths associated with obstruction; and (4) growths in the sigmoid colon with a short mesentery in obese patients with thick abdominal walls. I heartily concur in these contra indications. My feeling is that the original type of Mikulicz procedure is most aptly applied to a small annular scirrhous growth in a mobile segment of colon in an elderly patient who is unable to withstand any extensive opera-

Fig. 3 Mobilization completed. The mesenteric blood vessels are ligated and a wide expanse of mesentery is sacrificed. The growth is caught between clamps to be removed with cautery.

tive procedure and in whom, under local or light general anesthesia, the growth may be drawn rapidly into the wound without manipulation or attempts at mobilization. Infection around the growth as Sistrunk stated, or considerable obstruction especially if it be subacute or acute is a definite contra indication to operation because of the necessary manipulation which spreads this infection to the peritoneal cavity, with unhappy results.

The pre operative measures, which have been mentioned, consist of the following: (1) rehabilitation of the general condition; (2) attempts at reduction of local infection and obstruction by cleansing measures applied to the bowel itself; (3) the use of intraperitoneal vaccine; and (4) the use of spinal anesthesia. Fortunately the introduction of these methods has enabled me to overcome many of the difficulties which formerly attended operations on markedly infected or obstructive growths.

In acute intestinal obstruction even the most enthusiastic partisan would agree, I believe that there is little practicability in exteriorizing a growth without previously having provided for decompression above it and this procedure of decompression and exteriorization combined bears too high a mortality, as judged from statistical study. Paradoxically, the obstructive type of resection, which is under consideration cannot be done safely in the presence of obstruction of any type. As has been noted however my experience is that chronic intestinal obstruction confined to

Fig. 4 The clamp is *in situ*. The growth has been removed and peritonization of the lateral raw surface is begun.

the large bowel is borne readily over a long period of time and, what is more important, it may be reduced to a minimum in practically every case by the judicious use of cleansing measures applied over a considerable period of time on the average one week. Subacute obstruction and many times, almost complete obstruction of the large bowel due to a malignant condition can be removed by patience and persistence in the use of enemas and, occasionally of purgatives. Of course, one does not advocate anything but immediate operation in acute intestinal obstruction, regardless of its cause, but acute intestinal obstruction of the colon due to carcinoma is found in only 5 per cent of all cases of intestinal obstruction, and is not included in the type of case considered here.

TECHNIQUE

The technique of obstructive resection is in reality, similar to two stages of the Mikulicz operation employed in one step with the additional removal of a wide piece of mesentery and gland bearing tissue in proximity to the growth. The procedure is applicable as has been said only to mobile or mobilizable segments of the bowel. The steps of the operation are as follows: (1) incision over the growth and abdominal exploration; (2) mobilization of the growth; (3) ligation of the blood supply and dissection of lymph nodes; (4) resection of the growth between clamps, with the cautery; (5) peritonization and closure of the

Fig. 5 The peritoneum is brought under the loop and is sutured snugly around on all sides. This step holds serous surface to serous surface, permits early healing and does away with the necessity of sutures in wall of the bowel!

rent in the mesentery, and (6) closure of the abdominal wound around the growth (Figs 1 to 7).

It has been my custom to employ a two bladed clamp, which I use for aseptic anastomosis, else where, as the most satisfactory instrument for doing this obstructive resection. After mobilization of the growth, the clamp is applied to the two limbs of the bowel and at this stage of the operation one may always be certain of securing the blood supply to the loop. This is a most important step, and the blood supply may be determined under direct vision. The rent in the mesentery is closed without putting sutures into the bowel. The use of such sutures has never been a satisfactory practice and I have not been sorry to have omitted it. Peritonization of the raw surfaces lateral to the resected bowel is always easily accomplished. The clamp is now brought out of the wound at the point in the wound which leaves the structures most loose. The wound is closed snugly close to the clamp, and a tongue of peritoneum is pulled between the two limbs of the bowel, under the clamp. This brings up the peritoneum snugly around the bowel itself and does away with the necessity of sutures. Sometimes, when the loop has been short and has not come out of the abdomen readily, I have wrapped a piece of iodoform gauze around the clamp in the peritoneal cavity and then have closed the peritoneum snugly around it so as to avoid contamination in case of leakage. When the operation has been completed, and the wound has been closed tightly around the clamp, the bowel is left totally shut off for at least 60 hours,

Fig. 6 After the clamp has been removed and the wound is healed the spur is cut out of the two gun barrels by the application of clamps which necrose through it slowly. This step is similar to that of the Mikulicz operation.

and sometimes for as long as 72 hours. I never have seen unhappy sequelæ from this one step and never have had to take a clamp off sooner than 60 hours after operation. Patients have not been nauseated and up to this time have not vomited, but I have not given them food by mouth. Their food has been supplied by hypodermoclysis and intravenous administration of glucose and sodium chloride solution. At this time the proximal blade of the clamp is opened, but the distal blade is left closed, and the clamp is not removed. This is advantageous because agglutination has taken place, the bowel has healed into the wound, and, if gas has caused enough tension, it will blow out the cut end of the proximal loop and will relieve itself spontaneously. I do not open the colon, but

Fig. 7 Final stage of the operation showing closure of the colostomy opening. In more than half of the cases this step is unnecessary and spontaneous healing takes place.

prefer to let the agglutinated end be freed by distention from pressure within the colon. The clamp is allowed to stay on the distal loop until it drops off which usually occurs about the seventh day. The remainder of the operation is accomplished in a manner similar to that employed in the Mikulicz procedure—that is, the spur is cut out with an enterotome or with clamps, and the patient is then allowed either to return home or to wait for a period of at least a month before the subsequent step is undertaken. It has been my experience that in more than half of these cases if the spur is cut out properly the opening will close spontaneously without the necessity of the third stage of the operation.

It is obvious that there are many advantages to this type of resection over the former technique of exteriorization and resection of the large bowel. In my service I have come to look on it as the operation of choice in all non-obstructing mobilizable growths of the large bowel from the hepatic flexure of the colon to the middle of the sigmoid colon. From the standpoint of mortality and morbidity it leaves little to be desired. The period of hospitalization is short. After resection and removal of the spur between the two loops of bowel which in the average case have been done in 3 weeks it has been my custom to permit the patients to return home with the idea that the third stage of the operation or the necessary closure will be accomplished by nature rather than by surgical suture. I have been agreeably surprised to note that more than half of the patients have not had to undergo secondary closure. The number of stages of the procedure and the morbidity thus are reduced to a minimum. The record of mortality, approximately 3 per cent in this series, is so immeasurably better than that of the Mikulicz procedure that it does not require consideration. I am not optimistic that the mortality can be held at this figure but my mortality for resection of the colon which is

below 10 per cent is highly acceptable. A second obvious advantage is the radical type of operation which this procedure allows to be applied in removal of gland bearing tissues. Formerly procedures of exteriorization were simply for local removal of the malignant growth without dissection of lymph nodes and this in the light of present day knowledge of the enhancement of end results by block dissection of the adjacent groups of lymph nodes is unsurgical. It seems to me that it is just as desirable to apply radical methods with wide removal of adjacent tissues to malignant conditions of the large bowel as it is to apply them to malignant conditions of the lip, tongue, breast, stomach, or other organs. Any procedure which includes this among its accomplishments is highly advantageous.

The question immediately arises in connection with this obstructive type of resection as to whether or not it is feasible immediately to reestablish the lumen of the bowel with an aseptic type of operation. This no doubt would be the ideal procedure yet it unquestionably would be followed by an increase in mortality, an increase probably as high as 5 per cent. One is always tempted in doing a resection of the bowel when the bowel is mobilized satisfactorily, to make an anastomosis with perhaps an enterostomy for decompression proximal to it. However I have had sufficient unhappy experience with this type of maneuver in the past to be fearful of it although I recognize its great desirability. It is to be hoped that in the future with adequate co-operative management and proper selection of cases aseptic anastomosis in one stage with or without proximal decompression will become the operation of choice in a high percentage of cases of malignancy of the colon. At present I feel distinctly that the graded procedure will prove to give just as high a percentage of satisfactory end results and at the same time a considerably lower rate of mortality.

FROM THE SURGICAL CLINIC ST. JOSEPH'S HOSPITAL

THE TECHNIQUE OF VENTROFIXATION OF THE UTERUS

IRVIN ABELL M.A. M.D. F.A.C.S. LOUISVILLE, KENTUCKY

VENTROFIXATION of the uterus is indicated in the presence of complete protracted pregnancy with eversion of vagina in women beyond the menopause.

The preparation of the patient for operation is that usually employed for abdominal operations: cleansing and shaving of the abdomen on the day before operation and the application of 2 per cent tincture of iodine to the field of operation before patient is taken to the operating room and again when on the operating table.

The anæsthetic may be local, general, or spinal with preference given to preliminary morphine and atropine followed by nitrous gas oxygen in elderly patients. The relaxation of the vaginal outlet is first corrected by colpoperineorrhaphy. The patient is then placed in the Trendelenburg position and a 4 inch midline suprapubic incision is made. The fundus of the uterus is grasped with volsellum forceps and drawn well up into the incision. The cut edge of the anterior parietal peritoneum is then sewed to the peritoneal covering of the uterus with a running suture of No. 2 chromic catgut which begins in the lower angle of the incision in the anterior parietal peritoneum and unites its cut edges to the circumference of the uterus at a point between the fundus and the junction of body with the cervix, after which the remainder of the incision in the peritoneum is closed with a continuous suture of similar kind. The fundus of the uterus having been thus made extraperitoneal, the under surface of the fascia abdominis is prepared for anchorage of the fundus uteri by the separating of the underlying recti muscles from it for a distance of 1 inch from the cut edge on either side at the lower third of the incision. Sutures of No. 2 chromic catgut, one on either side, are then passed through the fascia from its upper surface. These sutures enter at points 1 inch from the midline, grasp the uterine muscle at or slightly below the cornua (depending on the size of the uterus), and pass back through the fascia from below (Fig. 1).

When these sutures are tied, the recti muscles are displaced to either side with the fundus uteri interposed between them, its superior surface coming in contact with a sufficiently large area of fascia to afford a firm anchorage. Two stay su-

tures (equidistant) are then inserted through skin, fat, fascia, and fundus of the uterus, one on its anterior and one on its posterior aspect and if desired one or two of similar material are inserted in the upper half of incision (Figs. 2 and 3).

The fascia abdominis is closed with a running suture of chromic catgut, the needle dipping into the uterine muscle at the point of its contact with fascia (Fig. 4).

The skin is closed with dermal suture after which the stay sutures are gently tied (Fig. 5).

The postoperative care is that of the ordinary closed abdominal section: rest in bed for 2 weeks with avoidance of severe physical exertion for a period of 6 weeks thereafter (Fig. 6).

ADVANTAGES OF THE OPERATION

1. The uterus becomes an integral part of the abdominal wall and is fixed to its unyielding fascia.
2. The suturing and anchorage are extra-peritoneal.
3. It affords adequate and permanent support for the relaxed pelvic structures.

Fig. 1. Suturing of cut edges of peritoneum to circumference of uterus.

Fig. 2 Separation of fascia from underlying rectus muscle.

Fig. 4 Stay sutures passing through entire abdominal wall down to and including uterine muscle.

Fig. 5 Closure of fascia.

Fig. 3 Sutures placed lateral to midline anchoring fascia to uterine cornua.

4 The normal vaginal depth and relations are retained.

5 The relaxation of the pelvic structures in complete procidentia is of such degree that no undue tension with consequent discomfort results.

6 The ease and rapidity of execution permit its employment in the aged granted no absolute contra indications to a surgical procedure exist.

Fig. 6 Position occupied by uterus completed operation.

RECONSTRUCTION OF THE EXTERNAL EAR¹

GEORGE WARREN PIERCE M D SAN FRANCISCO

THE reconstruction of an external ear is a difficult task. The normal auricle is composed of two layers of thin skin with little subcutaneous connective tissue, supported and given form by a thin intricately shaped cartilage. It is impossible to obtain skin of this type from other available parts of the body, and rib cartilage, the ear cartilage substitute, is not suitable for fashioning into a replica of the original support. Moreover, if so fashioned, it will not maintain its form and contour, but tends to fold up. This tendency of reconstructed auricles to shrink has been one of the apparently insurmountable difficulties of the task of reconstruction.

My method of reconstruction furnishes an ear which does not shrink and which maintains the normal angle to the head. It is more important to have the two ears of the same size than of exactly the same contour. The characteristics of the minor contours of the pinna vary so widely in people that less effort need be expended on their reproduction than on the size and proper angle of the ear. All stages of the reconstruction are done under anesthesia produced by the administration of a 1 per cent solution of novocain.

CASE 1. This patient referred by Dr. Russell Ryan is an illustration of the comparatively simple problem of restoring the size and general appearance of the ear after loss

Fig. 1. Pinna. Reproduced from Deaver's *Surgical Anatomy*. By permission of P. Blakiston's Son & Company, Philadelphia.

of the helix by burn from a gasoline explosion. Since the helix had been destroyed, there remained the antihelix with a thin scarred edge and a proportionate reduction in size of the pinna. The first operation was done October 19, 1925. The helix was reconstructed from a small tubed pedicle flap from the neck (Fig. 2a). This flap was transplanted upward in three stages; the pedicle was opened along the suture line and was then sutured to the split edge of the antihelix. The skin of the lower part of the neck is thinner than that of the upper part of the neck or of the chest and matches closely the color and texture of the normal helix. This is of great importance as material taken from other parts of the body so rarely has the requisite coloring and appearance for an auricle. Four operations were required for this case and were performed on October 19, December 1, and December 10, 1925. The progress of the case was uneventful, healing occurring by first intention. The final result is shown in Figure 2b reproduced from a photograph taken January 2, 1926.

CASE 2. This case illustrates practically the reconstruction of the entire pinna. The patient lost the external ear in an automobile accident and was referred to me by Dr. C. Coleman Berwick of San Francisco. Only the lobule, the tragus and the external auditory canal remained (Fig. 3a). The tragus and lobule are the simplest parts of the ear to reconstruct. The problem then was to construct the remainder of the pinna with its natural contour, coloring and size and with the proper angle between it and the head. It was necessary also that the completed member should show no tendency to shrink. This tendency has been one of the major difficulties of ear restoration.

The first operation was done August 14, 1926. At that operation the right eighth and ninth rib cartilages were removed. A strip of cartilage 4 centimeters by 6 centimeters was prepared from the eighth rib cartilage and the perichondrium was removed. This cartilage was placed in a tunnel between the skin of the scalp and the temporo-mandibular fascia through a small incision 6 centimeters above and behind the external auditory meatus. This strut of cartilage was then in position to thrust against the tissue which is closely adherent just above the meatus. The ninth rib cartilage and the remainder of the eighth were buried in the fat of the abdominal wall.

Fig. 2. a. Left. Loss of helix from burn. Tubed pedicle flap has been transferred upward at one end. b. Completed pinna. Tubed pedicle flap sutured to split remains of antihelix.

¹Read before the meeting of the California State Medical Society at Sacramento, California, May 3, 1925.

Fig. 3. a Loss of entire pinna except lobule and tragus. b Cartilage has been implanted under the scalp epithelial inlay done behind flap and one end of the tubed pedicle flap transplanted upward. c Stent has been removed from epithelial inlay and tubed pedicle flap again transplanted. d Tubed pedicle flap transplanted into lobule. e Opened

tubed pedicle flap sutured into split edge of scalp flap. f New helix has been trimmed and finer contours of pinna reproduced with implantations of rib cartilage. g Pinna near completion. Finer contours may be reproduced till further.

On October 1, 1926 a tubed pedicle flap of the Gilbes type was made on the lower part of the neck on the same side as the proposed pinna. The pedicle flap was 1 centimeter in diameter and 16 centimeters in length. It is surprising how small in diameter these pedicle flaps can be made and how well they maintain their nutrition through successive transplantations. The skin selected for the pedicle lies just above the clavicle and parallel to it.

On January 6, 1927 a semilunar incision was made in the shape of the proposed pinna with a radius of about 5 centimeters from the upper border of the external auditory meatus. The incision was carried through the temporo-mandibular fascia so that the cartilage had a protective covering on its inner surface. A model of the defect behind the flap was then made with warm dental modelling com-

pound and a Thiersch graft of one piece taken from the thigh was wrapped about the model raw surface out. The model and graft were then buried under the flap and the wound sutured. This is the typical epithelial inlay of Esser. The tubed pedicle from the neck was transferred upward at the same operation by cutting free the lower end and transplanting it upward to the upper part of the neck just below the lobule. This stage is shown in Figure 3b. Ten days later the suture line was opened above the epithelial inlay and the wax model was removed. As is usual with this method of skin grafting there was a complete take of the graft so that no raw areas remained and the flap with its cartilage support stood out at a proper angle from the head as shown in Figure 3c. On March 17, 1927 the lower end of the tubed pedicle was transplanted

Fig 4 a Loss of upper half of pinna by accident b First stage as in Figure 3b Scalp flap smaller c Stent removed Lower edge of flap sutured to upper edge of remainder of pinna d Pedicle flap transplanted upward e Pedicle flap transplanted to upper extremity of helix f Transplantation of pedicle to scalp flap complete g Posterior view of new pinna showing angulation to head h Pinna as at present Readjustments and reconstruction of finer details of antihelix to follow

On May 20 1927 the pedicle was freed at its distal end opened its full length along the scar of the suture line and sutured into the flap representing the antihelix after the flap had been split along the edge to receive the raw surface of the pedicle (Fig 3e) The result was only a crude representation of a pinna but it formed a substantial foundation for the rebuilding of the pinna's contours Several small readjusting operations were done at intervals Most notable of these were the narrowing of the pedicle now become helix and the implantation of a small strip of cartilage taken from the cache in the abdominal wall and placed to represent the superior border of the concha (Figs 3f and g) Since completion this ear has shown no evidence of shrinkage It has taken on a coloring almost indistinguishable from the opposite ear with

upward this time joining with the stump of the lobule and blending with it as shown in Figure 3d

Fig. 5. a Congenital absence of pinna. Lobule present but folded forward. Small amount of cartilage present beneath scalp. b Lobule unfolded and cartilage redistributed.

c Reconstructed pinna at present. Implanted rib cartilage has reproduced tragus. Further details of anti helix will be worked out with strips of rib cartilage.

the helix much pinker than the antihelix. The few hairs which came as a legacy with the scalp were removed by the use of the electric needle. In the author's opinion this is the only method by which hair should be removed from these flaps. A depilatory dose of roentgen ray is so close to a destructive dose that permanent damage may result or at least scarring and telangiectases.

CASE 3. This patient suffered the loss of the upper half of the pinna as the result of an accident. The healed stump is shown in Figure 4a. The same principle of reconstruction was used as had been successful in Case 2. The first operation was done on July 21, 1927, when the rib cartilage was buried beneath the scalp and the tubed pedicle constructed on the lower neck. On August 22, 1927, the flap was cut and the epithelial inlay was carried out while at the same time the lower end of the tubed pedicle was transplanted upward behind the lobule as shown in Figure 4b. One week later the wax model was removed as illustrated in Figure 4c. On September 3, 1927, the lower edge of the flap was sutured to the upper border of the remains of the pinna after both had been split. Transplantations of the tubed pedicle are shown in Figures 4d and e. Figure 4f indicates the completed suturing of the pedicle to the flap while Figure 4g, showing a posterior view, illustrates the manner in which the cartilage bearing flap stands out from the head. The reconstruction is not complete, as the patient is to return for further remodelling of the pinnal contours.

Congenital absence of the external ear is not unusual, occurring in about 1 in 20,000. At present I have under my care 5 cases of this type. This anomaly is generally accompanied by other evidences of maldevelopment on the affected side such as absence of the mastoid cells, the external auditory canal, the membrana tympani, the middle ear, the cochlea, or the semicircular canals. Also the seventh cranial nerve may run an anomalous course or may be only partially developed thus giving the symptoms of a facial paresis as in

one of my cases. Underdevelopment of the entire side of the face so that it has a dishd in appearance is common.

Some postmortem findings have been reported as follows:

J. C. Beck, in the *Laryngoscope* of November 1923, reported a case with a rudimentary ear. Postmortem examination showed that the internal auditory meatus of the defective side (right) was very small compared with that of the other side. Nerve was present in the canal but there was a question whether it was the facial or the auditory part of the nerve. No middle ear, no cochlea, and no mastoid cells were found but there were two vestiges of semicircular canals. The left ear was normal.

R. C. Lynch, in the *Laryngoscope* 1913, No. 23, reported a case of congenital absence of both ears. A skin incision was made where the mastoid should have been. When the periotomy was peeled away, the temporomaxillary joint was found instead of a canal behind the smooth outer table present in the squamous portions of the temporal bone. The facial nerve came out of the skull just behind the neck of the maxillary articulation without any evidence of a styloid process. When the outer table was clipped off the diploë was revealed.

I. P. Anzinger, in the *Ohio State Medical Journal* of December 1923, reported a case of congenital absence of the right ear with cleft of the upper left eyelid. The right ear was missing but there were three rudimentary skin tags just in front of the right ear zone. Postmortem section over the right temporal area showed the skull bone to be perfectly smooth with no evidence of auditory canal.

In the face of these facts it is in most cases not advisable to open the external auditory canal. Only in those cases showing radiographic evidence of well developed mastoid cells and an auditory canal and giving unmistakable evidence of hearing on the malformed side should the opening be attempted. H. B. Graham has successfully ac-

complished the opening of such a canal and writes me as follows

The patient a boy aged 3 years presented a lack of both canals with an absence, on one side of nearly the entire concha and on the other side with the cartilage of the concha buried beneath the skin of the head. X-ray examination showed a well formed middle ear and the maxillary joint well anterior to the mastoid process. The hearing was so poor that the child's speech was nearly unintelligible and he was very hard to manage. At operation an attempt was made to open the canal to a point as close to the promontory wall as possible the mastoid cells and anterior wall of the mastoid process being removed. A skin graft was then introduced and shaped around dental modelling compound in the attempt to secure the formation of an open canal. This was only partially accomplished but the hearing was improved to such an extent that the child soon learned to talk and became much more reasonable in his relations to other children and to the family. Further cosmetic surgery was left for a later date.

CASE 4. This case referred to me by Dr. Walter Harder (Fig. 5a, b and c) is an example of construction of the external ear in a patient in whom it was congenitally absent.

In this case the external ear consisted of a completely formed lobule which was folded forward. In addition three small fragments of cartilage just above the lobule presented the only evidence of pinna. The X-ray picture revealed fairly well developed mastoid cells and an auditory canal. The patient seems definitely to hear on this side probably by bone conduction.

At the first operation done August 17, 1927 the infolded lobule was unfolded and the cartilages rearranged (Fig. 5b). The procedures illustrated in Case 2 were then followed with the result shown in Figure 5c. The procedure is of course incomplete. There is a considerable store of cartilage still in the abdominal wall and this will be implanted in strips to give the proper contour to the antihelix and concha.

CONCLUSIONS

This method of reconstruction of the pinna possesses the following advantages

- 1 All stages of the reconstruction can readily be done under local anesthesia

- 2 The method requires for hospitalization only one period of a few days when the rib cartilage is removed and an occasional day when each succeeding stage is accomplished. In the intervals the patient is not disabled

- 3 The new auricle does not shrink or fold up

- 4 The coloring of the new helix and antihelix compares favorably with that of the normal ear

- 5 In point of size and angular contact with the head it may be constructed to match the opposite ear

- 6 With patience most of the finer details of contour may be attained

HEMOLYTIC ICTERUS AND THE TECHNIQUE OF SPLENECTOMY¹

HOBART M. FACS, WOODLAND, CALIFORNIA

From the Department of Surgery, Woodland Clinic

CHRONIC hemolytic icterus is a disease characterized by splenomegaly, jaundice, the absence of bile pigments in the urine, the presence of coloring matter in the stools and a diminished resistance of the red blood cells to hemolysis.

In 1890 Wilson first described cases of congenital jaundice associated with splenomegaly and in 1898, Hayem described similar cases that were acquired. The congenital form of hemolytic icterus later was associated with the names of Chauffard and Minkowski. The acquired type became known as the Hayem Widal form of the disease.

The Chauffard Minkowski form of the disease may be either congenital or familial. In the former instance jaundice appears very early in life while in the latter it appears later but usually during childhood. In both of these varieties, there is usually a history of other cases in the family. The Hayem Widal form may appear at any time, but usually during early adult life.

The symptoms of the congenital and the acquired types of hemolytic icterus are very similar. There is usually a marked difference in the intensity of the symptoms in the two types of the disease. In the congenital or familial the patients as Chauffard said are "more jaundiced than sick." They may lead normal lives and remain completely free from subjective symp-

toms. These patients may live to an advanced age with no serious inconvenience from their disease.

On the contrary, the acquired form is much more severe. The disease may begin insidiously with the appearance of a mild icterus, or by a violent sudden onset of pain, fever, and the development of a marked jaundice in an attack which simulates that of an obstruction of the common bile duct with a gall stone. The attack subsides but the jaundice persists though it becomes less intense. These attacks occur at varying periods of time. Anemia appears, increases and may become fatal unless treatment is given.

The etiology of the condition is obscure. It is generally believed to be based upon some toxic or infectious cause.

Our present conception of the origin of jaundice in hemolytic icterus is due to Ashoff's ideas of the reticulo endothelial system to Whipple's and Mann's apparently successful attempt to produce experimental jaundice in animals when the liver had been entirely excluded from the circulation and to Pearce's work on the spleen and its relation to hemolysis. The more accurate methods of detecting the slighter changes in the blood introduced by Van den Bergh have amplified the results obtained in earlier research and have led directly to the formulation of the new hypothesis of the mechanism of jaundice. The differential diagnosis between hemolytic and non hemolytic jaundice can often be established by this method.

McNee has classified jaundice as obstructive, hemolytic and toxic or infectious. This classification correlates very well with the clinical facts and experimental data now available. Hemolytic icterus is a disease of the entire hematopoietic system. The source of jaundice is chiefly from the liver, spleen and bone marrow.

The jaundice of hemolytic icterus is caused by an accumulation in the liver of the products of cell disintegration to such an extent that the liver is unable to take care of them properly and a certain amount of altered pigment is absorbed into the blood stream. This jaundice is unusual. It is mild, deepens during a crisis and never becomes dark brown as in a long standing obstructive jaundice; the urine does not contain bilirubin and the stools do not contain stercobilin, their normal coloring agent. No itching is present nor is there a decrease in the coagulability of the blood.

FIG. 1. Hematopoietic system

¹Read before the California State Medical Association at Concord, May 8, 1930.

Fig. 2 Division of lienogastric ligament

The spleen is a hæmolymph node and a part of the hæmatopoietic system (Fig. 1). It may be considered as a coarse filter for cellular elements of the blood that have outlived their usefulness especially for the breaking down and removal of degenerated red blood cells and as a limited source of white blood cells.

The pathogenesis of the disease has been explained in two ways. One group of investigators believes that it is essentially an increased fragility of the red cells or in other words that the cause of the disease is to be found in a perversion of the function of the bone marrow which produces cells that are more easily fragmented than normal cells. According to this theory the splenomegaly is merely the reaction of the spleen to the presence in the blood of an increased number of cells that are ready for destruction. The other school believes that the cause of the disease lies in the spleen. This organ for some reason is excited to overactivity and destroys more cells than under normal conditions. Neither of these theories is adequate to explain all of the findings in the disease.

The increase of fragility of the red cells is a demonstrated fact in so far as our methods are capable of demonstrating it. The resistance of the

Fig. 3 Freeing of adhesions over spleen

red blood cells has returned to normal in a large number of cases when successful splenectomy has been done. Frequently, even though the patient is clinically cured, this resistance of the red blood cells remains unchanged.

In the absence of the spleen, erythrocyte disintegration takes place in various remote areas of the body, probably the bone marrow and possibly the hæmolymph nodes. Under these circumstances the products of red cell destruction reach the liver by a longer route and in a less concentrated form. The liver is better able to take care of the material, and jaundice results only when red cell destruction has reached a higher degree than is required when the spleen is present.

It has also been suggested that the increased fragility of the red cells is due to the action of some toxins either produced in the spleen or in some way activated by it. This theory has little evidence to support it.

There is no characteristic pathological picture in hæmolytic icterus. There is a deep congestion of the pulp and active phagocytosis of the red cells both by the macrophages and by the polynuclears. The spleen is always enlarged some times enormously so and contains an increased

FIG. 4. Elevation of spleen and placing of gauze pack.

FIG. 5. Separation of pedicle into two parts and division.

amount of iron containing pigment. There is usually a slight degree of fibrosis and thickening of the capsule and areas of perisplenitis may be found.

The liver may be occasionally enlarged and show a biliary cirrhosis. The kidneys and bone marrow are also deeply pigmented. The bone marrow is of the erythroblastic type and offers no histological evidence of any abnormality in the mode of erythrocyte production.

Cholelithiasis is present in about 60 per cent of cases. Typical gall bladder disease may complicate the symptoms.

The blood picture varies with the degree of intensity. The red cells show well marked anisocytosis with a predominance of microcytes rather than macrocytes. These microcytes are often irregular in shape and have been described as fragmental forms of cells. Polychromatophilia is marked, but granular degeneration is not so frequent. There is a marked increase in reticulated reds stained by vital stains. Normoblasts are found occasionally. Myelocytes may be present. Megoblasts and myeloblasts are rare. The hemoglobin is usually low and the color index below 1.

The blood serum generally contains urobilin. Bilirubin is present as a rule only during a crisis. The urine contains urobilin often in very large quantities. The amount of urobilin in the stool and duodenal contents is increased to many times the normal amount.

The mortality when splenectomy is performed is 16 per cent in 63 cases as reported by Elbott in 1917. The statistics of the Mayo clinic show a mortality of 7 per cent in 37 cases. Recovery is as a rule rapid and complete. No operative procedure should be contemplated when active hemolysis is taking place. Preparation by transfusion is often a necessity.

The success of splenectomy depends in a large measure on the selection of the time of operation and careful pre-operative preparation.

Following are the reports of 2 cases illustrating the congenital and acquired types of this disease with complete symptomatic cure following splenectomy.

CASE 1. F. M. D., a male aged 6 weeks was first seen on March 9, 1926. His family history was essentially negative. The past history showed normal delivery, but the child had not gained well. He had been jaundiced and constipated for 1 week. Physical examination showed marked jaundice.

Fig. 6 Peritonizing raw surfaces of diaphragm and splenic pedicle

Fig. 7 Relationship of stomach, tail of pancreas and splenic flexure of colon to the spleen surface and pedicle and dangers encountered with injury to these organs in surgical removal

and anaemia. The spleen was much enlarged. Laboratory examination showed hæmoglobin 32 per cent, many normoblasts and megaloblasts, and moderate polychromatophilia. The red cells exhibited fragility within normal limits.

Transfusion was given March 13, 1926, with marked benefit. Jaundice lessened, hæmoglobin increased. Transfusions (12 in all) were given at short intervals with temporary benefit. The first 6 transfusions were given through the anterior fontanelle, the last 6 intraperitoneally. The child's attacks of increased jaundice and anaemia were frequent but only moderately severe. However, no permanent improvement could be obtained. The serum bilirubin was increased and the urine showed a considerable amount of bile. The fragility of the red blood cells was only slightly increased at any time.

Splenectomy was done on April 25, 1927. The weight of the spleen was 170 grams. The gall bladder was small, atrophic, thick-walled, and inflammatory; there were no stones. No hepatitis was discovered. The child's progress following splenectomy was entirely satisfactory. His growth and development were normal for his age. On April 8, 1928, the hæmoglobin was 75 per cent.

CASE 2. M. R., a male aged 15 years, was first seen January 1, 1925. His family history was essentially negative. He had had tonsillitis frequently; adenoids had been removed. The boy had been jaundiced at birth. This condition had cleared promptly and the patient had been perfectly well to the age of $2\frac{1}{2}$ years when he had been

jaundiced for 3 weeks, then he had been well to the age of 4 years when he had had an attack with high fever and abdominal pain. He had never been well since this attack. Following this he had had many attacks characterized by diarrhoea, severe headache, sore throat, and deep jaundice. There was no severe upper abdominal pain and little gas or sour stomach. He had periods of severe anaemia. Physical examination showed a very pale, anæmic, and jaundiced boy. His tonsils were markedly diseased. The spleen was enormously enlarged and tender. Laboratory examination gave the following results: hæmoglobin 43 per cent, poikilocytosis and anisocytosis, marked increase in fragility of the red cells, and urinalysis essentially negative.

Transfusion was given on January 2, 1925. The hæmoglobin on January 8 was 22 per cent.

Splenectomy was performed on January 14. The weight of the spleen was 2,000 grams. The gall bladder was thick-walled and there were no stones. The liver was normal. Transfusion was immediately given. The patient showed a rapid gain in strength and growth. On December 31, 1927, the hæmoglobin was 80 per cent. He has attained normal growth and size and shows marked thickening of the cranium.

Splenectomy was performed in the first instance on a child 15 months old and, at the present time, the patient is apparently normal. As far as my

Fig. 8. A. 1. Posterior or dorsal lumbar incision. Shaped midline incision. 2. Paramedian laparotomy with horizontal incision. B. 3. Thoraco abdominal incision. C. 4. Posterior or dorsal lumbar incision.

information goes this is the youngest patient with hemolytic icterus reported in the American literature. In England Taylor reported 3 cases of very young children 9, 11 and 13 months respectively on whom splenectomy was done.

My second case is classified as an acquired type because of the intensity of the symptoms. Repeated attacks of profound anemia followed one another over a number of years. Marked thickening of the skull occurred before splenectomy and the increase was about twice to three times normal thickness after splenectomy which illustrated the marked activity and involvement of the bone marrow. No bones except the skull were involved in this process. Wilson notes a similar condition in his patient. M. Ganssler states that 11 of his 27 patients had steep skulls.

The diagnosis of hemolytic icterus is difficult at times. To reach a definite conclusion observation must extend over a considerable length of time. As Kennedy has shown there is among children a considerable group of enlarged spleens which can not be classified.

The choice of operative incisions varies with the size of the spleen and the perisplenitis to be encountered. Figure 8 illustrates various possible approaches. The straight left rectus incision as advocated by Balfour is the most advantageous in splenic anemia. The stages of splenectomy are illustrated in Figures 3, 4, 5 and 6. The dangers of possible injury to the stomach, pancreas and large bowel due to their close proximity to the spleen are best illustrated in Figure 7.

CONCLUSIONS

1. Hemolytic icterus either acquired or congenital, requires splenectomy for permanent clinical cure which is obtained by this measure.

The mortality is comparatively low, when a careful preparation has been made.

RUPTURE OF TENDONS OF THE HAND

WITH A STUDY OF THE EXTENSOR TENDON INSERTIONS IN THE FINGERS

MICHAEL MASON M.D. CHICAGO

From the Department of Surgery, Northwestern University Medical School and Pasavant Memorial Hospital, Chicago

SO strong are the tendons that doubt has been expressed by some that rupture really occurs unless some pathological change be present in the tissue. In most cases (Honigsmann) the joints subluxate or luxate or the bones fracture or the muscles tear through at the musculotendinous junction or the tendinous insertion gives way (Bange) before the tendon itself tears through. Adams adds an interesting case to those reported in the literature illustrating the remarkable tensile strength of the tendons. A seaman caught the tips of the right middle and ring fingers in a door jamb and apparently jerked his hand away quickly, with a resultant crushing injury to the ring finger and amputation of the distal phalanx of the middle finger. The whole tendon and muscle belly of the flexor digitorum profundus (15 inches in all) pulled away with the amputated finger tip. Odermatt remarks that the condition may not be so rare as is supposed, noting that Gruber found two instances of complete rupture and one incomplete tendon rupture among 1,200 hands (600 cadavers). In our experience subcutaneous rupture is not of frequent occurrence though it is not improbable that in many instances the condition does not cause sufficient functional disability to lead the patient to a surgeon.

Subcutaneous tendon ruptures may be divided into a number of different types and classified in many ways. The most frequent classification is the one used by Stapelmoor who divided the conditions into those following a direct blow on the tendon, those following an indirect trauma and lastly the spontaneous tendon ruptures which may be either post-traumatic or due to a disease of the tendons. Those due to direct trauma are by far the most unusual though extensor tendon rupture over the proximal interphalangeal joint is said by Hauck to be usually due to direct trauma.

TABLE I—SUBCUTANEOUS TENDON RUPTURE

- A Direct trauma tendon caught between bone and traumatizing agent
- B Direct trauma forceful contracting tendon subjected to forceful passive force in opposite direction
- C Spontaneous rupture—
 - 1 Post-traumatic—e.g. epiphyseal injury or degeneration of tendon due to multiple severe or often repeated minor trauma
 - 2 Disease of tendon—e.g. tuberculous gonorrhea syphilis gout etc.

From the anatomical location tendon ruptures of the hand may be classified as follows

- A Rupture of the extensor tendons—
 - 1 At the insertion into the distal phalanx
 - At the insertion into the middle phalanx
 - 3 Rupture or dislocation over the metacarpophalangeal joint
 - 4 Rupture at the wrist
- B Rupture of the flexor tendons
 - 1 In the fingers
 - 2 At the wrist

RUPTURE OF THE EXTENSOR TENDONS

At the insertion into the distal phalanx. Indirect injury may lead to rupture of both normal and pathological tendons, the normal tendons which most frequently rupture following indirect injury are the extensors of the third, fourth, and fifth fingers at their insertion into the terminal phalanx. Schlatter in a group of 34 cases of tendon rupture over the terminal phalanx found 22 on the right side and 9 on the left side, 12 affecting the middle finger, 9 the ring finger and 10 the little finger. Males are more often affected than females. The injury appears to occur after apparently slight trauma. Thus in two cases reported by Durbán a mother and son were injured in exactly the same fashion, during the removal of stockings. While stripping the stocking from the leg the tip of the actively extended middle finger caught in the elastic seam at the top thus leading to a forceful passive flexion of the terminal phalanx, something seemed to crack and the finger tip was found flexed and could not be extended. In one case here illustrated the identical trauma, stripping off of stockings, led to rupture at the base of the distal phalanx of the right middle finger (Figure 1 shows result of operative repair). A patient recently seen caught his hand in a garage door which he was closing behind him (Fig. 2). The right middle finger was caught between the two leaves of the door in such a way that the finger was forcibly flexed at both interphalangeal joints while the metacarpophalangeal joint was still extended. This injury is not infrequently seen on the baseball field due to a blow on the tip of an extended finger and it is from this association that it receives its name of baseball finger. The injury consists usually of a capsular tear associated with a separation of the tendon from its insertion. Since the two structures, capsule and tendon, are here

Fig. 1 Result one and one half years after repair of ruptured extensor tendon over distal interphalangeal joint of the right middle finger. While removing the stockings the patient caught the tip of the actively extended finger

against the inelastic seam at the top of the stocking causing forcible passive flexion and subcutaneous rupture of the tendon

so intimately united that they cannot be dissected as separate and distinct structures it is difficult to say which broke through first. In some cases (Glass Durban Schlatter) the tendon in pulling away from the bone takes a small shell of the distal phalanx with it, a condition which can be nicely demonstrated by lateral roentgenograms.

Swelling associated with considerable pain comes on quite rapidly after the injury. The typical flexion deformity which results (Figs. 2 and 3) is often diagnosed as a dislocation and this is reduced and splinted in extension. Often not until the splint is removed is the true condition recognized and proper treatment instituted. A certain number (especially those in which a cortical fracture is present) will heal if kept splinted for from 6 to 8 weeks in slight hyperextension. For this purpose numerous ingenious removable metal and celluloid splints have been devised (Sonntag Glass) and good results have been obtained from their use. Lewin's splint (Fig. 3) has been used by us and found very satisfactory. The regenerative powers of the extensor tendons (which are not enclosed in sheaths) are such that if given a chance and good approximation healing will occur. Occasionally however the tendon heals in a lengthened condition even with the best of treatment. In a patient recently treated by Dr. Kanavel the tendon had healed but was too long to permit complete extension. To obtain shortening it was necessary to make a step cut incision

through the tendon and overlap the ends to obtain a shortening of 1 centimeter.

Since healing is likely to occur with the tendon in a lengthened condition with subsequent dropped finger tip and since the joint space is always opened into by the trauma with the possibility of tags of tissue lying within the joint which may become ankylosed operative repair of the injury is the method of treatment of choice. Exposure of the injured area is best done through an incision which does not lie directly over the line of proposed tendon and capsule suture which does not interfere with the nail bed and gives adequate space for suturing. This may be accomplished by an L shaped incision over the dorsum the long limb of the L running along the posterolateral surface of the finger and extending from a point 1 $\frac{1}{2}$ centimeters proximal to the distal interphalangeal joint to a point $\frac{3}{4}$ centimeter distal to the joint. The short arm of the L passes transversely across the finger proximal to the nail bed from the distal end of the longer incision. Usually little difficulty is experienced in approximating the tendons since separation is not great due to the attachment to the proximal interphalangeal joint. The joint cavity should be inspected for tags of tissue which may have found their way into it and if any are found they should be removed. The tendon and the joint capsule are then carefully repaired with fine silk sutures. During the suturing the terminal phalanx is held in slight hyperextension. After

Fig 2

Fig 3

Fig 2 left Typical deformity resulting from rupture of the extensor tendon insertion into the distal phalanx. The actively extended finger was caught in a garage door in such a fashion that the interphalangeal joints were forcibly flexed.

Fig 3 The Lewin splint for baseball finger i.e. rupture of extensor tendon over the distal phalanx. The splint may be used immediately after the injury or after operative repair. It holds the joint in hyperextension, an important point since the tendon is likely to heal in lengthened position.

skin closure, the finger is kept slightly hyperextended on a volar splint for 3 weeks at the end of which time movements are allowed and physical therapy instituted. The results are usually good if asepsis has been rigid and if healing occurs without infection.

Rupture of dorsal aponeurosis over the proximal interphalangeal joint of the fingers. While rupture of the extensor tendon over the joint between the middle and proximal phalanges of the fingers is not a common injury the anatomical arrangement of the aponeurosis at this place and the typical deformity produced make it an interesting study. The whole question has been studied exhaustively by Hauck (1923). The tendons or the common extensors (Fig 4), on approaching the metacarpophalangeal joint spread out fanlike and over the proximal phalanx of the finger divide into a central and two lateral bands. The central slip inserts along with the capsule of the joint into the base of the middle phalanx and sends a loose tendinous attachment to the proximal phalanx. The lateral slips pass to either side around the proximal interphalangeal joint converge over the middle phalanx distal to the proximal interphalangeal joint and insert into the joint capsule of the distal interphalangeal joint and base of the terminal phalanx. The interosseus and lumbrical tendons fuse with these three slips distal to the metacarpophalangeal joint. The triangular expansion of the interosseus lumbricalis insertion into the dorsal aponeurosis may be divided into two portions—a deep and a superficial. The su-

perficial fibers run into the middle portion of the dorsal aponeurosis in such a fashion that the more proximal run almost transversely and the distal more and more obliquely as the joint is approached. The deeper portion also runs transversely in its proximal part, becoming more and more oblique as the tendinous sheet is followed distally, and ends in the region of the proximal interphalangeal joint. Both superficial and deep portions of the interosseus lumbricalis tendons with the exception of a few distal fibers which insert into the joint capsule of the first interphalangeal joint, end in the lateral slips of the dorsal aponeurosis. In this manner the extensor tendon is strengthened both at its insertion into the middle phalanx and at its insertion into the distal phalanx by the tendons of the lumbricals and interossei. Although controversy exists as to whether fibers from the extensor tendon actually reach the distal phalanx Hauck's views supported by many anatomists appear to be correct to us viz. that the extensor tendon through its lateral slips gains attachment to the distal phalangeal bone.

The action of the extensor and lumbrical interosseus tendons on the finger is quite complicated. The dorsal tendon can extend the finger in all its joints unaided by the lumbricals and interossei but when the metacarpophalangeal joint passes from complete extension to hyperextension a flexion of the proximal and terminal interphalangeal joints occurs unless the interossei and lumbricals are brought into play. Hauck by an

Fig. 4. A left. The dorsal aponeurosis from the upper surface—the lateral fibers coming in from the lumbrical and interosseous muscles spread out fanlike to end in the central and lateral portions of the extensor aponeurosis. The majority of the central slip of the aponeurosis end in the distal part of the proximal interphalangeal joint capsule—tear of this insertion would permit herniation of the joint through a buttonhole like defect. B The dorsal aponeurosis seen from the under surface. From C Hauck.

ingenious model (Fig. 5) and by experiments on cadavers, has shown that this may be explained upon a purely mechanical basis. At first when pull is exerted upon an extensor tendon the traction is exerted upon the distal and middle phalanges which extend along with the metacarpophalangeal joint until full extension has been obtained in all the joints. However as soon as the tendon pull on the proximal phalanx has taken up all the slack in the loose tendon attachment the whole pull of the extensor tendon is transferred here allowing the distal portion to loosen and slight flexion to occur. These observations I have confirmed on cadaver hands. Although the joints in preserved material are not especially flexible it can be easily demonstrated that the pull exerted on the distal phalanx by force exerted on the extensor tendon is less when the finger is hyperextended than when the finger is flexed. In the living hand especially in such conditions as ulnar paralysis in which the lumbricals and interossei are not functioning this mechanism is beautifully illustrated particularly with reference to the ring and little fingers (Fig. 6). In the nor-

mal hand the extension of the two distal phalanges is accomplished by the extensor tendon and the lumbrical and interosseous tendons. When the proximal phalanx has been hyperextended actively, however, the two distal phalanges are extended by the latter two muscles; the extensor tendon no longer being able to do so.

The rupture of the dorsal aponeurosis over the proximal interphalangeal joint is due to either direct or indirect trauma. The middle finger is the most frequently affected though several cases have been reported in which the fifth finger was involved. The right hand is more frequently affected than the left. As to type of trauma two fairly definite etiological agents are present. In the one instance the fingers are being actively extended and a blow or a fall leads to forceful passive flexion. In the other type, and this seems the more frequent, a blow strikes the first interphalangeal joint while it is flexed. It would seem that the taut tendon is caught between the traumatizing agent and the bone and breaks or tears across. It is the middle portion of the dorsal aponeurosis which ruptures; the two lateral slips now loosened from their attachment about the joint slip volarward and the joint comes to lie between them as in a button hole. The volar dislocation is further increased by the pull of the lumbrical and interosseous muscles. The finger assumes then a typical deformity as shown in the accompanying photograph (Fig. 7) i.e. extension or hyperextension of the distal phalanx flexion of the middle phalanx and extension or even hyperextension of the proximal phalanx. The deformity is increased by anything leading to increased tension of the extensor tendons: active extension of the fingers or passive flexion of the wrist. Diminution of the tension of the extensor tendons causes a certain diminution of the deformity. Attempts at extension of the middle phalanx cause pain about the proximal interphalangeal joint and a sense of spring like rigidity along the side of the middle phalanx. Similarly flexion of the distal phalanx causes pain about the proximal interphalangeal joint and the same sense of a spring like tension. On making a fist the finger can be flexed almost to normal so that the tip almost but not quite touches the palm; however as soon as the finger is extended the hyperextension of the distal phalanx recurs before the metacarpophalangeal joint is entirely extended.

The deformity appears at the moment the injury is sustained and is associated with pain and immediate swelling. The pain subsides but the swelling does not entirely disappear. Functional disturbance as far as the finger itself is concerned

FIG. 5 G Hauck's patented model to illustrate the action of the extensor tendons on the fingers. The interosseous lumbrical tendon is shown by dotted line in 1. (This latter tendon has an insertion into the base of the proximal phalanx; this is not shown.) It is easily seen how

rupture of the extensor insertion into the base of the middle phalanx would allow the lateral slips of the tendon to be displaced volarward, thus causing the typical deformity of flexion of the proximal interphalangeal joint and extension of the distal interphalangeal joint.

is considerable though the uses to which the hand may be put would determine the degree. The roentgen ray usually shows no bony injury, though in a case observed by us (Fig. 7) an irregular shadow proximal to the joint showed the after result of a periosteal tear.

The condition responds well to operative treatment, though full free movements can scarcely be promised. When an incision is made over the joint the capsular tear is usually evident, the joint cavity being frequently opened up. In case of old injury, however, scar tissue may be present and conceal the location of the tear. The joint projects upward between the two lateral slips which are displaced volarward. In the repair the middle slip is sutured back into position after the lateral slips have been brought back dorsally to relieve the tension. Following this sutures are placed across the bone approximating the lateral slips to the midline to correct the volar dislocation. The finger should be kept in a splint in extension for 4 weeks after which active and passive movements and physical therapy should be instituted.

Dislocation of the dorsal tendons over the metacarpophalangeal joints. This rare condition in which the dorsal tendon slips to one side of the head of the metacarpal bone or in which a button-hole luxation of the joint through the tendon is present has been recently studied by Levy who following Maydl's classification divided the instances into the traumatic and the pathological dislocation. But 6 cases of undoubted traumatic dislocation could be found by Levy. The pathological type due to deforming arthritic changes about the joints or to some central nervous system disturbance associated with paralysis appears to be the more frequent. In a case of Levy's the condition was apparently congenital—the pa-

tient a medical student, could voluntarily dislocate the extensor tendon to the right middle and ring fingers; the girl's father could do likewise with the right and left middle fingers, and her paternal grandmother was said to have the same disability. Ritschl's case of button-hole dislocation of the metacarpophalangeal joint of the little finger through the extensor aponeurosis appears to be the best known. Too few cases are on record to make any worthwhile comments on the incidence of sex, age, or various tendons. The pathology appears to be little understood in the traumatic cases; some claim the binding apparatus between the tendon and the metacarpal and first phalanx is torn; others that the junctura tendinum is torn across. In the button-hole dislocation the same traumatic factor probably obtains as in other dorsal tendon ruptures and dislocations. Tearing off of bits of bone along with the tendinous attachment has been suggested by Levy.

Few symptoms are caused, weakness and easy tiring of the finger are noted. During flexion the tendon may be felt to snap down onto the side of the metacarpal head and there results some difficulty in extending the finger. Pain and some tenderness are present in the traumatic cases.

In early cases splinting in extension may lead to restoration of function to normal; with older cases, however, operative treatment is necessary; the dislocated tendon must be brought into position and held there by means of fascial bands over the head of the metacarpal and to the neighboring tendon. Iselin used tendon transplants for the connective tissue between the tendons. At times the junctura tendinum is too lax and should be shortened.

Rupture of tendons at the wrist. Inasmuch as normal tendon will not rupture without considerable trauma, spontaneous tendon rupture must

One of the effects of insertion into the middle phalanx as to the same typical deformity as is shown in Figure 8.

Fig 4 A left The dorsal aponeurosis from the upper surface—the lateral fibers coming in from the lumbrical and interosseous muscles spread out fanlike to end in the central and lateral portions of the extensor aponeurosis. The majority of the central slip of the aponeurosis end in the distal part of the proximal interphalangeal joint cap—tear of this inserti would permit herniation of the joint through a buttonhole like defect. B The dorsal aponeurosis seen from the under surface. From G. Hauck.

ingenious model (Fig 5) and by experiments on cadavers has shown that this may be explained upon a purely mechanical basis. At first when pull is exerted upon an extensor tendon the traction is exerted upon the distal and middle phalanges which extend along with the metacarpophalangeal joint until full extension has been obtained in all the joints. However as soon as the tendon pull on the proximal phalanx has taken up all the slack in the loose tendon attachment the whole pull of the extensor tendon is transferred here allowing the distal portion to loosen and slight flexion to occur. These observations I have confirmed on cadaver hands. Although the joints in preserved material are not especially flexible it can be easily demonstrated that the pull exerted on the distal phalanx by force exerted on the extensor tendon is less when the finger is hyperextended than when the finger is flexed. In the living hand especially in such conditions as ulnar paralysis in which the lumbricals and interossei are not functioning this mechanism is beautifully illustrated particularly with reference to the ring and little fingers (Fig 6). In the nor-

mal hand the extension of the two distal phalanges is accomplished by the extensor tendon and the lumbrical and interosseous tendons. When the proximal phalanx has been hyperextended actively, however, the two distal phalanges are extended by the latter two muscles—the extensor tendon no longer being able to do so.

The rupture of the dorsal aponeurosis over the proximal interphalangeal joint is due to either direct or indirect trauma. The middle finger is the most frequently affected though several cases have been reported in which the fifth finger was involved. The right hand is more frequently affected than the left. As to type of trauma two fairly definite etiological agents are present. In the one instance the fingers are being actively extended and a blow or a fall leads to forceful passive flexion. In the other type and this seems the more frequent a blow strikes the first interphalangeal joint while it is flexed. It would seem that the taut tendon is caught between the traumatizing agent and the bone and breaks or tears across. It is the middle portion of the dorsal aponeurosis which ruptures—the two lateral slips now loosened from their attachment about the joint slip volarward and the joint comes to lie between them as in a button hole. The volar dislocation is further increased by the pull of the lumbrical and interosseous muscles. The finger assumes then a typical deformity as shown in the accompanying photograph (Fig 7) i.e. extension or hyperextension of the distal phalanx, flexion of the middle phalanx and extension or even hyperextension of the proximal phalanx. The deformity is increased by anything leading to increased tension of the extensor tendons—active extension of the fingers or passive flexion of the wrist. Diminution of the tension of the extensor tendons causes a certain diminution of the deformity. Attempts at extension of the middle phalanx cause pain about the proximal interphalangeal joint and a sense of spring like rigidity along the side of the middle phalanx. Similarly flexion of the distal phalanx causes pain about the proximal interphalangeal joint and the same sense of a spring like tension. On making a fist the finger can be flexed almost to normal so that the tip almost but not quite touches the palm; however as soon as the finger is extended the hyperextension of the distal phalanx recurs before the metacarpophalangeal joint is entirely extended.

The deformity appears at the moment the injury is sustained and is associated with pain and immediate swelling. The pain subsides but the swelling does not entirely disappear. Functional disturbance as far as the finger itself is concerned

Fig 7 Typical deformity resulting from rupture of the extensor tendon over the proximal interphalangeal joint. The fully and strongly actively extended left ring finger was struck on the tip by a swift basketball. The roentgenograms show a bony proliferation due either to tearing away of periosteum or a chipping fracture.

of the dorsum of the forearm obliquely across the lower end of the radius and carpus crosses over the extensor carpi radialis longus and brevis which separate it from the carpal bones and, running over the medial and the dorsal surfaces of the first metacarpal reaches the dorsum of the phalanges and inserts into the base of the distal phalanx of the thumb. It is covered by an individual sheath from a point just proximal to the dorsal carpal ligament to the region of the head of the first metacarpal. Over the dorsum of the lower end of the radius it passes through a groove bounded on each side by osseous ridges to which the dorsal carpal ligament is attached which thus completes a dense osseo-ligamentous tunnel in which the tendon is confined. It forms the medial boundary of the anatomical snuff box (or *tabatiere*), the lateral boundary of which is formed by the extensor pollicis brevis and abductor pollicis longus. The extensor pollicis longus is an abductor of the thumb and its metacarpal extensor of the phalanges of the thumb; it assists the extensor pollicis brevis in extending the proximal phalanx but forms the sole extensor of the distal phalanx. A certain intermingling of fibers of the two thumb extensors takes place over the proximal phalanx. The tendon is covered by a tendon sheath as already described but a mesotenon is present through but a limited part of this sheath. It has

Fig 8 Deformity resulting from open division of the extensor tendon over the proximal interphalangeal joint. This deformity is exactly similar to that following subcutaneous rupture at the same location. The proximal interphalangeal joint rested in flexion with active motion possible between extension to 135 degrees and flexion to 90 degrees. The distal interphalangeal joint was extended to 180 degrees and could be flexed about 15 degrees. Operation revealed division of the extensor insertion into the middle phalanx and partial division and volar displacement of the radial slip of the extensor tendon.

been pointed out by Rau, Weigeldt, and others that after the age of 25 years the vascular supply to the tendon becomes progressively diminished. In its course the tendon is subject to two sharp turns both of which are at the distal end of the dorsal carpal ligament. One of these turns is in a horizontal plane as the tendon curves laterally from the groove on the radius about the distal end of the ridge forming the lateral border of the groove. The other turn is in a sagittal plane at the distal end of the dorsal carpal ligament. This latter change in direction is present only when the wrist is dorsiflexed. These are the essential factors which predispose to chronic tenosynovitis as result of use or trauma.

As studied first by Duems the condition was known as *Trommlelähmung* (drummer's palsy) or *Trommlesehne* (drummer's tendon) from the fact that the drummers in the German army were long known to be subject to a peculiar paralysis of the distal phalanx of the left thumb. Duems showed that the condition was not due to a paralysis of the long extensor of the thumb but to rupture of the tendon. Since then a few other occupations have been shown to predispose to the condition. Among these occupations may be noted that of waiters, tailors (Hunt), furniture polishers, carpenters (Barnes), rubber workers, and wood carvers. It is to be noted that these are all occupations calling for voluntary rather rigid

I' When these joints are slightly flexed there is increased power of extension of the interphalangeal joints.

B and B' and C and C' show the same phenomena in the middle and ring fingers respectively. In B and C the fingers are extended as far as possible. B' and C' show the degree of extension possible when the metacarpophalangeal joint is slightly flexed by digital pressure when the patient is attempting to actively extend the finger.

be preceded by some disease or injury leading to such weakening of the tendon structure that the tendon gradually gives way or quite minimal trauma leads to its separation. Although Volkmann spoke of a fragilitas tendinum modern writers do not accept this as a proved entity but rather assume that some quite definite agent has led to weakening of the tendon substance and its eventual rupture. Tuberculous tenosynovitis as has been shown by Kanavel will ultimately lead to involvement of the tendons themselves with fragmentation and division. Rarely is more than one tendon destroyed. The loss of function may not be noted by the patient due to the fact that the hand is little used. Occasionally the disability may occur suddenly but painlessly. Out of 21 available records of tuberculous tenosynovitis in Dr. Kanavel's files rupture or impending rupture of tendon was noted to occur in 10 instances. In 7 instances the flexor tendons were involved as follows:

Case 1 flexor digitorum sublimis and profundus to the index finger. Case 3, flexor digitorum sublimis and profundus to the ring and little fingers. Case 4 flexor digitorum sublimis to the fifth finger. Case 5 flexor digitorum sublimis to the little finger. Case 7 a slip of the flexor digitorum sublimis to the index finger. Case 9 flexor digitorum profundus to the index and middle fingers. Case 10 flexor digitorum sublimis and profundus to the little finger. In three instances extensor tendons were involved. Case 2 the extensor pollicis brevis. Case 6 all extensor tendons were thin wavy and thread like. Case 8, the extensor pollicis longus and brevis.

In most instances it has been possible to suture the ruptured tendon to adjacent tendons and secure good return of function as shown in case reports at the end of this paper. In a case recently operated upon by Dr. Kanavel however both extensors of the thumb had been destroyed and it was necessary to graft a tendon from the foot into the defect in the extensor pollicis longus (Fig. 10). This graft was removed as shown in Figure 9 and the hand put up with the thumb in extreme extension. Healing took place by primary intention and 2 months after operation (Fig. 11) the function of the thumb was perfect.

With other conditions such as gonorrhoea typhus fever lues gout or deforming arthritis leading to tendon rupture the author has had no personal experience. Tumors of tendons (Odermatt) may also lead to rupture though their great rarity makes this a very remote possible cause for spontaneous rupture.

Trauma is by far the most frequent cause for so called spontaneous rupture and inasmuch as but one tendon appears to be at all frequently affected the rupture of this tendon may be discussed. Spontaneous rupture of the extensor pollicis longus was first studied in the German army (Duerns) where it had long been looked upon as an isolated paralysis. The traumatic moment which is responsible for the condition may be either chronic irritative trauma or a single injury. A knowledge of the anatomy of this particular tendon explains the tendency to spontaneous rupture and of course the functional disability resulting therefrom. The tendon of the extensor pollicis longus passes from medial to lateral side

longus tendon and crushing of this tendon against the dorsal carpal ligament. Tearing and separation of tendon fibers occur as well as tears through the tendon sheath and interference with the blood supply. That some such factor must be present is further substantiated by the fact that often at operation no change in the bony groove is found, no radial or ridge fracture is present, and no displacement of the tendons demonstrated. The secondary factor is more important probably than the primary one for despite the numerous wrist injuries few tendon ruptures occur. This factor (Wiegandt) is the vascular supply of the tendon, no mesotenon being present over a considerable length of its course. After the age of 25 the vascular supply to the tendon is considerably diminished. This factor is important when we consider that most cases occur after the age of twenty-five.

Histologically the picture is that of an aseptic necrosis. The tendon fibers are swollen, the nuclei and fibers stain poorly, and considerable hyalinization is present. No inflammatory changes are noted.

The rupture occurs at variable intervals following the original trauma. In the cases collected by Honigsmann the limits were 12 days to 7 years, though 2 to 7 months seems to be the average time. As a rule the original trauma has been moderately severe so that immobilization has lasted for several weeks. The injury is about twice as frequent in males as in females and in 80 per cent of the cases affects the right hand (*Trommlersehne* always affects the left *extensor pollicis longus*). There is rarely any functional disturbance between the time of the original injury and the separation of the tendon except that incident to the original trauma, i.e. the individual has free and full use of the thumb up until the time of the rupture. The rupture always occurs at the same place,

Fig. 11 Same patient as in Figure 10. These photographs show the free function of the thumb 2 months after a graft was made to replace the destroyed segment of the *extensor pollicis longus*. The strong tendon is shown forming the ulnar boundary of the tabatière.

that is at the distal end of the dorsal carpal ligament and the trauma leading to it is quite minimal, as a rule no excessive use of the thumb has preceded the condition, the individual going about his usual work. A very few instances have followed heavy lifting, these are exceptions. Sewing, picking apples, putting the hand in the trousers pocket, using a scissors, and other household occupations appear in the reported histories. There is sudden usually painless loss of function in the thumb. In a few instances a cracking sound preceded the functional loss, in some moderately severe pain accompanied it and in one reported case a severe muscular cramp came on just before the loss of tendon function. Some swelling appears afterward but this is often of very moderate degree. The functional loss is typical and examination of the hand should lead to recognition of the underlying cause for the deformity. The medial border of the anatomical snuff box is gone due to the separation of the ends of the tendon. The distal phalanx of the thumb is flexed and can be extended only if the thumb is adducted and the metacarpal flexed into the palm at which time the *abductor brevis* and *flexor pollicis brevis* acting on the dorsal aponeurosis may cause some

Fig. 9. Tendon transplantation for repair of extensor pollicis longus destroyed by tuberculosis. *A* Extensor tendon of foot exposed leaving paratenonous tissues about it. Longitudinal incisions are made to either side of the tendon through the paratenonous tissues. At either end of these incisions catgut ligatures are passed around the tendon and tied in order to keep the tissues attached to the tendon. *B* Sutures passed through tendon and paratenonous tissues. After the suture is made the catgut ligature and the tendon it surrounds are excised. *C* and *F* Detail of suture lines. In *E* the uniting of paratenonous tissues is shown. *D* Suture at proximal line completed.

fixed position of the hand. The drummer grasps the stick (in the left hand) between the thumb and the second metacarpal while the vibratory motion of the stick leads to continuous highly frequent movements of the tendon of the thumb. The same factors are present in the other occupations named. According to Dittich the trauma to the tendon occurs over the distal end of the dorsal carpal ligament as suggested by Duems or over the osseous ridge of the radius—Steudel zur Verth. Excessive use of the tendon with its angulation leads to a chronic tenosynovitis with pain and swelling. The chronic aseptic inflammation continues with persistence of the trauma and leads to eventual division of the fibers.

When division follows a single injury the case is somewhat different. Here we have to deal with but one trauma, not repeated trauma which so disturbs the structure of the tendon that it leads to eventual rupture. The trauma which most frequently leads to spontaneous rupture is frac-

ture of the radius. Ashhurst remarks that in view of the anatomy of Colles' fracture the disability should really occur more frequently than it does. Honigmann in 4 cases of tendon rupture following wrist injury found 19 occurred after radius fracture at the wrist, 1 after lunate fracture and 3 after sprain with no demonstrable bony injuries. In such instances two primary factors are present. Hauck suggests that the wrist injury (fracture or sprain) leads to some displacement of the tendon due to bony changes in its canal or ligamentous tears. But as Honigmann and Odermatt as well as Hauck have noted displacement is not always present nor fracture demonstrated and a primary injury to the tendon at the time that the trauma was received must be assumed. Dittich suggests that the tendon is crushed over the angulation and that this sets up a chronic tenosynovitis. Falls on the outstretched palm with hand and thumb extended and with the muscles contracted lead to increase in the angulation of the extensor pollicis

longus tendon and crushing of this tendon against the dorsal carpal ligament. Tearing and separation of tendon fibers occur, as well as tears through the tendon sheath and interference with the blood supply. That some such factor must be present is further substantiated by the fact that often at operation no change in the bony groove is found, no radial or ridge fracture is present, and no displacement of the tendons demonstrated. The secondary factor is more important probably than the primary one for despite the numerous wrist injuries few tendon ruptures occur. This factor (Wiegandt) is the vascular supply of the tendon, no mesotenon being present over a considerable length of its course. After the age of 25 the vascular supply to the tendon is considerably diminished. This factor is important when we consider that most cases occur after the age of twenty-five.

Histologically the picture is that of an aseptic necrosis. The tendon fibers are swollen, the nuclei and fibers stain poorly, and considerable hyalinization is present. No inflammatory changes are noted.

The rupture occurs at variable intervals following the original trauma. In the cases collected by Honigsmann the limits were 12 days to 7 years, though 2 to 7 months seems to be the average time. As a rule the original trauma has been moderately severe so that immobilization has lasted for several weeks. The injury is about twice as frequent in males as in females and in 80 per cent of the cases affects the right hand (*Trommlersehen*). Always affects the left extensor pollicis longus. There is rarely any functional disturbance between the time of the original injury and the separation of the tendon except that incident to the original trauma, i.e. the individual has free and full use of the thumb up until the time of the rupture. The rupture always occurs at the same place,

that is, at the distal end of the dorsal carpal ligament and the trauma leading to it is quite minimal, as a rule no excessive use of the thumb has preceded the condition, the individual going about his usual work. A very few instances have followed heavy lifting; these are exceptions. Sewing, picking apples, putting the hand in the trousers pocket, using a scissors, and other household occupations appear in the reported histories. There is sudden, usually painless, loss of function in the thumb. In a few instances a cracking sound preceded the functional loss, in some moderately severe pain accompanied it, and in one reported case a severe muscular cramp came on just before the loss of tendon function. Some swelling appears afterward but this is often of very moderate degree. The functional loss is typical and examination of the hand should lead to recognition of the underlying cause for the deformity. The medial border of the anatomical snuff box is gone due to the separation of the ends of the tendon. The distal phalanx of the thumb is flexed and can be extended only if the thumb is adducted and the metacarpal flexed into the palm at which time the abductor brevis and flexor pollicis brevis acting on the dorsal aponeurosis may cause some

At either end of these incisions catgut ligatures are passed around the tendon and tied in order to keep the tissues attached to the tendon. *B* Sutures passed through tendon and paratenonous tissues. After the sutures are made the catgut ligature and the tendon it surrounds are excised. *C* and *F* Details of suture lines. *E* The suture of paratenonous tissues is shown. *D* Suture at proximal line completed.

fixed position of the hand. The drummer grasps the stick (in the left hand) between the thumb and the second metacarpal while the vibratory motion of the stick leads to continuous highly frequent movements of the tendon of the thumb. The same factors are present in the other occupations named. According to Duttrich the trauma to the tendon occurs over the distal end of the dorsal carpal ligament as suggested by Duems or over the osseous ridge of the radius—Steudel zur Verth. Excessive use of the tendon with its angulation leads to a chronic tenosynovitis with pain and swelling. The chronic aseptic inflammation continues with persistence of the trauma and leads to eventual division of the fibers.

When division follows a single injury the case is somewhat different. Here we have to deal with but one trauma not repeated trauma which so disturbs the structure of the tendon that it leads to eventual rupture. The trauma which most frequently leads to spontaneous rupture is frac-

ture of the radius. Ashhurst remarks that in view of the anatomy of Colles' fracture the disability should really occur more frequently than it does. Honigmann in 4 cases of tendon rupture following wrist injury found 18 occurred after radius fracture at the wrist, 1 after lunate fracture and 5 after sprain with no demonstrable bony injuries. In such instances two primary factors are present. Hauck suggests that the wrist injury (fracture or sprain) leads to some displacement of the tendon due to bony changes in its canal or ligamentous tears. But as Honigmann and Odermatt as well as Hauck have noted displacement is not always present nor fracture demonstrated, and a primary injury to the tendon at the time that the trauma was received must be assumed. Duttrich suggests that the tendon is crushed over the angulation and that this sets up a chronic tendonitis. Falls on the outstretched palm with hand and thumb extended and with the muscles contracted lead to increase in the angulation of the extensor pollicis

FIG. 10 Tuberculous tenosynovitis of dorsum of right wrist. Two pictures at left show condition of wrist before operation (scar from operations performed elsewhere). Picture at right shows condition of the wrist after second operation: shows extension disability of thumb.

FIG. 11 Same patient as in Figure 10. These photographs show the free function of the thumb 2 months after a graft was made to replace the destroyed segment of the extensor pollicis longus. The strong tendon is shown forming the ulnar boundary of the tabetiere.

longus tendon and crushing of this tendon against the dorsal carpal ligament. Tearing and separation of tendon fibers occur, as well as tears through the tendon sheath and interference with the blood supply. That some such factor must be present is further substantiated by the fact that often at operation no change in the bony groove is found; no radial or ridge fracture is present and no displacement of the tendons demonstrated. The secondary factor is more important probably than the primary one for despite the numerous wrist injuries, few tendon ruptures occur. This factor (Wiegandt) is the vascular supply of the tendon; no mesotenon being present over a considerable length of its course. After the age of 25 the vascular supply to the tendon is considerably diminished. This factor is important when we consider that most cases occur after the age of twenty-five.

Histologically the picture is that of an aseptic necrosis. The tendon fibers are swollen, the nuclei and fibers stain poorly, and considerable hyalinization is present. No inflammatory changes are noted.

The rupture occurs at variable intervals following the original trauma. In the cases collected by Homigmann the limits were 12 days to 7 years, though 2 to 7 months seems to be the average time. As a rule the original trauma has been moderately severe so that immobilization has lasted for several weeks. The injury is about twice as frequent in males as in females and in 80 per cent of the cases affects the right hand (*Trommlerselne* always affects the left extensor pollicis longus). There is rarely any functional disturbance between the time of the original injury and the separation of the tendon except that incident to the original trauma, i.e. the individual has free and full use of the thumb up until the time of the rupture. The rupture always occurs at the same place,

that is, at the distal end of the dorsal carpal ligament and the trauma leading to it is quite minimal. As a rule no excessive use of the thumb has preceded the condition; the individual going about his usual work. A very few instances have followed heavy lifting; these are exceptions. Sewing, picking apples, putting the hand in the trousers pocket, using a scissors, and other household occupations appear in the reported histories. There is sudden, usually painless, loss of function in the thumb. In a few instances a cracking sound preceded the functional loss, in some moderately severe pain accompanied it and in one reported case a severe muscular cramp came on just before the loss of tendon function. Some swelling appears afterward but this is often of very moderate degree. The functional loss is typical, and examination of the hand should lead to recognition of the underlying cause for the deformity. The medial border of the anatomical snuff box is gone due to the separation of the ends of the tendon. The distal phalanx of the thumb is flexed and can be extended only if the thumb is adducted and the metacarpal flexed into the palm at which time the abductor brevis and flexor pollicis brevis acting on the dorsal aponeurosis may cause some

fixed position of the hand. The drummer grasps the stick (in the left hand) between the thumb and the second metacarpal while the vibratory motion of the stick leads to continuous highly frequent movements of the tendon of the thumb. The same factors are present in the other occupations named. According to Dittrich the trauma to the tendon occurs over the distal end of the dorsal carpal ligament as suggested by Duems or over the osseous ridge of the radius—Steudel zur Verth. Excessive use of the tendon with its angulation leads to a chronic tenosynovitis with pain and swelling. The chronic aseptic inflammation continues with persistence of the trauma and leads to eventual division of the fibers.

When division follows a single injury the case is somewhat different. Here we have to deal with but one trauma, not repeated trauma which so disturbs the structure of the tendon that it leads to eventual rupture. The trauma which most frequently leads to spontaneous rupture is frac-

ture of the radius. Ashhurst remarks that in view of the anatomy of Colles' fracture the disability should really occur more frequently than it does. Honigsmann in 24 cases of tendon rupture following wrist injury found 18 occurred after radius fracture at the wrist, 1 after lunate fracture and 5 after sprain with no demonstrable bony injuries. In such instances two primary factors are present. Hauck suggests that the wrist injury (fracture or sprain) leads to some displacement of the tendon due to bony changes in its canal or ligamentous tears. But as Honigsmann and Oederhelt as well as Hauck have noted displacement is not always present nor fracture demonstrated and a primary injury to the tendon at the time that the trauma was received must be assumed. Dittrich suggests that the tendon is crushed over the angulation and that this sets up a chronic tendinitis. Falls on the outstretched palm with hand and thumb extended and with the muscles contracted lead to increase in the angulation of the extensor pollicis

FIG. 14 Tuberculous tenosynovitis of right wrist. Destruction of flexor digitorum sublimis tendons to ring and little fingers. A and B show limits of function of hand before operation. C and D show the result two and one half years later.

tient was thrown from a horse while grasping tightly to the horn of the saddle. The deep flexor of the left little finger ruptured over the middle phalanx. The terminal phalanx could not be flexed. On operation the proximal end of the tendon was found curled up in the tendon sheath at the base of the finger. In Lessing's case the patient fell on the outstretched hand rupturing the flexor profundus tendon of the ring finger. Though as a rule the rupture occurs on the finger the tear may occur anywhere along the course, in Thorn's case the rupture was found in the wrist.

The following two cases are worthy of report.

M. G. (patient of Dr. Allen B. Kanavel) a young man of 29 was struck on the tip of the fully extended right middle finger by a swiftly traveling baseball. The distal phalanx was dislocated dorsally and was reduced by the patient at the time with an audible snap. A splint was applied and left on for 6 days. On its removal the patient was unable to flex the terminal phalanx and there was no improvement following physical therapy. Six months later examination showed (Fig. 12) complete function in the proximal interphalangeal and metacarpophalangeal joints but inability to flex the distal interphalangeal joint. There was considerable diminution of passive flexion in the distal interphalangeal joint. The operation showed the profundus tendon completely torn loose from its insertion into the distal phalanx. There was marked periarthral fibrosis. The sublimis tendon was bound down by adhesions to the proximal interphalangeal joint. The profundus tendon was released from adhesions and sutured with silk to the periotrium over the distal phalanx and the finger splinted in flexion. The end result (4½ years later) is not entirely satisfactory due to the fibrosis about the joint resulting from the associated dislocation.

The second patient presents a rather puzzling story. He had been operated upon twice before Dr. Sumner L.

Koch saw him and the original pathological picture was thus obscured. A healthy man of 40 years 8 years previous to entrance suffered an injury to the right thumb while buckling an overshoe. Immediately after the injury he was unable to flex the distal phalanx of the thumb. He did nothing for this condition for several years despite the disability. Four years ago he consulted a surgeon who operated upon the thumb and found the flexor pollicis longus tendon movable laterally over the base of the proximal phalanx. The tendon was split and sutured to the base of the proximal phalanx. There was no improvement following this operation. Three years later he was operated upon again and the surgeon told him that the tendon was broken in the region of the proximal phalanx. An end to end suture of the tendon was performed and resulted in a 20 degrees power of flexion of the distal phalanx. In July 1928 he consulted Dr. Koch who found a dense scar over the ulnar and palmar surface of the thumb. Flexion of the distal phalanx of the thumb was possible for 15-20 degrees but there was obvious adherence to this scar. At operation the flexor pollicis longus tendon was found degenerated at its distal end for some 2.5 inches and markedly adherent to the proximal phalanx. It was not possible at this time to determine the original pathological process. The thick skin scar was excised and the degenerated tendon replaced by a tendon graft taken from the dorsum of the foot and secured to the distal phalanx by passing it through a drill hole in the bone. Six months after operation the patient states that the thumb is reasonably strong and can be used in grasping, but that the tendon seems to be too short and interferes with extension.

RÉSUMÉ OF CASE HISTORIES OF PATIENTS WITH RUPTURE OF TENDONS

Rupture of Extensor Tendons on Distal Phalanx of the Fingers

CASE 1 J. L. (W. 117636) Female aged 50 years. The injury occurred during the removal of stockings. The tips

Fig. 12 left Rupture of flexor digitorum profundus tendon from its insertion in the distal phalanx of the right ring finger. Operative repair 6 months after the injury was only partially successful due to the great amount of peri articular fibrosis following associated dorsal dislocation.

Fig. 13 Typical deformity of the left ring finger following rupture of the extensor tendon at its insertion into the distal phalanx. The finger is shown in complete flexion and extension.

extension. The last phase of extension of the proximal phalanx and of the first metacarpal is also lost. Abduction and adduction of the thumb are weakened. The thumb cannot be brought to the radial side of the index finger but is displaced somewhat volarward (Hauck). Rarely the two ends of the tendon may be felt over the meta carpal and under the dorsal carpal ligament.

Operative repair is the only treatment worth considering. Splinting in hyperextension has never lead to spontaneous repair. On opening the canal and sheath the tendon ends will be found frayed and brush like, yellowish white in color and often quite soft. Except in very recent cases the great displacement cannot be overcome by pulling on the ends or extension of the wrist. This fact, together with the necrosis of the ends makes end to end suture difficult or impossible. The tendon stumps are so changed here that they are not suitable for any plastic work. The tendon may be lengthened by one of the various operations described for this procedure and in this fashion suture may be possible. Suture of the distal end to a slip split from the extensor carpi radialis longus has long been practiced and has given some good results. In some instances success has been attained by suturing the two stumps to an adjacent tendon. After union of the stumps with the tendon has taken place the operative field is again exposed and the adherent stumps with their uniting section of normal tendon are

separated longitudinally from the sound tendon. Replacement of the tendon by silk catgut or preserved tendon may also be tried. Silk seems to be best for this service. Autoplastic tendon grafts are however the most logical means of closing the gap between the two divided ends. This graft may be taken from the dorsum of the foot or from the palmaris longus should be sutured into place after careful trimming of the ends of the injured tendons, and should be surrounded by its own paratenon (Fig. 9). It is probably not necessary to repair the dorsal ligament. Other types of autoplastic grafts, fascial, arterial, venous or the cutis strips as used by Rehn, present no advantage over tendon and lacking paratenon are probably not so good.

Whatever the technique used to secure union the thumb should be held out in complete extension by means of plastic or aluminum splints for 2 or 3 weeks after which active and passive motion combined with physical therapy should be started. The functional results appear to be quite good.

RUPTURE OF FLEXOR TENDONS

Traumatic subcutaneous rupture of the normal flexor tendon is extremely rare. We have seen but two cases and only a few have been reported (Schlatter, Stapelmohr). It appears to follow a sudden extension of a tightly flexed finger as in the case reported by Schlatter in which the pa-

was carefully dissected away and the ends of the extensor pollicis brevis were sutured. Eight years later the patient had excellent use of the hand and no evidence of return of the process.

CASE 3 M S (W 103348) Female aged 26 years. Tuberculous tenosynovitis of the right wrist and palm. The process began as a flexion deformity of the little finger some 10 years previous to operation. Later a swelling appeared on the wrist and palm associated with much pain which radiated up the forearm. Except for the flexion contracture of the ring and little fingers there was no motor disability. The tuberculous process was found to have involved the ulnar bursa and to have spread into the midpalmar space. The flexor tendons of the ring and little fingers were fragmented and shredded and after removal of the tuberculous tissue it was necessary to suture them. No reply to numerous inquiries.

CASE 4 W T C (W 112774) Male aged 50 years. Tuberculous tenosynovitis of the flexor tendons of the left wrist. There was extensive involvement with marked infiltration and thickening. The flexor digitorum sublimis to the little finger had been completely divided by the process while several other tendons especially the flexor pollicis longus were badly fragmented. All the tuberculous tissue was carefully dissected away and the distal stump of the divided tendon sutured to the corresponding tendon of the ring finger. The patient made an uneventful recovery but died 2 months later from a cardiac attack.

CASE 5 P M (W 117167) Female aged 33 years. Massive tuberculous tenosynovitis of the right wrist (Fig 14) which began with swelling of the little finger and wrist 10 years previously. There was considerable pain and numbness and the patient could not completely flex the fingers. At operation the sheaths of both radial and ulnar bursae were found to be markedly thickened and infiltrated with grayish red granulation tissue. The flexor digitorum sublimis tendons to the little and ring fingers were destroyed from a point just proximal to the wrist downward to the middle of the palm. The tuberculous tissue was removed the sublimis tendon of the ring finger sutured to that of the middle finger and the sublimis of the little finger sutured to its profundus tendon. Healing occurred *per primam*. Two and one half years later the anatomical function was perfect (Fig 14).

CASE 6 O P (W 122957) Male aged 31 years. Tuberculous tenosynovitis of the dorsum of the left wrist. The process began 3 years previously following an injury and had been operated upon twice elsewhere without results. There was slight impairment of extension of the wrist and fingers. At operation there was found extensive involvement of all the sheaths on the dorsum of the wrist. There were no ruptured tendons but all were remarkably small some thread like. The tuberculous tissue was all dissected away and the incision closed. Healing *per primam*. No reply to follow up letters.

CASE 7 G K (W 130020) Tenosynovitis of the sheath of the flexor tendons of the index finger. Five months previously the patient cut the finger with a piece of glass. The wound healed properly but a month later began to cause pain and swelling developed which has persisted. There was some slight impairment in flexion of the finger. At operation the sheath of the flexor tendons was found to be infiltrated by a mass of soft tuberculous granulation tissue. One slip of the flexor digitorum sublimis was infiltrated for a distance of an inch and this along with the other tuberculous tissue was removed. Healing took place by first intention and with physical therapy full function returned.

CASE 8 B M (W 134930 137,99 P, 08) (Figs 10 and 11) Tuberculous tenosynovitis of all tendons on the

dorsum of the right wrist. Two and one half years previous to admittance to the hospital the patient sprained the wrist following which a walnut sized lump developed. Three operations had been performed previously for removal of this mass but each time it had recurred. Upon examination there was found a tense irregular nodular swelling lying over the extensor tendons on the wrist. This was found to be tuberculous at operation and was cleanly dissected. The wound healed well and the man returned to work with free use of the hand. Four months later a recurrence about the extensor pollicis longus and brevis and abductor pollicis longus was excised and at this time the tendon of the extensor pollicis longus was found to be slightly invaded. The tuberculous tissue was excised and the involved strip of extensor pollicis longus was excised. Healing was prompt but recurrence took place 12 to 14 months later. At the third operation the extensor pollicis brevis was found to have been entirely destroyed and the extensor pollicis longus so involved that a large section had to be removed. This was replaced by a graft taken from the dorsum of the foot. The thumb was functioning perfectly 2 months after operation (Fig 11).

CASE 9 W Cr (W 141304) Male aged 58 years. Tuberculous tenosynovitis of both wrists on flexor surface. The process began with pain and swelling in the left hand 3 years ago and has slowly increased since the onset. He cannot fully extend the fingers but there is no loss of movement. At operation on the right hand the deep flexors to the index and middle fingers were found to be invaded and partially destroyed and the sublimis tendons to the same fingers were somewhat infiltrated. There was some involvement of the radiocarpal joint. After removal of the tuberculous tissue the distal stumps of the profundus tendons to the index and middle fingers were sutured to the sublimis tendons of the same fingers. (The left hand was operated upon later but the tendons were not invaded.) Healing occurred *per primam* and excellent function resulted.

CASE 10 R W (W 142434 144308) Female aged 28 years. Tuberculous tenosynovitis of right wrist. The condition began a year previously with intermittent pain and swelling of the wrist. Gradually the swelling reached the palm and volar surface of the thumb since which time the swelling has not receded. There was considerable limitation of motion in the fingers and thumb but no movement was lost except flexion of the interphalangeal joints of the fifth finger. At operation considerable involvement was found to be present. The radial bursa was invaded distally to the insertion of the flexor pollicis longus the ulnar bursa well into the palm but not into the little finger and the sheath of the flexors of the index finger were found to be infiltrated. Both flexor tendons to the little finger had been destroyed in the wrist and their distal stumps were sutured to the adjacent tendons of the ring finger. The condition recurred above the wrist 5 months later and a second operation was necessary. Function was returning in the fifth finger at that time.

The writer is indebted to Dr. Allen B. Kanavel and Dr. Sumner I. Koch for permission to study and report the cases upon which this article is based.

of the actively extended fingers were caught in the seam at the top of the hose. The patient heard a snap and experienced a sharp pain in the right middle finger. On examination he found she could no longer extend the distal phalanx. At operation 2 weeks following the injury the extensor tendon was found to have ruptured across at the level of the joint. It was repaired with fine silk and the finger splinted in extension. In reply to an inquiry 1 year later the patient reported complete functional recovery (Fig. 5).

CASE 2 I D (W 137424) Male. The right middle finger was caught in a closing garage door in such a manner that both interphalangeal joints were sharply flexed. The typical deformity resulted immediately (Fig. 2). The injury was treated elsewhere on a splint in extension but on removal of the splint the deformity recurred at once. Operative repair of the ruptured tendon was performed several weeks after the injury, and the man wore a metal splint for a number of weeks. Final result not known.

CASE 3 H B (W 140720) Male aged 45. While rubbing a spot off the leather upholstery in his car the tip of the left index finger caught on a button or some other projection; the patient heard a snap and noted that the finger tip was flexed. He had been unable since then to extend the distal phalanx of the finger. A month and 10 days later he presented himself for treatment. The finger tip was flexed at about 120 degrees at rest and could be flexed to 90 degrees and extended back again to 120 degrees, i.e. there was motion through an arc of 30 degrees. On operation the extensor tendon was found to have torn loose from its attachment to the distal phalanx. The tendon had healed and pull upon it extended the distal phalanx. It was however too long to effect complete extension. Repair was done by making a step-cut incision through the tendon scar and overlapping the two stumps. The finger was then put up in hyperextension of the distal phalanx. Healing occurred *per primam*. Two months later the terminal phalanx could be extended to 170 degrees. Motions were still slightly stiff but improvement was looked for.

CASE 4 H R B (W 141453) Male aged 42. One month previously while taking an automobile tire from a high shelf he was struck on the tip of the left ring finger by the falling tire. There was no great pain associated with the accident but the finger tip was flexed and could not be extended. It was brought back into position and a splint applied but the deformity recurred as soon as the splint was removed. The typical deformity and degrees of movement of the finger are shown in Figure 13. At operation the tendon was found to have healed but in a lengthened state so that shortening was necessary. This was accomplished by dividing the tendon obliquely overlapping the ends and suturing them with silk. The finger was then placed in moderate hyperextension. Healing *per primam*.

Rupture of Extensor Tendons of the Proximal Interphalangeal Joint

CASE 5 S V (W 121751) Male aged 16. Three years previous to entrance into hospital the patient was struck on the end of the actively extended left ring finger by a swift baseball. This produced a sharp flexion of the finger at the proximal interphalangeal joint. It was immediately straightened out and placed in a splint which was left on for 6 days. On removal of the splint the deformity recurred but movement was so painful that he would allow no one to straighten the finger for several weeks. The pain gradually disappeared but the flexion deformity persisted. Upon examination 3 years following the injury the proximal interphalangeal joint of the left ring finger was found

to be flexed to a right angle (Fig. 7). The joint could not be actively extended but passive extension to an angle of 120 degrees was possible. Roentgen ray examination demonstrated an irregular shadow proximal to the joint which probably indicated a healed periosteal tear. At operation the tendon was found to be frayed over the joint and one slip displaced ulnarward. The displaced slip was brought to the midline where it was held by silk sutures. This procedure brought the joint into extension. The finger was then splinted in extension. We have received no answer to follow up letters.

Rupture or Dislocation of Metacarpophalangeal Joint

No examples

Rupture of Extensor Tendons at the Wrist (See cases of tuberculous tenosynovitis)

Rupture of the Flexor Tendons

CASE 6 M G (W 109,62) (Reported in text.) Male of 28 years struck on top of right middle finger with base ball causing backward dislocation of distal phalanx. Came to operation 4 months later at which time the flexor digitorum profundus was found to have ruptured from its insertion. It was sutured in place.

CASE 7 W C (W 139486) Male aged 40 (Reported in text.) Injury to right thumb occurred eight years previously while bucking an over-hoe. Rupture of flexor pollicis longus. Several operations performed previous to the time patient was seen by Dr Sumner L. Koch. Last operation July 1928 at which time a graft was made replacing about 2 1/2 inches of the degenerated tendon. Six months after operation patient states that the thumb is reasonably strong and can be used in grasping but that the tendon seems to be too short and interferes with extension.

Rupture of Tendons Due to Tuberculous Infiltration

In ten instances taken from a series of cases of tuberculous tenosynovitis of the hand rupture of tendons had taken place or was impending.

CASE 1 S K (W 86002) Female aged 60 years. Tuberculous tenosynovitis of flexor tendon of the right hand. Gradual onset 12 years before operation with stiffness in the fingers later swelling on anterior surface of left wrist and forearm. For some time she had been unable to flex the interphalangeal joints of the index finger. There was found extensive involvement of the radial and ulnar bursa above the wrist extending distally into the tendon sheaths of the thumb and little finger. The sheaths were distended with clear yellow fluid and a homogeneous mass of granulation tissue in places caseous. The flexor tendons of the index finger had separated at the level of the transverse carpal ligament as if cut or broken the severed ends still joined by a strand of fibrous tissue. After thorough removal of all tuberculous tissue the distal ends of the flexor tendons of the index finger were sutured to the corresponding tendon of the middle finger. The patient reported 8 years after the operation that function of the hand was excellent.

CASE 2 R S (W 94649) Male aged 28 years. Process began on the right wrist 10 months ago as slight swelling and pain which had gradually increased in size and severity. The tuberculous process was found to involve the sheaths of the extensor pollicis longus and brevis, abductor pollicis longus, extensor digitorum communis, extensor carpi radialis longus and brevis and the extensor digiti quinti proprius. The extensor pollicis brevis had been nearly separated by the process. The tuberculous tissue

AN OPERATION FOR TUBERCULOSIS OF THE EPIDIDYMIS

ARTHUR B. CLICHÉ, B. A. M. D. FACS, LOS ANGELES

From the People's Hospital and the Good Hope Hospital (China)

EPIDIDYMECTOMY for tuberculosis of the epididymis has not been an entirely satisfactory procedure. It has been found particularly unsatisfactory when done in the presence of sinuses. The operation as usually performed has in a great many instances been followed by breaking down of the wound by sinus formation and not uncommonly by loss of the testicle. These unsatisfactory results have led to illogical conclusions as to the proper method of dealing with this disease. Basing one's judgment upon the poor outcome from surgical treatment it has been recommended that tuberculosis of the epididymis be left entirely alone. It has been recommended that treatment be limited to the opening of abscesses when they occur irrespective of the fact that this leaves a persistent draining

sinus. In extreme cases as a result of this indecisive method of treatment it has not uncommonly been necessary to do a complete castration. Now, it is evident that a man is better off without tuberculosis of the epididymis than he is with it but he may be better off with it than to have his condition made worse by surgery.

The technique which I wish to describe has for its object the clean removal of the epididymis and sinuses and the securing of primary healing.

The stages of this technique are as follows: An tuberculous sinuses are painted with pure carbolic acid after the scrotum has been cleaned up. Next the scrotum is seized as shown in Figure 1 and gentle pressure is made above the testicle. An elliptical incision is then made through the skin around the sinus. Now while the pressure above

THE REFLUX OF PANCREATIC AND DUODENAL SECRETIONS THROUGH A DRAINAGE TUBE IN THE COMMON BILE DUCT¹

WALTMAN WALTERS M.D. F.A.C.S. ROCHESTER MINNESOTA

Division of Surgery The Mayo Clinic

AND

JAMES M. MARSHALL M.D. ROCHESTER MINNESOTA

Fellow in Surgery The Mayo Foundation

THE reflux of pancreatic and duodenal secretions through a drainage tube in the common bile duct is a somewhat rare and distressing postoperative complication of operation on the biliary tract. Scant mention of such occurrence is found in the literature and difficulty is encountered in finding the cases because they have not been reported under titles that might give clues to their identity. That such cases do occur, however, seems beyond question. Codman (1908) reported a case in which following operation for stone in the common bile duct, with perforation and abscess, there was profuse drainage of sour smelling bile stained fluid both through and around the rubber tube in the duct. The skin and tissues in contact with the draining fluid were digested and the patient's general condition declined rapidly. Codman recognized the complication and reoperated, closing the hole in the common bile duct. The patient recovered. Davis described two cases in which there was undoubtedly drainage of pancreatic and duodenal secretions from a tube in the common bile duct. Judd observed several such cases before the T tube came into use but none since. During the last 2 years we have observed this phenomenon in 4 cases. They are reported herewith.

CASE 1. The patient, a Sioux Indian, aged 48 years, came to the clinic October 17, 1921, complaining of recurring attacks of epigastric colic with jaundice. Twelve months and 9 months previous to admission he had had severe right upper abdominal colic like pains and had vomited morphine was required for relief. Each attack was followed by jaundice for a few days. During the few months prior to examination he had much upper epigastric discomfort and soreness with considerable gaseous indigestion but no colic. He had known he had diabetes mellitus and he had been on dietary treatment.

The serum bilirubin was 5.2 milligrams for each 100 cubic centimeters and the Van den Bergh reaction was direct. There was considerable tenderness under the right costal margin. The blood sugar was normal and the urine was free from sugar. All other laboratory tests were negative.

At operation November 1 the right upper quadrant of the abdomen was a mass of oedematous indistinguishable structures. There was a large stone about 2.5 centimeters in diameter which could be felt in the common bile duct. This was removed by opening the common bile duct directly over the stone. The stone was crumbly of the type

usually found in the common bile duct and was necessarily removed in fragments. After removal of the stone the duct was thoroughly washed out with a solution of sodium chloride. The diameter of the duct was about 2 centimeters and the finger could be easily passed up to the hepatic duct and down to the sphincter of Oddi which could be felt to be dilated abnormally. A No. 20 catheter was sutured into the duct with its end up in the hepatic duct. Further exploring was not done on account of the inflammatory condition of the area. The gall bladder was not seen. It was probably buried in the mass of oedematous tissue. Three Penrose drains were left in the wound.

Drainage through the tubes was profuse. On the third day the drainage reached 1,670 cubic centimeters and on the fourth day 3,860 cubic centimeters. The fluid was thin and had a rancid odor and the wound became red and inflamed. The patient appeared very ill. There was some leakage around the tube and the margins of the wound began to slough. The profuse drainage continued to be between 1,000 and 2,300 cubic centimeters daily until the tenth day when the tube was removed. After this there was drainage from the sinus for 48 hours, then it gradually stopped and the stools were of normal color. Tests were not made for the presence of enzymes. Fluids were given freely by mouth and subcutaneously and glucose 10 per cent and sodium chloride 1 per cent was given intravenously. A constant suction apparatus was used in the sloughing wound to keep it dry. After the drainage stopped the patient's general condition improved rapidly. The wound healed slowly but was completely healed on the twenty-ninth day after operation. The patient left the hospital on the thirtieth day free from jaundice and in good condition.

CASE 2. A woman aged 62 years came to the clinic November 20, 1923 complaining of recurring chills and fever, pain in the upper part of the abdomen and jaundice. Cholecystectomy had been performed elsewhere 10 months previously. It was reported that the gall bladder was full of mud bile but it did not contain stones. Recovery from the operation had been uneventful. In August 1923 pain had appeared in the upper part of the abdomen with chills and fever up to 102 degrees F. Recovery without jaundice took place in 1 week. October 23 there was a recurrence of the chills and fever with marked weakness and jaundice. These symptoms persisted until admission to the clinic November 20.

The patient was emaciated and deeply jaundiced. The serum bilirubin was 18 milligrams for each 100 cubic centimeters and the Van den Bergh reaction was direct. The coagulation time was 17 minutes. The hemoglobin was 60 per cent, erythrocytes numbered 3,170,000 and leucocytes 6,000. She was kept under observation in the hospital for several days. The serum bilirubin and coagulation time remained high and repeated duodenal drainage was negative for bile. Five cubic centimeters of 10 per cent calcium chloride was given intravenously for 3 days and 500 cubic centimeters of citrated blood was given on the day of operation.

Fig 8 Vas pushed up through incision in groin. Clamp and vas wrapped in gauze and strapped to abdomen. Vas sutured to stab wound.

the testicle is still maintained with the hand very light elliptical cuts are made concentrically dividing bands of tissue directly down to the tunica vaginalis. These concentric cuts are kept close around the elliptical skin incision. It will be seen that if the cuts are kept close to the central portion of skin a thick scrotal wall will be maintained also the opening of any abscesses may be avoided as these can be seen and the tissues can then be cut lightly further out. As the cuts are made the testicle and epididymis begin to extrude from the scrotum at the same time one can easily see and ligate every bleeding point. This is important to insure a dry scrotal bed to which to return the testicle.

In this manner the testicle is extruded through the wound rather than delivered as is done when a so called high incision is made and trauma is avoided. The scrotum which has not been in any way contaminated is immediately wrapped with salt packs covered with a towel and kept absolutely surgically clean. Packs under the testicle complete the preparations for epididymectomy are complete. The tunica vaginalis is opened and the epididymis is separated from the testicle (Figs 3 and 4). The epididymis and testicle are both wrapped in warm salt packs and set aside (Fig 5). A clamp is pushed up along the vas

Fig 9 Closure of scrotum by through and through dermal suture without drainage.

until it corresponds with the external ring (Fig 6). A small nick is made over the tip of this clamp and another clamp is pushed down along the same path (Fig 7). This clamp is used for clamping off the vas (Fig 7). The vas is cut between two clamps thoroughly carbolyzed. The clamp and vas are then drawn upward to bring the vas out in the groin but at no time is the clamp removed from the vas nor is the vas ligated as all such attempts are likely to infect the wound.

A single stitch is passed through the nick (Fig 8). This stitch passes through the outmost covering of the vas. The clamp with the vas still fastened in it is wrapped in gauze and strapped to the abdomen (Fig 8). The scrotum is pulled down over the testicle and closed by interrupted dermal sutures. The wound is covered with colodion. The scrotum is supported with a binder.

In about 7 or 8 days the vas comes away at the level of the skin much as the umbilical cord shrivels and dies. In some instances the vas has seemed to keep up its blood supply, and in these cases a ligature of catgut has been lightly tied around the vas at the skin level thereby causing it to slough away.

ADVANTAGES

The advantages of this operation over the so-called high incision procedure are

- 1 At no time is the scrotal bed soiled
- 2 Extrusion of the testicle through the scrotum with the sinus formation attached avoids multiple incisions
- 3 Trauma is avoided
- 4 The entire thickness of the scrotum is preserved
- 5 Bleeding points can be seen and taken up as concentric cuts are made
- 6 The vas is not allowed to soil the wound
- 7 The wound heals per primam in a large majority of instances

THE REFLUX OF PANCREATIC AND DUODENAL SECRETIONS THROUGH A DRAINAGE TUBE IN THE COMMON BILE DUCT¹

WALTMAN WALTERS M.D. F.A.C.S. ROCHESTER, MINNESOTA

Division of Surgery The Mayo Clinic

Davis described two cases in which there was undoubtedly drainage of pancreatic and duodenal secretions from a tube in the common bile duct. Judd observed several such cases before the T-tube came into use but none since. During the last 2 years we have observed this phenomenon in 4 cases. They are reported herewith.

CASE 1 The patient a Sioux Indian aged 48 years came to the clinic October 17, 1927 complaining of recurring attacks of epigastric colic with jaundice. Twelve months and 9 months previous to admission he had had severe right upper abdominal colic like pains and had vomited morphine was required for relief. Each attack was followed by jaundice for a few days. During the few months prior to examination he had much upper epigastric discomfort and soreness with considerable gaseous indigestion but no colic. He had known he had diabetes mellitus and he had been on dietary treatment.

The serum bilirubin was 5.2 milligrams for each 100 cubic centimeters and the Van den Bergh reaction was direct. There was considerable tenderness under the right costal margin. The blood sugar was normal and the urine was free from sugar. All other laboratory tests were negative.

At operation November 1 the right upper quadrant of the abdomen was a mass of edematous indistinguishable structures. There was a large stone about 2.5 centimeters in diameter which could be felt in the common bile duct. This was removed by opening the common bile duct directly over the stone. The stone was crumbly of the type

usually found in the common bile duct and was necessarily removed in fragments. After removal of the stone the duct was thoroughly washed out with a solution of sodium chloride. The diameter of the duct was about 2 centimeters and the finger could be easily passed up to the hepatic duct and down to the sphincter of Oddi which could be felt to be dilated abnormally. A No. 20 catheter was sutured into the duct with its end up in the hepatic duct. Further exploring was not done on account of the inflammatory condition of the area. The gall bladder was not seen. It was probably buried in the mass of edematous tissue. Three Penrose drains were left in the wound.

Drainage through the tubes was profuse. On the third day the drainage reached 1,670 cubic centimeters and on the fourth day 3,360 cubic centimeters. The fluid was thin and had a rancid odor and the wound became red and inflamed. The patient appeared very ill. There was some leakage around the tube and the margins of the wound began to slough. The profuse drainage continued to be between 1,000 and 2,500 cubic centimeters daily until the tenth day when the tube was removed. After this there was drainage from the sinus for 48 hours then it gradually stopped and the stools were of normal color. Tests were not made for the presence of enzymes. Fluids were given freely by mouth and subcutaneously and glucose 10 per cent and sodium chloride 1 per cent was given intravenously. A constant suction apparatus was used in the sloughing wound to keep it dry. After the drainage stopped the patient's general condition improved rapidly. The wound healed slowly but was completely healed on the twentieth day after operation. The patient left the hospital on the thirtieth day free from jaundice and in good condition.

CASE 2 A woman aged 62 years came to the clinic November 20, 1928 complaining of recurring chills and fever pain in the upper part of the abdomen and jaundice. Cholecystectomy had been performed elsewhere 10 months previously. It was reported that the gall bladder was full of mud bile but it did not contain stones. Recovery from the operation had been uneventful. In August 1928 pain had appeared in the upper part of the abdomen with chills and fever up to 102 degrees F. Recovery without jaundice took place in 1 week. October 25 there was a recurrence of the chills and fever with marked weakness and jaundice. These symptoms persisted until admission to the clinic November 20.

The patient was emaciated and deeply jaundiced. The serum bilirubin was 18 milligrams for each 100 cubic centimeters and the Van den Bergh reaction was direct. The coagulation time was 17 minutes. The hemoglobin was 60 per cent erythrocytes numbered 3,100,000 and leucocytes 6,000. She was kept under observation in the hospital for several days. The serum bilirubin and coagulation time remained high and repeated duodenal drainage was negative for bile. Five cubic centimeters of 10 per cent calcium chloride was given intravenously for 3 days and 500 cubic centimeters of citrated blood was given on the day of operation.

¹Submitted for publication August 29, 1929.

At operation December 11 the common bile duct was found to be dilated to a diameter of approximately 2 centimeters. It was opened with the drainage of about 250 cubic centimeters of greenish bile. Scoops were introduced into the lower part of the duct and appeared to enter the duodenum through the ampulla. It was not possible to trace the duct upward to the liver. In view of the extreme jaundice and the patient's poor general condition it seemed advisable to attempt only drainage of the duct. Structure in the upper portion of the duct seemed the most likely cause for the obstruction but the accumulation of a large amount of bile in the lower part of the duct made it seem probable that the upper part of the duct was patent. A Mayo-Robson hepaticus drain was inserted in the common bile duct pointing downward toward the duodenum and the opening of the duct was stitched around it. There is a possibility that a stone was pushed into the duodenum. The abdomen was closed and two Penrose drains were left in the wound.

During the first few days there was an increasing amount of drainage of thin flocculent bile colored, sour smelling liquid reaching 1,400 cubic centimeters on the sixth day. Methylene blue given by mouth came through the tube copiously. Analysis of the fluid showed the presence of considerable starch splitting enzyme. There was no leakage around the tube and the wound and skin were not irritated. Fluids were given liberally by mouth and intravenously in the form of physiological sodium chloride solution and the chemistry of the blood was kept within normal limits. By the tenth day the drainage began to diminish and there was bile in the stools. The Mayo-Robson tube was removed on the eighteenth day, the color of the stools was normal. The patient left the hospital on the twenty ninth day in good general condition and with the wound healed. In a recent letter she reported that she has remained in good health.

CASE 3. A woman aged 62 years came to the clinic April 25, 1929 complaining of recurring attacks of colic in the right upper part of the abdomen of 3 1/2 years duration. Cholecystectomy had been done elsewhere in December, 1921, and stones were found in the gall bladder. The colic continued after operation even more severe than before. Jaundice had not been present.

Examination disclosed mild general arteriosclerosis, the systolic blood pressure was 180 and the diastolic was 88. Tenderness was elicited in the right upper quadrant of the abdomen in the region of the old operative scar. Examinations of the urine and blood including the Wassermann reaction on the blood were negative. The serum bilirubin was 1.2 milligrams for each 100 cubic centimeters and the Van den Bergh reaction was indirect. The blood urea was 28 milligrams for each 100 cubic centimeters. Roentgenograms of the chest, stomach, kidneys, ureters and the urinary bladder were negative. Gastric analysis showed a total acidity of 60 and free hydrochloric acid of 40.

At operation April 30, 1929 a pouch about 1 centimeter in diameter was found in the stump of the cystic duct. The pouch was filled with small stones about 1 millimeter in diameter. The common bile duct was slightly enlarged. It was opened and explored with the finger tip down to the ampulla and stones were not encountered. The pouched stump of the cystic duct was dissected free and was removed. A medium sized T tube was sutured in place in the common bile duct. Examination of the duodenum, right kidney and pelvis was negative.

On the fourth postoperative day large amounts of foul smelling bile drained through the T tube 1,125 cubic centimeters in 24 hours and on the succeeding day 1,200 cubic centimeters. There was some leakage around the tube and the skin and margins of the wound became red

and irritated. Laboratory examination of this drained fluid showed the presence of considerable starch splitting enzyme. Methylene blue given by mouth appeared in the drainage material within a few minutes. Believing that we were dealing with a reflux of pancreatic and duodenal secretions we began clamping the tube in an attempt to force the bile down into the duodenum and establish the normal direction of flow. Fluids were given freely by mouth and intravenously in the form of physiological sodium chloride solution and the chemistry of the blood stayed within normal limits. Bile appeared in the stools. The T tube was removed on the thirteenth day. There was profuse drainage from the fistula for 24 hours and then the fistula closed rapidly. It was completely closed on the seventeenth day. Dry radiant heat was applied to the wound and a soothing application was applied to the irritated skin. By the seventeenth day all signs of irritation had disappeared and the patient left the hospital on the eighteenth day in good general condition.

CASE 4. A man aged 58 years came to the clinic May 30, 1929 complaining of recurring attacks of severe pain in the upper part of the abdomen. Twenty two years before he had had a severe attack of colic followed by jaundice. The colic recurred at infrequent intervals until operation was performed elsewhere in April, 1928. Cholecystostomy was done and stones were removed from the gall bladder. The wound drained for 3 1/2 weeks and then closed. He was then well until 6 weeks before admission when he had a severe typical attack of gall tone colic and one week later he noticed dark urine and clay colored stools. During the 3 weeks prior to admission he had had 3 attacks of upper abdominal pain with chills and fever, the last one with jaundice 10 days before admission. Otherwise he had a rather typical history of peptic ulcer dating back 8 or 10 years with pain coming on 2 to 3 hours after meals and relieved by taking food or alkaline powder.

The patient was somewhat emaciated and 23 pounds under his usual weight. He was faintly jaundiced, the serum bilirubin was 4.3 milligrams for each 100 cubic centimeters and the Van den Bergh reaction was direct. Tenderness was elicited in the right upper part of the abdomen. The blood urea was 34 milligrams for each 100 cubic centimeters. Roentgenograms of the stomach and duodenum showed duodenal ulcer. All other laboratory examinations were negative.

At operation June 6 the gall bladder was found to be somewhat distended but did not contain stones. The common bile duct was opened and was explored with a scoop but stones were not found. The scoop passed readily through the ampulla into the duodenum. There was a large subacute duodenal ulcer on the anterior surface of the duodenum. The patient's general condition was not good so a rubber catheter was stitched into the jejunum after the method of Witzel instead of gastro-enterostomy. This was brought out through a stab wound in the left rectus abdominis muscle. A Mayo-Robson hepaticus drain was left in the common bile duct and a dressed tube was left in the gall bladder.

During the first 4 days after operation there was profuse drainage of a rancid, sour smelling, thin flocculent bile colored fluid 1,115, 1,530 and 1,425 cubic centimeters respectively. Methylene blue given by mouth appeared copiously in the drainage material. Examination of the material showed the presence of a large amount of starch splitting enzyme. On the third day the blood urea was 67 and on the fourth day 74 milligrams for each 100 cubic centimeters and the patient appeared extremely ill. The margins of the wound were reddened and irritated from contact with the drainage material. On the fourth day the end of the Mayo-Robson drain was connected directly

with the jejunostomy tube so that the fluid draining from the common bile duct was poured directly back into the jejunum. The patient was given fluids in abundance including physiological sodium chloride solution intravenously 2,000 cubic centimeters daily. He seemed to improve but on the seventh day bronchopneumonia developed and he died on the eleventh day.

At necropsy the Mayo-Robson tube was found in place in the common bile duct. There was slight necrosis of tissue around the tube as it coursed over the duodenum. The common bile duct was 12 millimeters in diameter and there was a stone 6 by 8 millimeters impacted in the ampulla. The pancreatic duct entered the common bile duct 1 centimeter above the sphincter of Oddi and therefore proximal to the impacted stone. Other stones were not found in the ducts or gall bladder. A large subacute ulcer on the anterior surface of the duodenum and two smaller ulcers on the posterior wall were found. The lungs showed extensive bilateral bronchopneumonia.

SUMMARY AND COMMENTS

Certain features were common to all of the cases. There was a copious amount of drainage material, in each case amounting to more than 1,500 cubic centimeters in 24 hours. The draining fluid was thin flocculent and had a sour, rancid odor. Methylene blue given by mouth appeared promptly in the drainage material. Pancreatic enzymes were found in the drainage material in two of the cases (Cases 2 and 4). In one case (Case 3), in which there was leakage around the tube, there was considerable irritation and actual digestion of the skin and tissues around the wound such as is typical in pancreatic and duodenal fistulae. All of the patients appeared to be more seriously ill than is usual in disorders of the common bile duct. In Case 2 the reflux stopped after 4 or 5 days and the patient recovered uneventfully. In Case 3 it was possible to force the bile down through the duct by clamping the T tube gradually the reflux was overcome and recovery ensued. In Case 4, when it was found that reflux was present the Mayo-Robson tube was connected to the jejunostomy tube by means of a glass tube connector. Thus the bile and duodenal secretions that were draining from the tube in the common bile duct were poured directly back into the jejunum. This seemed to be an ideal arrangement under the circumstances. The patient began to improve but pneumonia set in and he died on the eleventh day from bilateral bronchopneumonia. In Case 1 the profuse drainage stopped soon after the drainage tube was removed and recovery followed.

The reason why there should be a reflux is not clear. Higgins and Mann working on healthy guinea pigs saw portions of test meals injected into the duodenum pass directly into the common bile duct. McArthur reported that reflux of barium from the duodenum coated a stone in the

common bile duct. Certainly in most cases of obstruction of the common bile duct such phenomena do not occur. Codman suggested that pressure of the root of the mesentery on the transverse portion of the duodenum causing back pressure was an etiological factor in his case. Abdominal distention with partial or complete ileus might be a contributing factor, especially when it occurs in cases in which the atonic duct and sphincter of Oddi are dilated. In all of the cases dilatation of the common bile duct was marked, and a sphincter was present through which a large sized scoop could be readily passed into the duodenum. This undoubtedly is a factor which tends to facilitate reflux but the presence of an additional factor seems necessary because of the many cases of dilated ducts in which such a phenomenon does not take place. It is possible that in cases in which the pancreatic duct empties into the common bile duct well up in the ampulla that a spasm below the opening or a stone impacted in the tip of the ampulla causes reflux of pancreatic secretion up the common bile duct and out of the drainage tube. Such a stone was found in Case 4 of the series.

The abnormal physiological changes in these cases are essentially the same as those in external duodenal fistula. Walters and Bollman emphasized the significance of the loss of fluids and chlorides in such cases and found that complete loss of pancreatic fluid is incompatible with life for more than a short period.

The early diagnosis of the complication is important. Drainage of more than 1,000 cubic centimeters of bile in 24 hours if it persists should arouse suspicion. If pancreatic and duodenal secretions are present the drainage material is thin often flocculent, and has a sour rancid odor. If it comes in contact with the skin or tissues in the wound, there is hyperemia and later actual digestion of tissue. Methylene blue given by mouth should appear in considerable amounts in the drainage material a few minutes after its ingestion. Finally laboratory examination of the fluid will reveal the presence of digestive enzymes.

The treatment of such cases should be directed toward the prevention of the loss of these secretions and to combat the effect of the loss. It is essentially the same as for external duodenal fistula. Effort should be made to re-establish flow in the normal direction. Fluids should be given in abundance orally subcutaneously and intravenously to keep the chemistry of the blood within normal limits and to restore fluid and chemical loss. If under conservative and supportive treatment the condition does not promptly correct

itself, jejunostomy may be done. The draining fluid can then be injected into the jejunum with a syringe or by directly connecting the drainage tube of the common bile duct with the jejunostomy tube as was done in Case 4. I have successfully treated duodenal fistula by passing a tube by mouth into the proximal portion of the jejunum and feeding through the tube.

CARCINOMA OF THE THORACIC PORTION OF THE ESOPHAGUS

CARL IGGER, M.D., F.A.C.S., NEW YORK

IN spite of the stimulus given esophageal surgery by the successful removal of carcinoma of the thoracic portion of the esophagus in a few cases, and in spite of the numerous and ingenious methods proposed, progress in this difficult field of surgery continues to be slow.

Sixteen years have passed since Torek reported his first successful case of resection of the thoracic portion of the esophagus for carcinoma. Hopes were raised at that time that one successful case would rapidly be followed by others. Unfortunately this has not proved true. In analyzing the reasons for this, it is at once apparent that no progress can be made until patients in better general condition and with the local lesion less advanced than is usually the case are referred to the surgeons.

The disease is insidious in its onset and the flexible esophagus is able to accommodate itself to the expansion of a new growth until actual obstruction occurs. At the time medical aid is sought it is often beyond the operable stage. The patients themselves are usually in poor general condition, they frequently have emphysema, myocarditis, arteriosclerosis or nephritis and are poor operative risks even if the local lesion is amenable to treatment.

In the report of my first successful case of esophagus resection in 1915 I mentioned the difficulties connected with esophageal surgery and called attention to the various methods employed to overcome them. It was pointed out that even in a so-called favorable case the operation is a formidable one. It is no wonder that

surgeons hesitate to operate and that medical men are averse to referring their patients for a radical operation.

All important surgical procedures have taken time to develop and not until a so-called standard method has been employed in a large series of cases has it been possible to reduce materially the mortality. It is so with esophageal surgery. It appears necessary to establish the operation of resection of the esophagus on a firm basis in order to gain the confidence of the medical profession as well as the public. For this reason every case should be reported; hence I present my second successful resection in detail.

Mrs. A. I., aged 55 years, came under my care January 23, 1919, with an established diagnosis of obstruction of the esophagus for the relief of which a gastrostomy had been done at another hospital in November, 1918.

She stated that the first symptoms were noted about 7 months before when in June, 1918, she experienced difficulty in swallowing. Food seemed to stick opposite the lower end of the sternum. After taking some water it would be washed down. About the same time she began to have a little sticking pain under the sternum at intervals. It was never severe and sometimes disappeared entirely. She paid no attention to the symptoms and did not inform her family of her condition until 3 months after the onset. A careful medical examination made at that time was followed by an X-ray examination which disclosed an esophageal obstruction (Fig. 1).

Of late the patient had complained a great deal of burning pain under the sternum, occasional pain in the back, and loss of weight and strength. There was nothing in the past history which had any bearing on her present complaint. Except for nervousness and a disposition to worry she had been quite well.

The physical examination showed no evidence of organic disease. She was thin and looked as if she had lost weight.

Her weight was 128 $\frac{1}{4}$ pounds whereas her normal weight would have been 15 pounds. She was cheerful and rather anxious to undergo an operation for the relief of her symptoms. The gastrostomy functioned well and since its establishment she had been able to take fluids by mouth in moderation. There was considerable pain during deglutition.

A clinical diagnosis of carcinoma had been made the family of the patient had been thoroughly familiarized with the prognosis if the condition were left untreated and they had also been informed of the dangers of surgical interference. They desired operation if there were any prospect of removing the growth. The patient's general condition was quite satisfactory her heart action was good the lungs were clear and she had no kidney disease. The entire question hinged on operability of the lesion. There were no metastases to be felt and the X-ray examination of the chest showed no abnormal shadows. For the purpose of doing a biopsy to establish the diagnosis definitely and to help determine operability the patient was admitted to the Lenox Hill Hospital. An oesophagoscopy and biopsy were done by Dr. John D. Kernan who reported an ulcerating lesion beginning at about the level of the arch of the aorta. He felt that the tumor was operable. The pathological report by Dr. Frederick D. Hullock showed squamous cell epithelioma deeply infiltrating the muscular wall.

In spite of a carefully supervised diet the patient continued to lose weight. Nevertheless we considered her rather a better risk than the usual patient with oesophageal carcinoma and operation was decided on.

Operation was performed February 6, 1929, under gas oxygen-ether anesthesia administered by Dr. Charles Sanford using the Gwathmey apparatus. The patient was placed on her right side and an incision was made along the left seventh intercostal space for almost its entire length and was then carried upward posteriorly behind the angle of the ribs over the seventh, sixth and fifth ribs. The ribs were divided the intercostal vessels ligated and the thorax opened. A rib spreader was inserted and good exposure obtained. The lung was not adherent and was soft. It was allowed to collapse partly in order to explore the mediastinal region. One small hard nodule suggestive of a metastasis was felt in the hilus of the lung. An incision was made through the parietal pleura along the inner margin of the aorta and the mediastinum was entered. The oesophagus was exposed below and freed from its bed. By means of a tape it was drawn upward. The plexus of vagus fibers which enveloped it was pushed aside and the branches were saved as much as possible.

The dissection of the oesophagus was continued upward and a hard nodular tumor was encountered just below the arch of the aorta and extending upward behind it. With great care partly by blunt partly by sharp dissection the tumor mass was gradually mobilized. A large nodule projected toward the right side and involved the right pleura. After a portion of this parietal pleura had been sacrificed the tumor could be completely mobilized. Moist gauze packs were inserted into the mediastinum under the oesophagus and the latter was then doubly ligated with heavy silk well below the tumor and divided between the ligatures with a cautery. The lower stump was inverted by a silk pursestring suture into the stomach and two separate silk sutures were placed over the pursestring to reinforce it. The parietal pleura above the arch of the aorta was now split, the oesophagus was isolated there and after it had been freed downward to the tumor mass it could be drawn upward from behind the arch. It was temporarily wrapped in moist gauze. Attention was now given to the mediastinum below the arch. Oesophagus and tumor had been removed and the bed was clean. Unfortunately the

Fig. 1. Oesophageal obstruction beginning at the level of the arch of the aorta.

right pleura was open but on account of the moist packing over the opening there had been no serious change in the patient's condition. The right pleura could not be grasped in order to close it but the soft tissues of the mediastinum were allowed to fall together and over this the left parietal pleura was carefully closed by continuous plain catgut suture from the undersurface of the arch to the diaphragm. This effectually reestablished two pleural cavities. The dissection of the oesophagus was now continued upward in to the neck. The lung in the upper part of the chest was quite adherent and offered some obstacles which were overcome. A hard nodule could be felt in the apex but whether it was a metastasis or an old fibrous tuberculous nodule could not be determined. When the oesophagus was sufficiently mobilized the patient was turned on her back. An incision was now made in front of the sternocleidomastoid muscle at the lowest part of the neck and by blunt dissection aided by a finger extending upward through the thoracic wound the oesophagus was liberated and the entire organ with the tumor at its lower end brought out of the neck wound. It was wrapped in moist gauze and temporarily left there. The patient was now again turned on her side and the thorax wound re-opened wide. The parietal pleura above the arch of the aorta was sutured with continuous plain catgut to prevent leakage of air into the neck. The thorax looked clean and dry. Drainage was established by means of a stab wound through one of the lower posterior intercostal spaces. A $\frac{1}{2}$ inch soft rubber tube was inserted and allowed to project 3 inches into the thorax. It was fastened to the chest wall by one suture. The lung was now fully inflated and the thoracic wound closed. Plain catgut was used to suture the intercostal

Fig Temperature chart first week after operation

tissues chromic catgut for the muscles of the chest wall and silk for the skin. The rib end approximated nicely without any difficulty. The wound was dressed and the patient turned on her back. Attention was now directed to the neck wound and the projecting esophagus. It was planned to remove the tumor with a safe margin of normal esophagus and then draw the esophageal stump through a subcutaneous tunnel and implant it on the upper thoracic wall. When I was ready to divide the esophagus I noticed a small tumor metastasis or implant in the muscular wall well above the main tumor. This necessitated division of the esophagus at a higher level than had been contemplated, leaving only a short stump which had to be implanted in the neck above the clavicle with some tension. It was first fixed to the neck muscles with a few catgut sutures to make retraction less likely and its open end was sutured to the skin with interrupted silk sutures. A small split tube drain was inserted next to the esophageal stump and a dry dressing was applied.

The patient stood the operation quite well. The complete operating time was 7 hours. The drainage tube with its end lower than the fluid level was connected with a drainage bottle in order to maintain closed drainage.

The patient reacted well after the operation. She was quite cyanotic for a while but by the following day the color was more normal. Respiration was a little difficult and jerky. There was a moderate amount of discharge from the esophageal stump and the dressing was there fore changed. Physical examination showed good resonance over both lungs with breath sounds heard all over. There

was drainage of about 100 cubic centimeters of sero-sanguineous fluid into the bottle during the first 4 hours.

The heart action was good and regular; the pulse was 120 and the temperature was 103.6 degrees. Her general appearance gave a good impression.

During the first 24 hours water was given by hypodermic syringe. Then administration of fluids through the gastrostomy tube was started and 4 ounces was given every 2 hours. An X ray of the chest made the day after operation showed both lungs completely expanded with no fluid at either base. The rib fragments were in perfect position.

On the second day the temperature and pulse rate fell somewhat (Fig. 1) and the patient looked better. There was only 100 cubic centimeters of drainage during the second 4 hours.

On the third day no drainage from the chest was noticed. The drainage tube was therefore removed and the wound was covered with a dry dressing. The drain from the neck wound was likewise removed as well as all the sutures from this wound except those holding the esophagus stump.

On the seventh day the patient was allowed out of bed. She was given fluids by mouth which were at first expelled through the esophageal stump and caught in a pus basin in order to clear out the tract. Then a rubber tube was inserted into the stump and connected with the gastrostomy tube (Fig. 3).

Thereafter the patient was permitted to take fluids by mouth and swallow them the normal way to pass down through her rubber esophagus into the stomach or she

was fed through the gastrostomy tube as she desired. At first she was somewhat timid about swallowing through the tube but after a while she became quite adept at it and had the pleasure of tasting food of which she had been deprived for some time.

Swallowing through the tube was never as satisfactory in this case as it was in Torek's case or in my first case. There was frequently leakage along side the tube, no doubt due to the shortness of the oesophageal stump. When the tube was put in too far it would impinge against the posterior pharyngeal wall or irritate the larynx and annoy the patient. The most troublesome condition however was regurgitation of food from the stomach all the way up through the rubber oesophagus into the throat. It took some time to learn to overcome this and the exact reason for it was never definitely determined. It seemed to be due to the fact that the stomach was constricted in its mid portion as the result of plication while performing the gastrostomy. The food entered only the distal or prepyloric region of the stomach and was regurgitated from there. Only if forcible pressure was made on the tube or vigorous swallowing efforts were made was the food distributed through the entire stomach. We were able to demonstrate this by means of a barium meal given through the gastrostomy tube.

Convalescence was uneventful aside from this and except for a great deal of pain at the site of the rib division. A superficial low grade infection developed which took considerable time to heal.

The patient was discharged March 31, 1929, well able to take care of herself. During the following months she continued to lose a little weight and she was never entirely free from pain which she referred chiefly to the upper part of her back and to the left shoulder region. On examination no metastases could be made out until May 28 when a deep-seated ill defined swelling was noted on the left side of the neck. When the patient was next seen a few weeks later a large mass had formed which occupied the region of and apparently involved the thyroid gland and the lymph nodes of the upper mediastinum and lower neck on the left side. It was quite fixed and surgically irremovable. There was no discharge from the oesophageal stump suggestive of ulceration of the mucosa and swallowing was not painful. Deep roentgen ray treatment was advised and is being continued at the present time. The mass has considerably shrunk in size. Roentgen ray examination of the lungs is negative for metastases and there are no symptoms or signs of disease below the diaphragm.

We were dealing with a patient 55 years of age who came to operation about 7 months after the onset of symptoms, which were then of an obstructive nature. Although the tumor was an epithelioma it was not of the flat variety but elevated and cauliflower like and therefore gave rise to difficulty with swallowing early in the disease. An X ray examination or an oesophagoscopy at that time would no doubt, have established this diagnosis and an operation would have given her a much better chance. As it was after months of symptoms with the associated loss of weight she was still a fairly good surgical risk but from the standpoint of cancer surgery her chances were considerably diminished. There is reason to believe that she had metastases at the time of

Fig 3 Rubber oesophagus connecting oesophageal stump with gastrostomy

operation but that could not be definitely established. Pain was an outstanding symptom in her case and that is usually prognostically a bad sign as it indicates involvement of the surrounding tissue.

Of interest in this case was the extension of the tumor into the opposite pleura, requiring resection of a portion of that layer. It has been found that patients do not stand opening of both pleurae well but that an acute pneumothorax supervenes from which they do not recover. By being able to suture the left parietal pleura, both above and below the arch of the aorta, this danger was averted, and X rays taken on the day after operation showed full inflation of both lungs.

Although this case with its present metastatic tumor of the neck presages an unsatisfactory outcome, it nevertheless has to be counted as a successful surgical case. Whether the patient is permanently cured is not the point at the present time. We all know that in cancer of the oesophagus we have to deal with the same conditions that we encounter in cancer affecting other organs and that we are likely to have recurrences and metastases until patients are referred for surgical treat-

ment sufficiently early to improve the prognosis from a cancer standpoint. The most important thing at the present time is to establish the feasibility of successful operative removal. In planning the operation it must be the aim of the surgeon to have the patient reasonably comfortable after its performance. To operate with results which make life unbearable for the patient is not justified.

It is recognized that patients may be quite comfortable with a gastrostomy and in the opinion of the majority of surgeons this is the pro-

cedure of choice as soon as the patient reaches the stage of inability to swallow. The operation, however, is not curative but simply palliative. If, in addition to performing a gastrostomy, the tumor can be removed a great deal has been gained. If, however, in addition to removal of the tumor mastication and deglutition can be re-established, even through a rubber oesophagus outside the body as in Torek's case and my 2 cases, we are still nearer the ideal which is the direct internal connection between the resected oesophagus stump and the stomach.

THE IMPLANTATION METHOD OF SKIN GRAFTING

OWEN H. WANGENSTEIN, B.A., M.D., F.A.C.S., MINNEAPOLIS, MINNESOTA

From the Department of Surgery of the University of Minnesota

In 1906 Wilhelm Braun of the Friedrichshain Hospital in Berlin described a new method of skin grafting. The method consisted in the implantation of small pieces of skin about 2 to 4 square millimeters in size directly into the granulations in such a manner that the implant just disappears from sight, much as one would deposit seed in the ground.

This is a very simple but effective means of covering a denuded area. An advantage of the method is that it can be employed in cases in which the commonly practised methods of skin grafting would fail. The only condition that must be fulfilled in employing the procedure is that granulation tissue must be present in the wound. The method, however, works well in the presence of infection and it is not necessary that the granulations be healthy. I have implanted these grafts with a satisfactory result into the granulations of a wound in which the wound edges were widely separated while faces from a colostomy were being discharged over the wound. I first employed the method in September 1915 in an aged man who developed a large pressure sore (Fig. 4) over one of the ischial tuberosities with considerable undermining of the skin following a thigh amputation for arteriosclerotic gangrene. As soon as granulations appeared in the wound these grafts were implanted and with surprising rapidity the defect became covered with epithelium.

We have employed the method now at the University of Minnesota Hospital in more than 60 cases. It is a method of transplantation of skin that can be used on ambulatory patients and on

a number of occasions we have used it in the outpatient department. In several of the instances in which we have employed these implantations, the Keverdin, the Davis, small deep or Thiersch grafts undoubtedly would have been satisfactory. The absolute indication for the method is in those cases in which other methods would fail, as in osteomyelitic cavities, chronic empyema cavities and decubitus ulcers with undermining of the skin. In a patient suffering from a paraplegia due to metastasis from carcinoma of the cervix uteri the method was employed in grafting a deep pressure ulcer that developed over the sacrum (Fig. 5). Shortly before the patient's death 7 weeks later a photograph (Fig. 6) showed that the defect was practically healed. The healing had taken place even though the patient lay on her back a good deal of the time and in spite of urinary and fecal incontinence.

TECHNIQUE

The skin employed for grafting is obtained in the same manner as Thiersch skin grafts are cut from the anterior surface of the thigh (Fig. 1). Skin sterilization is accomplished by applying two coats of half strength tincture of iodine followed when dry by a saturated solution of sodium thiosulphate in 70 per cent alcohol. Anesthesia of the area from which the skin is to be removed is obtained with infiltration of 1 per cent

This is the routine for paralytic ulcers. Hospital and
in the upper leg, the grafts are cut from the thigh and
my hand, the grafts are cut from the thigh and
duced 8 years ago by Dr. F. E. Richards, M.D., of the
in the hospital.

Fig. 1 Method of obtaining skin for implantation

procaine The surface into which the granulations are to be implanted is painted with 2 per cent mercurochrome. We have found that the implantation into the granulating surface can often be made without anæsthesia. When pain is complained of ethylene anæsthesia is given. The skin over the thigh is then held taut with two ordinary dinner plate knives and a thin sliver of skin about $1\frac{1}{2}$ to 2 inches in width is cut with an easy sawing motion with a straight edge razor or a sharp amputating knife. A piece of skin about 3 inches in length will serve to cover a very large skin defect by this method. With a fine sharp scissors this Thiersch graft is then cut into many small pieces from about 2 to 4 square millimeters in size and the small segments of skin are placed on a towel that covers a sterile board. An ordinary small straight sewing needle is then grasped end on with a small Kelly hemostat such that the eye of the needle is at the free end. The small pieces of skin are then impaled (Fig. 2) with the blunt end of the needle and pushed obliquely into the granulation tissue until the graft just disappears from sight (Fig. 3). An ordinary tissue forceps is used to retain the graft while the needle is being withdrawn.

The entire granulating surface is seeded in this manner the grafts being placed about 1 to 1.5 centimeters apart. An unusually large defect can

Fig. 2 Above The Thiersch graft is cut into small fragments about 2 square millimeters in diameter and these are impaled with the blunt end of an ordinary sewing needle

Fig. 3 Implanting the grafts

be covered with a small amount of skin by this method. It apparently does not matter whether the skin side of the graft is up or down. These grafts really constitute a tissue culture *in vivo* and should have a good chance of survival.¹

Fig. 4 A sketch made 10 days after implantation of grafts into a large undermined decubitus ulcer. The epithelial buds are sprouting and epithelium is being proliferated from the implants.

¹ In Peck Le skin is Cl. in C. E. S. W. skin is macerated and injected subcutaneously to the granulation with a needle and syringe. Attention of a method of the implantation of skin applied by Al. for more than 20 years should perhaps not be omitted. With a turette Al. makes small excisions in the granulation into each of which he places a fragment of skin about the size of the ordinary small deep graft.

Fig. 5 Sketch made at the time of implantation of a large decubitus ulcer in a patient with paraplegia (A sinus tract is incorrectly labelled fistula in the drawing)

Following the completion of the procedure the grafted area and the site from which the skin was removed are covered with vaseline gauze. No pressure need be applied to the surface where the skin has been implanted. After 3 or 4 days the vaseline gauze is removed from the grafted area.

Fig. 6 Photograph of the same lesion a few days before the patient died (carcinoma of cervix with metastases). The ulcer that was implanted is practically healed. There is a newly formed smaller decubitus ulcer below.

Fig. 7 Drawing made 14 days after implants were applied. An area of excavation is present about each implant. A single Thiersch graft was placed on the lower portion of the wound.

Fig. 8 left Photograph of same case taken a few days later

Fig. 9 Condition on discharge area practically healed but cosmetic result not very satisfactory. The skin is thin and with numerous large vessels in the regenerated epithelium

Fig. 10 left Condition on dismissal from the hospital, good cosmetic result in an extensive burn in which the implantation method of skin grafting was employed

Fig. 11 Lateral view of same patient a few small areas were uncovered at time of discharge. Subsequent examinations show the result to be very satisfactory

and similar strips are placed around the periphery of the wound and Dakin's solution is applied to the grafted surface sufficiently often to keep the discharge minimal. Bathing of the wound with Dakin's solution will not wash off the grafts.

After about 8 days the implants make their appearance as whitish necrotic areas. These rapidly increase in size and a thin layer of epithelium spreads out from these implants gradually covering the granulations. In some of the earlier cases grafted by this method a depressed area was frequently present in the granulations about the implant (Fig. 7). However since smaller grafts have been implanted and since Dakin's solution has been employed routinely to inhibit the excessive growth of granulations these saucer-like areas of excavation or depression around the implants have not been observed.

Carrel and Hartmann, during the period of the war, emphasized the importance of keeping wounds free from discharge to encourage healing. In their measurements of the rapidity of wound healing they found that when infection occurred in a wound the healing process stopped and the curve of wound healing flattened off directly.

It is frequently remarkable how quickly a granulating surface becomes covered with epithelium after the implants have made their appearance above the surface. The rapidity of healing is due, however, in no small measure to the contraction of the healthy tissues about the granulating surface. Tracings made of the wound during varying stages of healing demonstrate this feature very well. This reduction in the actual size of the wound Carrel (3) described as granulous retraction. Unlike the small deep graft this implant fuses with the rest of the skin and does not preserve its identity. The ultimate appearance of the wound in which these implants have been used is not unlike that in which all the epithelization has obtained from the periphery as in the ordinary healing of granulating wounds.

The cosmetic result in some extensive burns in which these implants were used has not been above criticism. In one such instance an unusually red thin skin with numerous visible vessels in

the regenerated epithelium obtained following the procedure (Fig. 9). In a few burns there has been a definite tendency toward keloid formation in the new epithelium. However the original severe nature of the injury to the tissues in these instances may have been as much or more responsible for the unsatisfactory result as the method employed in covering the defect. In several other burns in which the destruction has been less intense very satisfactory cosmetic results have been obtained (Fig. 10). A tendency to keloid formation in other types of wounds in which such implants have been made has not been observed. The percentage of takes by this method is high. Should a portion of the wound lag behind in becoming covered with epithelium this area may be reimplanted. Not infrequently one or two small granulating areas persist after the greater portion is entirely covered with epithelium. These areas are usually slow to heal. Keeping the granulations moistened with Dakin's solution during the period of wound healing and free from discharge will inhibit the heaping up of granulations and obviate the occurrence of isolated slow healing areas.

For the epithelization of excavated defects this simple method of skin grafting has no equal. The only requisite is that granulations be present, failure to obtain wound sterility is not a hindrance to the success of the procedure.

RUPTURE OF THE URETHRA

REPORT OF TWELVE CASES

C C HIGGINS M.D. CLEVELAND OHIO
Cleveland Clinic

DURING recent years the number of cases of traumatic rupture of the urethra has apparently decreased. This is due probably to the increased number of safety devices and appliances in industrial pursuits. In past years numerous cases were seen in seaport cities where the injury occurred in sailors on the old sailing vessels. Nowadays the accident seems to occur almost exclusively in children who accidentally fall astride of some object or in men who are engaged in carpenter work, building construction, or some similar industrial occupation.

TYPES OF RUPTURE OF THE URETHRA

There are 3 types of rupture of the urethra: rupture of the pendulous urethra, rupture of the bulbous urethra, and intra pelvic rupture of the urethra. Rupture of the pendulous urethra occurs but rarely and none of the cases reported here is of this type. However during erection this condition may occur, or as Guyon states, the injury can occur during coitus.

By far the most common type of urethral injury is rupture of the bulbous urethra.

RUPTURE OF THE BULBOUS URETHRA

Symptoms and signs. Patients who present themselves for examination immediately after rupture of the bulbous urethra has occurred usually complain of pain, hæmorrhage from the meatus, difficulty or inability to void, tenderness and tumefaction.

The pain at first is sharp and steady, in character and rarely is localized in the region of the rupture. Later it becomes more or less continuous in the perineum especially as the perineal hæmatoma develops. As this progresses and infection develops throbbing pain, fever, tenderness and chills may occur and all the usual toxic manifestations may appear.

Hæmorrhage from the meatus always occurs. It is always well to remember that the degree of hæmorrhage does not always indicate the extent of the rupture. Hæmorrhage may be so profuse as to necessitate a transfusion, even in cases in which the urethra is only partially ruptured. In such cases the passing of a large catheter may control the bleeding while in others in which the

hæmorrhage is not so profuse, surgical intervention may be required.

Inability to void is a frequent symptom immediately after the injury is sustained. This is due to the contraction of the lacerated urethra and spasm of the compressor urethral muscle. That this is the case is indicated by the fact that when the patient is placed under spinal anæsthesia in preparation for operation, he may void. Later, the congestion, the hæmatoma and the infection are factors which produce the inability to void.

Due to the fact that reflex spasm of the compressor muscle prevents extravasation for a few hours and as a result of earlier diagnosis extensive extravasations are not as common now as in the past. When the rupture occurs above the bulbous urethra, extravasation into the cellular structures of the pelvis occurs immediately, thus rendering the condition more serious. Thus, an accurate diagnosis influences measurably the complications of the condition.

As tumefaction is primarily the effect of hæmorrhage and extravasation, it will not be discussed at this time. Later, this tumefaction is influenced by urinary extravasation and superimposed infection. The extravasation which follows the fascial spaces has been discussed by Campbell.

Perineal hæmatoma, of course is usually present. Legueu states that the gravest ruptures are associated with the largest hæmatomata. From our experience, however, the size of the hæmatoma is not always a true index to the gravity of the condition. Occasionally the injury to the bulb of the urethra and its sheath may be marked, while the mucosa of the urethra is only slightly damaged. In one of our cases the urethra was almost completely ruptured, but only a small perineal hæmatoma was present.

Diagnosis. The diagnosis of rupture of the urethra is not always easy, and difficulty may be encountered in ascertaining the extent of the rupture. The symptoms and signs do not always indicate the degree of trauma. Although inability to void may be due to a reflex spasm of the compressor urethral muscle as the result of an injury, and clots may pass from a minor injury, usually the history of trauma of hæmorrhage from the meatus and of a perineal hæmatoma associated

ABSTRACTS OF HISTORIES OF CASES OF INJURIES OF THE URETHRA

No	Date	Injury	Cause of injury	Symptoms	Operation
1	?	Rupture of mucous membrane of urethra	Not stated	Considerable bleeding from urethra for week or 10 days but began at night	Application of adrenalin and urethra packed with gauze within urethroscope removed 3 weeks later \ recurrence
2	11-24-02	Ruptured urethra	While being led over to get a shower was struck from behind by nose of a bucket which hit him on left tuber ischi and perineum	Immediately desirous to urinate but could not swelling left side of perineum slight abrasion considerable bruising over perineum penis edematous	Perineal section urethra separated about an inch from bulbomembranous portion. Suture end to end fine catgut bulbous part sewed deeper structures. Catheter left in place 2 days later later introduced 1 gth of time it then remained not stated.
3	2-15-03	Ruptured urethra	While partially intoxicated slipped getting out of wagon with foot on hub and fell astride wheel	Difficult slight and painful micturition. Catheter passed at first but impossible 8 days later. Bladder distended extrusion of urine and ecchymosis in perineum	End to end anastomosis with fine catgut without going through mucous membrane
4 age 16 years	5-5-03	Complete rupture of urethra	While being led down from upper story by a rope slipped and fell about 10 feet landing against an iron rod	No micturition great pain all night attempt by physician to pass sound could reach perineum but no more. Some blood clots and considerable urine passed later. Bladder greatly distended scrotum black and edematous. Ecchymosis	Scrotal and perineal incision suture end to end.
5	12-7-04	Ruptured	Fell astride carriage wheel	No micturition bleeding from urethra marked ecchymosis penis and scrotum edematous	Perineal section drainage of bladder
6 age 12	6-16-07	Rupture of urethra (complete laceration)	Slid from hay loft and fell astride a barrel—3 days before operation	Not given	Perineal section blood clot evacuated bladder catheterized separated ends of urethra united with fine linen suture isodermic drain.
7	1-24-11	Ruptured urethra	Fell astride buggy wheel 4 weeks before	Severe pain in perineum blood from meatus. In bed 2 weeks with hospitalization to perineum welts, genital testis, ecchymosis, hematuria. No blood except just after accident. Increasing difficulty in urination	Found almost complete division of urethra. Plastic operation performed
8	5-28-12	Ruptured urethra	Not stated	Not stated	End to end anastomosis.
9	5-20-13	Ruptured urethra	Pile of lumber fell on patient 15 m. in the air. Pelvis fractured in three places, and bladder ruptured. Bladder repaired. Drainage could be established through urethra but repeated attempts made	Not given	End to end anastomosis.
10	2-12-15	Ruptured urethra	Slid down a faucet which struck him a little to right of midline and about 3 inches in front of anus	Distention voluntary micturition impossible involuntary micturition slight bleeding from penis.	Bladder catheterized with considerable difficulty. Good diuresis. Hemorrhage. No other treatment except catheterization.
11	10-5-21	Ruptured urethra (carcinoma)	Slipped and hurt rectum 3 years before. Catheterized bladder which for several months drained urine into rectum	No urine through penis at first. Cut headed, then urine through penis until 2 years ago. Then urethra closed and opening made through perineum. This opening closed a day ago and no urine is possible. Has had chills, pyrexia, rectum some fever urine dark and bloody.	Anastomosis of severed ends of urethra to perineum, making new urethra. Much scar tissue found which proved to be carcinoma.
12	5-25-23	Ruptured urethra			Urethra was found to be entirely divided the divided ends being surrounded by a large hematoma. Plastic operation performed.

with inability to void indicates the presence of a rupture of the urethra. Catheterization under strictly aseptic conditions should be attempted. The soft rubber catheter is passed first and if it fails to pass into the bladder, then the coude catheter should be tried. By curving the tip of

the catheter it may follow the roof of the urethra which frequently remains intact.

In view of the injured devitalized and lacerated tissue together with the presence of a hematoma a fertile field awaits infection to avoid which every precaution should be exercised.

Fig 1 Rupture of the urethra Anastomosis of ruptured urethra over a catheter

Fig 2 Rupture of the urethra Perineal extravasation of urine

In one case, a urethroscopic examination demonstrated the lacerated urethra but usually the hemorrhage is so profuse that visualization of the urethra is difficult.

Treatment Controversy still exists as to the treatment of incomplete rupture of the urethra. Personally I am satisfied if a soft rubber catheter can be passed into the bladder.

Some French authors state that incomplete rupture is an etiological factor in the formation of strictures, but I am certain that adequate dilatation at a later date will overcome this obstacle.

Perineal section has been advised by Reginald Harrison and by others. However, if possible I believe it should be avoided. If infection supervenes, or we are unable to pass a catheter into the bladder, then perineal section is necessary.

The types of operations in complete rupture of the urethra are the following: (1) end to end anastomosis, (2) insertion of catheter, (3) Rutherford technique, (4) suture of roof of urethra.

In this series perineal section with end to end anastomosis was the procedure of preference in the cases which required surgical intervention.

The lacerated, devitalized tissues at the point of injury to the urethra are excised and the anastomosis is performed over a catheter, as in the illustration (Fig 1), the two posterior sutures being placed first and followed by the anterior sutures. The catheter is then strapped to the penis by adhesive to prevent its slipping out.

Heitz Boyers recommends removal of the catheter immediately after anastomosis, the urinary stream being diverted by a suprapubic cystostomy. In one case cystostomy with retrograde catheterization followed by incision and drainage in the areas showing extravasation, gave a good result.

In 1904 Rutherford described the sutureless method which seems satisfactory, especially in

cases in which infection and extravasation have occurred. He recommended suprapubic cystostomy followed by immediate perineal section. A catheter was then passed from the meatus into the bladder and no sutures were inserted, the perineal wound being packed open. He stated that when the patient was in the recumbent position, the cut ends of the urethra would come into close approximation over the catheter and union would take place, the catheter acting as a splint.

Rutherford Morrison's technique consists in suturing only the roof of the urethra, this being accomplished by interrupted catgut sutures. Then if a cystostomy is also performed, it is not necessary to insert a catheter. The perineal wound is packed open with gauze.

INTRAPELVIC RUPTURE OF THE URETHRA

Intrapelvic rupture of the urethra occurs less frequently than rupture of the bulbous urethra, and no case was encountered in this series. In such cases, the urethra is torn in association with crushing injuries of the pelvis. The seriousness of the condition can be comprehended when we realize the shock which is present in patients with a fractured pelvis, even without urethral injury. Thus this complication is serious. The rupture is usually at the apex of the prostate and tears the prostate from the membranous urethra.

Symptoms Symptoms of fracture of the pelvis are usually present and a grating sensation is elicited when pressure is applied to the iliac crests. Hemorrhage from the meatus also is a constant symptom and frequently is quite profuse.

Pain is usually very severe, and tenderness over bladder and hypochondrium is elicited. Rigidity over lower abdomen is present in some degree.

Bailey states that the extravasation usually is more prominent on one side or the other of the lower abdomen. Usually no tumefaction is present in the perineum.

Diagnosis The differential diagnosis between this condition and rupture of the bladder may be very difficult. However, if the bladder is distended and palpable, the rupture is below the vesical sphincter.

Treatment In the presence of this condition, immediate surgical intervention is necessary. Suprapubic cystostomy and drainage of the space of Retzius should be done as soon as possible. Due to rupture of the puboprostatic ligaments, the neck of the bladder and the prostate are displaced backward, as also by the pressure exerted by the extravasated urine in the space of Retzius. This displacement must be corrected as soon as possible before these parts become adherent to the adjacent tissue, so that their return to their normal position becomes possible. Moreover a permanent suprapubic fistula will result if this displacement is not corrected.

The patient's condition is such that 'he who hesitates is lost' and the operation must be performed as rapidly as possible. The perineal operation is performed 48 to 72 hours after the preliminary cystostomy.

The catheter is passed in a retrograde direction from the bladder to the perineum and is then passed out through the meatus. This catheter acts as a splint holding the bladder neck in normal position until the cut ends of the urethra unite. Fortunately, the membranous urethra in contrast to the bulbous urethra has but little tendency to stricture formation.

The complications which may accompany an intrapelvic rupture of the urethra are traumatic stricture, extravasation of urine, and infection and gangrene.

Some degree of traumatic stricture usually ensues and it must be impressed upon the patient's mind that treatment must be continued after he leaves the hospital. The catheter is usually removed in 48 to 72 hours. After 10 to 16 days in instrumentation can be safely instituted. The further treatment is based upon urethroscopic study.

Extravasation follows the arrangement of definite anatomical structures, namely, the external and internal pelvic fasciae. Extravasation which occurs anterior to the triangular ligament spreads over a route limited by Colles fascia in the scrotum, perineum and penis and in the abdomen by Scarpa's fascia. Since these cases at the present time are seen and treated soon after the receipt of the injury, the extravasation is now usually

perineal and scrotal in type (Fig. 2). Formerly in cases seen later the extravasation had extended to the penis and lower abdomen. In cases in which the pendulous urethra is ruptured the penile extravasation is localized by Buck's fascia and rarely extends upward to the abdomen.

If the lesion occurs posterior to the triangular ligament, the extravasation usually involves the retroprostatic region and invades the upper inner aspect of thigh, the ischio-rectal fossa and buttocks.

If the lesion occurs between the layers of the triangular ligament, the extravasation may spread externally or toward the pelvis. Campbell reports 4 cases in which the extravasation extended to the ischio-rectal spaces. However in such cases the extravasation usually spreads externally.

When extravasation is due to an intrapelvic rupture of the urethra, it extends to the prevesical and perivesical regions, and as Bailey states, one side is usually more involved than the other.

Infection from the urine or that due to poor asepsis results in an extensive phlegmon which requires free incision of the involved regions. Albarran states that this phlegmon is due to anaerobic bacterial invasion and that the fluid is an inflammatory exudate. However as shown by Kidd, urea can usually be found in the fluid.

MORTALITY AND END-RESULTS

The mortality of rupture of the urethra is low if the case is seen immediately, but it is influenced by the time which elapses after the injury is received. With our present understanding of the condition it should be reduced to practically nil.

Stricture may result but under judicious, conscientious care this will respond to treatment. Better some degree of stricture than a dead patient.

SPECULATIONS ON CONTROL OF INTESTINAL FUNCTION

THE romance of medicine lies in inductive philosophy, in which tomorrow is the great day. Yesterday furnishes the deductive philosophy, which acts as a compass to keep our directions true.

In mammals the testis is the primitive procreative organ, and because of its long heredity it is relatively free from disease, the ovary, secondary to the testis, is a more recent acquisition which has not yet achieved the same resistance. So, too, the sigmoid, a convenient storage organ but of more recent development, has not yet achieved the stability of the primitive small intestine. The right half of the large intestine is derived from the midgut, and in the embryo has the same type of epithelium as the small intestine and carries on an absorptive function. The sigmoid is derived from the hindgut and has relatively little absorptive function. By reverse peristalsis derivatives of the food end products are returned for further elaboration and absorption until the faecal stage is reached.

Certain recent investigations by Alvarez and his colleagues have shown the influence of food products on mass. Among the various types of food which form a mass, such common articles of diet as potatoes and milk form a relatively large mass, whereas red meats induce a large amount of bacterial action. Three fourths of the peoples of the world eat rice or carbohydrate and more or less fish for protein. Rice not only has a high calorie content, but also it liquefies and forms only a very small mass, such articles of diet as fish also form a small mass.

We are getting new light on the sympathetic nervous system, which acts as a brake on intestinal progress.

Speaking picturesquely, one notes various types of control over the vegetative functions, for example, the linking up of non-striated muscle with the nodal system and with the internal secretions so largely instrumental in carrying on gastro intestinal functions. These controls are shown in the occurrence of intestinal peristalsis once or twice in each minute and intestinal contractions eighteen or twenty times in each minute, the latter movements serving as a motor pump to propel venous blood in the portal system to the liver. All of these forms of stimulation are linked with the sympathetic nervous system and through the sympathetic ganglions with the central nervous system. Our knowledge of this interrelationship we owe to the fundamental work of Gaskell and Langley.

The work of Hunter and Royle stimulated fresh surgical interest in the sympathetic nervous system. In this field Adson and his associates have been able to relieve megacolon,

which so closely resembles the dilated œsophagus in cardiospasm, by removal of the lumbar sympathetic ganglions and their communicating branches. Learmonth points out that the operation effects its purpose probably by leaving the sacral sympathetic outflow, which is motor to the distal part of the colon, in sole control of this part of the bowel. Adson and his coworkers also have brought about marvelous relief in Raynaud's disease, in certain types of contraction of the blood vessels of the extremities leading to gangrene, and in certain types of arthritis, by removal of the appropriate sympathetic ganglions and their communicating branches.

TOTAL VERSUS SUBTOTAL ABDOMINAL HYSTERECTOMY

THE question whether a total or subtotal hysterectomy should be performed when hysterectomy is indicated is not settled. This assumption is correct since the issue is frequently discussed at medical meetings. There is no unity of opinion among general surgeons and gynecologists, some have discarded the one in favor of the other. During the past ten years many have advocated total hysterectomy for fibromyomata when removal of the uterus was indicated. The training and experience of gynecologists with this procedure are of course greater than of most surgeons, so that it is hardly fair to expect the occasional operator to adopt a technique with which he has had little experience.

There is a definite field for both procedures although I feel that total hysterectomy should be performed by experienced surgeons in most instances in which removal of the uterus is indicated, in which the cervix is definitely diseased, and when the patient is in good general

condition. On the other hand, if the cervix is small and there is no evidence of cystic disease or infection, the supravaginal or subtotal operation can be performed.

That the cervix is a source of infection and should be removed in all instances in which it is chronically diseased and in which hysterectomy also is indicated, has been shown by Rosenow, Moench, Benedict, and Nickel. Rosenow regards the cervix in the same light as the tonsils, as a focus of infection. Moench has found that the most conspicuous organism isolated from the cervix in cases of leucorrhœa is the streptococcus. Here, too, Benedict and his associates have shown the relationship between chronic cervical infection and lesions of the eye. Nickel recently produced hemorrhagic lesions around the trigone in bladders of dogs which had been injected with a culture from the cervical stump of a patient suffering from a Hunner's ulcer. Perhaps the most cogent reason for performing a total hysterectomy, whenever possible, is the fact that carcinoma is all too commonly seen in the cervical stump after the subtotal operation.

From statistics in most modern hospitals, carcinoma occurs in the cervical stump in about 1 per cent of the cases. Masson found that from 1910 to 1926 16 cases of carcinoma of the cervix were observed at The Mayo Clinic from 3 to 15 years after subtotal abdominal hysterectomy for benign lesions, and 13 cases in which it was not possible to determine whether or not malignancy had existed prior to the early operation. In about the same number of cases the cervix had been removed for troublesome leucorrhœa in cases in which subtotal hysterectomy had been performed previously.

The mortality for total abdominal hysterectomy should not be greater than for subtotal abdominal hysterectomy if the cervix

has been properly prepared. The vagina and cervix should be cleansed with soap and water and alcohol and then painted with three to five per cent iodine solution. If the cervix is soft and has a tendency to discharge a mucopurulent secretion, a small strip of iodine gauze should be placed in the cervical canal, or the cervix may be closed by means of three or four interrupted sutures.

At The Mayo Clinic during 1928 subtotal abdominal hysterectomy was performed 251 times in benign conditions with 2 hospital deaths (0.79 per cent), while total abdominal hysterectomy was performed 219 times with 1 hospital death (0.45 per cent). The death rate (5.88) for total hysterectomy in malignant conditions of the fundus is somewhat higher than in benign conditions. This increase in rate is not due to the type of operation but is attributed to the fact that many of the patients are usually senile, anæmic, and often cachectic. Death from either total or subtotal abdominal hysterectomy can be assigned to accidental causes. Pulmonary embolism is responsible for about 50 per cent of the deaths. This accident is being very materially reduced by administering thyroid extract, massage, passive movements of arms and legs, and tight abdominal binders after operation, as advised by Walters and Coffey.

Coming out the gland bearing area of the cervix or its destruction by the electric cautery following a subtotal abdominal hysterectomy has been offered as a substitute for total abdominal hysterectomy in the presence of a diseased cervix other than from cancer, and when hysterectomy is indicated as a safer procedure for those who have less ex-

perience with the latter operation. This will not safeguard the patient against future infection or carcinoma in the cervix because it is practically impossible to destroy all the glandular area in this manner.

The cervix and cervical canal should be inspected under direct vision preliminary to either a total or subtotal abdominal hysterectomy. Extensive infection often exists along the cervical canal near the internal os in an otherwise healthy appearing cervix. Early malignant growths may occur in the fundus and extend through the internal os to be overlooked through a subtotal hysterectomy, since carcinoma is associated in 5 per cent of fibromyomata.

Prolapse of the vaginal vault which is seen occasionally following either operation should not occur if the broad and round ligaments are accurately measured and sutured to the vaginal vault or the cervical stump. The approximations of these ligaments should be such that sufficient allowance has been made for contraction of the scar, so that sufficient mobility will follow without prolapse.

Subtotal abdominal hysterectomy should be performed in benign conditions when it is necessary to remove the greater part of the body of the uterus and when the cervix is in good general condition. Total abdominal hysterectomy is the best operation when any lesion other than carcinoma exists in the cervix and an abdominal hysterectomy is advisable, or when the history suggests the possibility of malignant change in the fibromyoma or an associated malignant condition in the fundus of the uterus.

VIRGIL S. COUNSELLER

MASTER SURGEONS OF AMERICA

DONALD MACLEAN

DONALD Maclean was born at Seymour, Canada, December 4, 1839. His early education was obtained partly at Oliphant's School, Edinburgh, and partly at Coburg, Belleville and Queen's College, Canada. In 1858 he entered the medical department of the University of Edinburgh, becoming a licentiate of the Royal College of Surgeons in 1862.

Upon his return to the United States he became an assistant surgeon in the Army and served at various stations, among which were hospitals at St. Louis and Louisville.

In 1864, having returned to Canada, he was appointed professor of surgery in the Royal College of Physicians and Surgeons at Kingston, Ontario. In 1872 he accepted the position of lecturer and later professor of surgery in the medical department of the University of Michigan. He occupied this chair until the year 1889 when he resigned and entered private practice in Detroit, Michigan. Here he remained until his death, which occurred July 24, 1903.

Among the many honors bestowed upon him during his active life the following may be mentioned. In 1884 he was elected president of the Michigan State Medical Society. In 1894 he was president of the American Medical Association. He was elected to honorary membership in the Ohio State Medical Society and the New York State Medical Society. He was a member of the Royal College of Surgeons of Edinburgh, as well as a Fellow of the Royal College of Physicians.

Donald Maclean is best remembered as a great teacher. He inspired enthusiasm in his pupils and was sponsor for many great surgeons, some of whom have become famous. Of spare build, about five feet ten inches high, handsome and bold, he conducted his clinic in a dramatic manner and his kindly personality made him many friends in the medical profession.

OLD MASTERPIECES IN SURGERY

ALFRED BROWN M D F A C S OMAHA NEBRASKA

THE WOUND SURGERY OF CÆSAR MAGATUS

DURING the closing years of the sixteenth century, the attention of the surgical profession centered upon the treatment of wounds. The old methods of treatment with boiling oil, the cautery and many forms of medicated dressings did not achieve the desired results and attempts were made by many surgeons to find improved methods which ranged from the weapon salve which Paracelsus tried to repopularize to the puppy dog fat of Paré.

Possibly the weapon salve was more efficacious in treatment than Paré's fat for at least in its use the wound was not dressed daily or two or three times a day but one of the rules of technique was to dress the wound and then let it alone for 7 days meanwhile covering the weapon with the salve or powder and then disturbing it daily or oftener with a new dressing while it was kept warm and dry and away from dust and wind. This method of treatment had the advantage that while it could not possibly harm the implement which caused the wound it did serve to protect the wound against too much meddling surgical trauma.

Apparently some of the Roman surgeons recognized the harmfulness of frequently disturbing wounds for on one of his visits to Rome Cæsar Magatus learned of this method of treatment and was much struck with its benefits.

Magatus an Italian was born in 1579 in Scandiano. After studying at Bologna where he received his degree of doctor of philosophy and medicine he went to Rome to continue his medical studies. He probably had the opportunity at this time to observe the effects of the non interference method of treating wounds for he states in his work that the idea was not original with him but he had observed the technique in Rome and the results appealed to him. Returning to his home he at once obtained a great reputation for his surgical work and in 1617 was given the chair of surgery at the University of Ferrara then one of the great medical schools of the world. Four years after his appointment as professor he published his book which he called *Concerning an uncommon treatment of wounds or concerning the binding of wounds infrequently*. Magatus led a most active life for many years teaching and practicing. He was then taken with a severe illness which left him extremely weak and evidently thoroughly worn out for he renounced the world and

worldly things and sought peace for his remaining years by entering the mendicant order of Franciscan monks known as the Capuchins. His desire for peace and quietude was not to be granted, however for his reputation had become so great that frequent demands were made for his services. Evidently as his health returned so did his desire to get back into the harness for he obtained from the authorities of the order a special dispensation to practice in the principal cities of Italy and again took up work, remaining in practice until his death which occurred at Bologna in 1647 following an operation for the stone.

Magatus states on the title page of his book that there are two important questions that he intends to decide in the work. First, whether it is better to unloosen and care for wounds daily or whether several days should be allowed to intervene between dressings and, second whether the use of tents and sponges are necessary in the cure of wounds.

Both of these questions he decides. The first in favor of less frequent dressings and the latter in the negative. He begins by giving the fourteen reasons why daily dressing of wounds is said to be necessary. The following are examples of these reasons. By uncovering the wound the putrefaction is exposed to view—even gangrene may supervene if wounds are not dressed frequently—it is necessary to renew the medicaments daily and observe their effects—to give a daily prognosis—to remove causes of irritation—and finally it has always been done hence why change. In this final reason Magatus states that authors say

A method which brings about health is not to be changed has been stated by Hippocrates. So by this method which uncovers wipes off and cares for wounds often the wounds are brought to excellent condition as experience shows therefore it should not be changed. Therefore a wound should be dressed daily. Magatus then goes on to combat the arguments for daily dressings and shows that the same reasons may be given for less frequent dressings. He then gives his reasons for discarding the ancient practice all logically stated and in contradiction to the final argument for frequent dressings and states

That method of cure under which wounds are healed more happily and quickly than under another is the most excellent and judicious and as experience has shown that under this new method wounds are healed more happily and quickly than under another, therefore this new method is the most excellent and judicious.

ciples of treatment of the various types of nephritis are outlined and the procedures available to combat uræmia oedema and high blood pressure associated with renal failure are described. A well selected list of references adds to the value of the book. It provides an admirable summary of our present knowledge of an inexhaustible subject.

WALTER H. NADLER

THE small volume by Dr H. Hyslop Thomson on *Tuberculosis: Its Prevention and Home Treatment: a Guide for the Use of Patients*¹ merits careful reading by those afflicted with pulmonary tuberculosis and by those medical men into whose practice cases of this type occur.

While in the main, nothing new is injected in the book that has not been written by other authors many of the chapters are so concise and so impressive that it makes the book worth while. His emphasis of the value of sanatorium treatment and the necessity for after care is so forceful that if every patient ready for discharge from an institution could read it and follow his advice breakdowns would be less frequent. His chapter on personal measures involving such questions as rest exercise occupation sleep marriage and likewise, is of the greatest importance.

A very full index completes what is, in my mind 96 pages of good thought and good advice in the field of tuberculosis.

MAX BRESNATH

A COMPLETE review of the subject of abdominal drainage is found in the book by Cadenat and Patel.² The first portion of the work is historical, then follow brief chapters on the physics of drainage and a brief resume of peritoneal physiology. The remainder is devoted to a discussion of indications and contra indications for drainage in abdominal and pelvic operations.

Most surgeons will agree with the authors in their viewpoint on drainage. They are quite conservative in the use of drainage but oddly enough, while willing to omit drainage in suppurative appendicitis they feel unsafe in closing the abdomen after cholecystectomy because of the uncertainty of ligatures and sutures in the biliary ducts.

J. R. BUCHBINDER

THE history, etiology pathology, symptomatology and treatment of gonococcus infection of the hip joint is presented by Lamy.³ One of the leading authorities of Paris. The illustrations of arthritis of the hip are excellent.

The various types of arthritis are given including polyarthritis monarthritis osteoarthritis and the type associated with spondylose rhizomelique and

the puerperal and infantile types described. Complications include dislocations and acetabular protrusion.

The medical and surgical treatment is discussed and the abstracts of 160 cases taken from the literature.

PHILIP LEWIN

TWO international authors wrote the book on *Orthopedic Surgery*.⁴ Since the appearance of the first edition one of the authors (Lovett) died. Three additional names appear those of Allison Ober, and Platt, all of international reputation and acknowledged ability. The first edition was dominated by a military atmosphere, the second edition fortunately is not.

There are many changes from the first edition—some of omission, some additions and some rewriting. Many advances have been made since the first edition appeared. For this reason every chapter has been reviewed, especially the sections on stiffness of joints and operative treatment arthritis deformans, affections of adult bone anterior poliomyelitis obstetrical paralysis and lateral curvature of the spine.

Entirely new chapters have been added on subjects of affection of tendons muscles, and fascia peripheral nerve lesions, pyogenic affection of bone vascular lesions of extremities, amputations, and artificial limbs.

The operative side of orthopedic surgery is well presented. The subject of adhesions is well treated as it is one of the subjects closest to the heart of one of the authors (Jones).

The sequence of subjects treated differs from other textbooks and is a welcome change. This volume will continue to serve as a standard orthopedic text and reference book. The bibliography is helpful though incomplete. The work of the publisher is excellent.

This book should be of great value to the student to the interne to the general practitioner and to the orthopedic specialist. It confirms the fact that Jones is the master orthopedic teacher of the world.

If Lovett could see this edition he would be proud.

PHILIP LEWIN

IN our books there is such a dearth of useful information on diseases of the oesophagus that Aabel's monograph on *Oesophageal Obstruction*⁵ fills a void. The reviewer knows of no other single volume on the subject. Every angle is covered in a masterful and complete manner. No omissions could be discovered. Special praise should be given to the chapter on diverticula.

The following minor criticisms might be offered (1) In the handling of cardiospasm the treatment

¹TUBERCULOSIS: ITS PREVENTION AND HOME TREATMENT: A GUIDE FOR THE USE OF PATIENTS. By H. Hyslop Thomson M.D. D.P.H. New York and London: Oxford University Press 1928.

²ABDOMINAL DRAINAGE IN CHIRURGICAL ABDOMINALS. By Dr F. M. Cadenat and Dr M. Patel. Paris: Gaston Douin et Cie 1928.

³LA GONORRHOË. By Marthe Lamy. Paris: Gauthier Villars et Cie 1929.

⁴ORTHOPEDIC SURGERY. By Sir Robert Jones Bart. A.B.E. CB. CB. M. (Liverpool) F.R.C.S. (England, Ireland & Edinburgh) F.A.C.S. (U.S.A.) and Robert W. Lovett M.D. F.A.C.S. 2d ed. New York: William Wood & Company 1929.

⁵OEOPHAGEAL OBSTRUCTION: ITS PATHOLOGY, DIAGNOSIS AND TREATMENT. By A. Lawrence Aabel M.S. (London) F.R.C.S. (Eng.) New York and London: Oxford University Press 1929.

REVIEWS OF NEW BOOKS

THE principles and methods of treatment which are practised by the present Master of Rotunda Hospital are described in *Tweedy's Practical Obstetrics*¹. The subject matter has been well arranged and the book is well printed. Many of the views expressed vary somewhat from the attitude and teaching in the United States. The author still recommends submammary hypodermoclysis. The disadvantage of breast complications arising from this procedure in the nursing mother has led many to substitute the axillary region for this purpose. The reviewer regrets that the author still recommends intra uterine douching.

Happily the author has included a short chapter on prenatal care.

This book is recommended chiefly to the practising physician and not the student since the details in the pathology treatment are glossed over rather hurriedly.

F I CORNELL

THE small book on *Diagnosis and Treatment of Deformities in Infancy and Early Childhood*² is intended to supplement the larger textbooks of orthopedics in a preparatory way its object being to stimulate general practitioners and those in charge of obstetrics and infant welfare clinics to be on the lookout for signs of early deformity in those who may come under their care. The subject matter is well chosen and is presented in good sequence. It deals largely and in a practical way with preventive treatment. The choice of illustrations and the execution of same are satisfactory. The operative side of the treatment of the conditions discussed is not given much attention.

This volume should be of value to the medical student, the interne and the general practitioner.

PHILIP LEWIS

ONLY the treatment of injuries of the skeleton is dealt with in Forrester's *Traumatic Surgery*³. The treatment of the various phases of trauma to the soft tissues with the exception of a chapter on surgical and non surgical treatment of peripheral nerve injuries is not included. The book is beautifully illustrated and gives adequate description of the author's method of handling various fractures and dislocations, his experience being based on many years of practice in the field of industrial surgery with additional experience obtained in the British orthopedic service during the War.

¹TWEEDY'S PRACTICAL OBSTETRICS. Ed ted and largely rewritten by Bethel Vol. more M.D. F.R.C.P. M.R.I.A. 6th ed. New York O ford University Press 1919

²DIAGNOSIS AND TREATMENT OF DEFORMITIES IN INFANCY AND EARLY CHILDHOOD. By M. F. Forrester B.own, M. D. (Lond.) With a foreword by Sir Robert Jones Bart, M.B.E. C.B. F.R.C.S. New York and Lo don Oxford Univ. Press 1939

³OPERATIVE TRAUMATIC SURGERY WITH SPECIAL REFERENCE TO AFTERCARE AND PROGNOSIS. By C. R. G. Forrester M.D. F.A.C.S. New York Paul B Hoeber Inc 1939

One of the novel features of this volume is the attempt made by the author to estimate the average length of disability from the various skeletal injuries which exemplifies his viewpoint as a practical industrial surgeon. He gives indications and suggests the time in the course of management for the various injuries when massage manipulation and other physical treatment should be instituted. His viewpoint in regard to operative treatment is in general conservative. He is inclined to use wires for securing apposition of fractured bones more frequently than the average American surgeon now uses them. He describes his technique for forceful manipulation of stiffened shoulders and apparently is inclined to follow the teaching of the British school. He also describes Morrison's technique for the injection of "bipp" in osteomyelitis and recommends the methods of treating this disease in vogue in the British army during the War. He recommends the use of the Steinmann nail almost to the exclusion of calipers.

This volume is a valuable addition to the library of the industrial surgeon. It gives in pertinent English one man's view of the surgical management of these injuries.

HARRY E. MOCK

THE book on *Nephritis*⁴ is an amplification of the Goulstonian Lectures delivered before the Royal College of Physicians in the spring of 1918. Despite the brevity of the work the author succeeds in presenting a survey of nephritis that provides a basis for reflection of the problems concerned with the study of this inexhaustible subject. The results of recent investigations are incorporated and their significance indicated. The modern conception of the relation of uræmia, œdema and blood pressure to nephritis is outlined and the direction from which further aid in their explanation may be expected is indicated. Thus it is shown how the study of uræmia involves inquiry into broad biochemical principles how œdema is probably always a manifestation of damage to tissues outside the kidney and how high blood pressure is more often a cause than a result of nephritis.

The classification presented has been found by the author compatible both with existing clinical and pathological knowledge. It resembles in the main that of Volhard and Fahr. Nephritis is conceived to comprise (1) the nephroses (lipoid nephrosis, chemical nephropathies and amyloid disease) (2) glomerulo nephritis (acute diffuse chronic diffuse focal and embolic) (3) arteriosclerosis (pre-nephritic stage or essential hypertension later stage with cirrhosis of spleen and kidneys and renal failure the so called chronic interstitial nephritis the malignant renal sclerosis of Fahr). The prin

⁴NEPHRITIS ITS PROBLEMS AND TREATMENT. By T. Lind Emmett M.D. (Lond.) F.R.C.P. New York and Lo don Oxford Univ. Press 1939

modern medicine could regret reading. In the last chapter, 'Fever Ho-pital Problems' is a discussion of many topics not usually found in a volume of this character.

Twelve important contagious diseases are described in detail yet in untiring completeness. There are 32 plates 14 of which are in color. The excellence of these illustrations not only makes the book more attractive but adds to its value as well. Numerous fever charts and also some tables are included.

Possibly the only improvement in Ker's *Infectious Diseases* which could be brought about Claude Rundle has accomplished in the revised third edition. This last edition has simply been brought up to date by the incorporation of advances which have been made in medicine during the past ten years. In this respect measles and scarlet fever have received particular attention. About one fifth of the total (614) pages is devoted to typhoid under the name enteric fever.

The book in its present form is much more convenient to handle than when it appeared in the size of the original edition. It should be studied and used for reference by all those desiring clear dependable knowledge concerning contagious diseases. A H

THE volume written by Alfred Gosset¹ and associates presents much of interest. In the first chapter Gosset, chief of the clinic sketches the history, the present organization, and the functioning of the surgical clinic and the anti cancer center of the Salpêtrière.

Chapter II likewise from his pen, is devoted to the description of the technique of the operation for the cure of cancer of the breast. It serves to emphasize the principles laid down by Halsted and by

Handley. Of special interest is the chapter on the combined radium and operative treatment of cervico-uterine cancer. They have performed an extensive hysterectomy of the Wertheim type five or six weeks after exposure to radium. Of seventy four cases thus treated there were three fatalities. Thirty two consecutive Wertheim operations did not have a single death. Fifty five and five tenths per cent are alive and well more than three years after the operation. There are chapters dealing with general anesthesia, resection of the right colon for malignant tumor in two stages, strawberry gallbladder, chronic hemorrhagic proctitis, and others.

The book is richly illustrated.

G H

THE book by Hartmann on *Travaux de Chirurgie*² consists of fifteen separate monographs on the surgery of the stomach and duodenum. A statistical study is presented of all cases operated upon during the period 1914 to 1918. The causes of all deaths are discussed. A careful clinicopathologic study of chronic peptic ulcer of the lesser curvature is presented. While apparently favoring gastric resection, Hartmann emphasizes that he had had good results with excision of the ulcer plus a simple gastroenterostomy. He is opposed to intervention for a severe hemorrhage from an ulcer. Carcinoma is thought to develop rarely from a chronic gastric ulcer. There is a valuable and timely contribution on the anomalies and chronic dilatation of the duodenum. Mesenteric compression and periduodenitis are discussed as the etiological factors. Indications and technique of duodenojejunostomy are presented. Gastric resection with a posterior terminolateral anastomosis is carefully described and illustrated.

might have been given in a more explicit manner (2) The œsophagoscope has far less value than one is apt to gather from this treatise. The reviewer believes that the œsophagoscope, aside from its use in the removal of foreign bodies, has a very limited field.

This unique and practical monograph cannot be too highly praised. It should be in all medical libraries.

A. A. GOLDSMITH

ELEVEN lectures on gastro intestinal problems given at St. Andrews during the winter of 1927 by prominent English physicians and surgeons are published in book form under the title *Gastro-Intestinal Diseases*.¹ The subjects are clinical and statistical as regards symptoms and results of treatment. They are usually the personal views of the speaker derived from his own clinic. They do not seem to be the formal presentation of research but are more in the nature of discussion of common problems giving personal opinions and deductions rather than scientific conclusions. As such the lectures are interesting, some seem a little old-fashioned, some are disappointing, but all are worth reading as giving the ideas of good men.

PALL STARR

An unusually good book has been written by Oscar Mercier on the diagnosis of urinary disease.² A short commendatory preface has been written by Professor Marion. The significance of chemical, microscopical and bacteriological findings of the urine are clearly discussed in detail. Urea nitrogen retention in the blood, Ambard's constant and the excretion of phenolsulphonephthalein are given as the most accurate methods of testing renal function. About one third of the treatise is given over to modern radiographic studies of the kidney, pelvis, ureter and bladder. The presentation of the value of lateral cystography is amply illustrated. The cystoscopic appearance of various lesions of the bladder and urethra is discussed in detail and each condition is clearly depicted in colored illustration. The book is a valuable contribution on the utilization of modern urologic methods of diagnosis and apparently is intended for the specialist rather than the general practitioner.

VINCENT J. O'CONNOR

MODERN urologic diagnosis is dependent not only on cystoscopy but on ureteral catheterization, a study of renal function, roentgen ray examinations and pyelography. These subjects as well as operative cystoscopy are considered by Dr. Eugen Joseph, the author of *Lehrbuch der diagnostischen und operativen Cystoskopie*.³ Because of its completeness the book is a novel departure.

¹GASTRO-INTESTINAL DISEASES. LECTURES DELIVERED AT THE JAMES MACKENZIE LECTURE FOR CLINICAL RESEARCH, ST. ANDREWS WINTER SESSION 1927. Edited by FR. JESSOP, D. M. & W. GIBSON, M.A. M.D. F.R.C.S. (Edin.). New York: Oxford University Press, 1928.

²NEPHROLOGIE URÉNAIRE. By OSCAR MERCIER. Preface by G. MARION. PARIS: AM. D. LÉGER, 1927.

³LEHRBUCH DER DIAGNOSTISCHEN UND OPERATIVEN CYSTOSKOPIE. By DR. EUGEN JOSEPH. Berlin: Julius Springer, 1929.

About one half of the book is devoted to the subject of cystoscopy exposition. A point that is well taken and of such importance that it is rightly stressed by the author is the value of the history and a careful physical examination before the cystoscopy is done. The various types of cystoscopes and the technique involved in achieving the best results in cystoscopic examination as well as the various kinds of anesthesia are thoroughly discussed.

The different cystoscopic findings in the usual and the rare bladder lesions are given. The cystoscopic pictures and even such rare lesions as bilharzia and malacoplakia are well illustrated.

The value of roentgen ray examination and the subject of pyelography are carefully presented and well illustrated.

A subject that is ably treated by the author is operative cystoscopy, and because of the lucid manner in which it is handled an interesting and instructive chapter is added to the book.

The endovesical treatment of bladder tumors, the crushing of stones in the bladder under vision, the treatment of stones in the ureter and the technique of ureteral dilatation receive the attention which these subjects should always receive in a work on operative cystoscopy, but it is not often that the descriptions are as detailed as in this illuminating and profusely illustrated work.

AS the title page states, the book by Laurin⁴ is a general study of the subject of artificial sterilization from the gynecological point of view. After a brief introduction and historical resume the author presents his essay de justification limited to discussion of the sociological and medico-legal argument. The indications for sterilization follow the well beaten path of those diseases of vital import: tuberculosis, the cardiopathies, renal affections, blood disorders, neuropsychosis and contracted pelvis. The argument is ably reinforced with statistics from recent clinical reports from French and German sources. In discussing eugenics as an indication, however, the author makes efficient use of reports from various states in our own country.

The second part comprises a review of methods of sterilization in which most of the better known procedures are set forth. In general the material made use of is well presented and set forth clearly, definitely and in an orderly manner. Particularly well formulated are the author's conclusions. A somewhat lengthy but not comprehensive bibliography is appended.

CHOLECYSTITIS A BACTERIOLOGIC AND EXPERIMENTAL STUDY OF THREE HUNDRED SURGICALLY RESECTED GALL BLADDERS¹

ALLEN C. NICKEL, M.D., ROCHESTER, MINNESOTA

Division of Experimental Bacteriology, The Mayo Foundation

AND

E. STARR JUDD, M.D., F.A.C.S., ROCHESTER, MINNESOTA

VARIABLE bacteria have been isolated by different investigators, from surgically resected gall bladders that have been the site of cholecystitis. That some of these bacteria are causative is shown by the fact that they produce lesions of the gall bladder when injected into experimental animals. This has been shown by various investigators (2, 4, 6, 7, 10, 11, 12). Some have been unable to duplicate Rosenow's results whereas others, such as Wilkie, have reproduced his results culturally as well as experimentally. Wilkie has isolated, as has Rosenow, the causative streptococcus in the biliary lymph node as well as in the wall of the gall bladder in a very high percentage of cases. He also has reproduced the lesions in rabbits in a striking manner, by injecting the streptococcus in different ways.

Recently at The Mayo Clinic we have made cultures from 300 consecutive gall bladders, using Rosenow's technique and in some instances Wilkie's modification. The cultures were made irrespective of the reasons for removal of the gall bladders and irrespective of the amount of pathological change visible. Twenty-three per cent of the patients were men, 77 per cent were women of whom 69 per cent were married. Many of the women gave a history of cholecystitis starting or recurring shortly after childbirth. Most of the patients

were more than 40 years of age, the youngest was 19 years of age, and the oldest 77 years. The majority (85 per cent) of all of these patients had potential foci of infection, such as pulpless teeth, chronic lacunar or follicular tonsillitis, prostatitis, endocervicitis, and sinusitis. The majority of those who returned to The Mayo Clinic later for re-examination still retained such foci even though there were consultant's notes on the charts advising their removal.

The cases were divided into four groups according to the symptoms (tabulation). Any patient who had a typical history of disease of the gall bladder was placed in group 1 or 2. If the condition was of 4 months' duration or less the patient was placed in group 1, if of more than 4 months' duration, in group 2. Group 3 included those patients who had indistinct or vague symptoms not exactly typical of disease of the gall bladder. Group 4 included those patients in whom a stone in the cystic or common bile duct was the essential finding. According to this classification, there were 6 cases in group 4, in 3 of which cultures made from the gall bladder were sterile and in the other 3 of which the predominating organism was a gram-negative bacillus, in none was a streptococcus found. There were 116 patients in group 3, and cultures made from 75

made a culture from the remaining portion of the wall, consisting largely of the mucosa, after it had been washed in sterile solution of sodium chloride. It sometimes happened that cultures of the outer portion of the wall contained staphylococci alone or staphylococci mixed with streptococci, or bacilli, whereas the mucosal portion of the wall was sterile or contained the streptococci or bacilli without the staphylococci. This also was true of *bacillus subtilis* in a few instances. Consequently, we feel that sometimes at least, *bacillus subtilis* and *staphylococcus albus* were contaminants. In this respect our results correspond with those of Mestitz and Rittner, who examined smears and sections of the gall bladder immediately after surgical removal of the gall bladder and again after culturing the tissue. They found that in some cases in which the direct examination was negative, cultures showed staphylococci, or in cases in which the direct examination showed other organisms, after incubation the tissues showed the other organisms and staphylococci.

It is known that bile inhibits the growth of organisms, especially streptococci. In our experience it did not do so unless present in rather large amounts. This seems to be contrary to the experience of Wilkie. In only one instance did the outer portion of the wall yield a streptococcus when the inner portion remained sterile, and the growth of this streptococcus was not inhibited when 5 drops of the bile were added to 15 cubic centimeters of the culture medium before it was inoculated with 2 drops of a culture of the streptococcus in question. In tubes containing the macerated tissue of the gall bladder we have often added, with a Pasteur pipet, up to 10 drops of bile (later proved sterile) from the same gall bladder and have found that in the tubes which contained the bile the streptococcus and other organisms grew as well as in those to which bile had not been added. This was true no matter if the sterile bile came from gall bladders the walls of which contained streptococci, or were sterile. After we had determined this fact often enough to convince ourselves we discontinued culturing the wall piecemeal and simply washed the tissue in several changes of sterile solution of sodium chloride.

The number of our positive results in this series is not as high as that obtained several years previously with the same technique, nor as high as that obtained by Rosenow or by Wilkie. One of us (g) has reported previously that tethiothalein sodium N N R (iodeikon) has a marked bacteriostatic action for streptococci, and we thought that its extensive use for diagnostic purposes at The Mayo Clinic in the last 2 to 3 years might be responsible for the lowered incidence of positive cultures. Thus, we determined the time interval between the giving of the dye and the making of the cultures from the resected gall bladders in the cases with negative cultures on the one hand and in those with positive cultures on the other hand. Ninety nine, or approximately a third of the patients, did not receive dye. Most of these 99 cases, in which bacteria, especially streptococci, were found, were classified in group 1, in these cases rather acute conditions prevailed and a dye test was not advisable or necessary. In contrast, the majority of negative cultures in the 99 cases were from group 3, in which the symptoms were not typical of cholecystitis.

Of the 201 remaining patients who received the dye, the time interval in days between the giving of the dye and the making of the culture from the gall bladder was determined. This time interval was least in the group in which cultures remained sterile, and was 8.2 days. In the group in which a bacillus was isolated, the time interval was 8.4 days. In the group in which various forms of staphylococci and diphtheroid organisms were isolated, the time interval was 10.4 days, and in the group in which a streptococcus was isolated the average time interval was 11.2 days whereas in the group in which the streptococci were isolated in pure culture the average time interval was 12.8 days.

Rabbits were given intravenous injections of freshly isolated cultures of the various organisms, both with pure cultures and with mixed cultures, according to the technique described in previous publications. The animals usually were given injections on three successive days and were allowed to live from 1 to 6 weeks. During the experiments we discovered, as Cecil had discovered in experi-

of the gall bladders (65 per cent) were sterile, of the remaining 41 cultures, the predominant organisms were staphylococci and various bacilli. In only 8 of the 41 was there a green producing or indifferent streptococcus. There were 82 cultures of gall bladders of patients from group 2, 40 of which were sterile and 42 of which contained streptococci, staphylococci, or bacilli. Group 1 consisted of 96 cultures and only 32 per cent were sterile. Of the 64 positive cultures in group 1, 45 (70 per cent) contained streptococci, 35 of the 45 were pure cultures of streptococci. Thus, in group 1, in which one would expect good cultural results if the bacteria are of etiological significance 68 per cent of the cultures were positive, with streptococci predominating. In group 2, in which the condition had become chronic, 51 per cent of the cultures were positive. In group 3, in which most of the symptoms were vague and indistinct only 35 per cent of the cultures were positive. In group 4 in which obstruction to the ducts was the main finding, 50 per cent of the cultures contained a bacillus, but in no instance was a streptococcus isolated.

Altogether cultures were made from 300 gall bladders of which 150 (50 per cent) were sterile. Of the 150 cases in which the cultures were positive, in 66 (44 per cent), the predominating organism was a streptococcus, in 45 (30 per cent), a bacillus, and in 39 (26 per cent), a staphylococcus or other related cocci.

In this series of 300 gall bladders there were 65 "strawberry" gall bladders of which 46 (71 per cent) were sterile. From 9 gall bladders a streptococcus was isolated, from 7, a bacillus and from 3, staphylococcus albus. In most of the cases in which a positive culture was obtained from "strawberry" gall bladders there also was a complicating factor such as a stone in the cystic or common bile duct, or there was perihepatitis definite enough to be mentioned in the surgeon's report.

We also made cultures from numerous cystic lymph nodes. Cultures therefrom approximately paralleled those obtained from the walls of the gall bladders.

The streptococci usually produced distinct, green colonies on blood agar, often requiring a gradient of oxygen tension for growth. The

majority did not grow on a streaked blood agar plate until after at least one culture had been made in glucose brain broth. The bacilli were mainly gram negative bacilli, usually they fermented dextrose, but the reactions of fermentation were variable in the other sugars. In three instances the reactions in sugars were those of typhoid bacilli. In a few instances, a gram positive, spore bearing bacillus was isolated. This was considered either a contaminant or a secondary invader, since it never produced any gross lesions in rabbits. According to the reactions in sugars, the streptococci most frequently isolated were streptococcus faecalis and streptococcus mutior. The other two types encountered to a lesser extent were streptococcus non haemolyticus 1 and 3. Neither the streptococci isolated from the bile or from the wall could be placed in any particular group since all the strains were isolated at times only from the wall, at other times only from the bile and at times from both the wall and the bile. Much stress has been placed recently on the relationship between streptococci and enterococci. As yet there is no definite agreement as to what constitutes an enterococcus. Some German authors (5) believe the enterococcus to be a variant of streptococcus viridans. Practically all of the strains that we have isolated are not enterococci according to the standards as summarized by Dible. They belong rather to the streptococcus viridans group called green producing streptococci by Rosenow to distinguish them from the streptococcus viridans lenta described first by Schottmueller.

Whenever extensive hemorrhagic chole cystitis or marked empyema of the gall bladder was encountered cultures therefrom almost invariably contained a gram negative bacillus, alone or in mixture with the streptococcus, and the gram negative bacillus usually fermented dextrose. According to cultural and experimental results staphylococcus albus was considered more often a coincidental than a causal factor, although in some instances the staphylococcus could not be considered a contaminant. Frequently, in making cultures from the wall of the gall bladder, we dissected off a piece of serosa and muscle and made a culture from it separately. We then, also,

made a culture from the remaining portion of the wall, consisting largely of the mucosa, after it had been washed in sterile solution of sodium chloride. It sometimes happened that cultures of the outer portion of the wall contained staphylococci alone or staphylococci mixed with streptococci, or bacilli, whereas the mucosal portion of the wall was sterile or contained the streptococci or bacilli without the staphylococci. This also was true of bacillus subtilis in a few instances. Consequently, we feel that sometimes at least, bacillus subtilis and staphylococcus albus were contaminants. In this respect our results correspond with those of McStitz and Rittner, who examined smears and sections of the gall bladder immediately after surgical removal of the gall bladder and again after culturing the tissue. They found that in some cases in which the direct examination was negative, cultures showed staphylococci, or in cases in which the direct examination showed other organisms, after incubation the tissues showed the other organisms and staphylococci.

It is known that bile inhibits the growth of organisms, especially streptococci. In our experience it did not do so unless present in rather large amounts. This seems to be contrary to the experience of Wilkie. In only one instance did the outer portion of the wall yield a streptococcus when the inner portion remained sterile, and the growth of this streptococcus was not inhibited when 5 drops of the bile were added to 15 cubic centimeters of the culture medium before it was inoculated with 2 drops of a culture of the streptococcus in question. In tubes containing the macerated tissue of the gall bladder we have often added, with a Pasteur pipet, up to 10 drops of bile (later proved sterile) from the same gall bladder and have found that in the tubes which contained the bile the streptococcus and other organisms grew as well as in those to which bile had not been added. This was true no matter if the sterile bile came from gall bladders the walls of which contained streptococci, or were sterile. After we had determined this fact often enough to convince ourselves, we discontinued culturing the wall piecemeal and simply washed the tissue in several changes of sterile solution of sodium chloride.

The number of our positive results in this series is not as high as that obtained several years previously with the same technique, nor as high as that obtained by Rosenow or by Wilkie. One of us (9) has reported previously that tetrathalein sodium N N R (iodeikon) has a marked bacteriostatic action for streptococci, and we thought that its extensive use for diagnostic purposes at The Mayo Clinic in the last 2 to 3 years might be responsible for the lowered incidence of positive cultures. Thus, we determined the time interval between the giving of the dye and the making of the cultures from the resected gall bladders in the cases with negative cultures on the one hand and in those with positive cultures on the other hand. Ninety nine, or approximately a third of the patients, did not receive dye. Most of these 99 cases, in which bacteria especially streptococci, were found, were classified in group 1, in these cases rather acute conditions prevailed and a dye test was not advisable or necessary. In contrast, the majority of negative cultures in the 99 cases were from group 3, in which the symptoms were not typical of cholecystitis.

Of the 201 remaining patients who received the dye, the time interval in days between the giving of the dye and the making of the culture from the gall bladder was determined. This time interval was least in the group in which cultures remained sterile, and was 8.2 days. In the group in which a bacillus was isolated the time interval was 8.4 days. In the group in which various forms of staphylococci and diphtheroid organisms were isolated, the time interval was 10.4 days, and in the group in which a streptococcus was isolated, the average time interval was 11.2 days, whereas in the group in which the streptococci were isolated in pure culture the average time interval was 12.8 days.

Rabbits were given intravenous injections of freshly isolated cultures of the various organisms both with pure cultures and with mixed cultures, according to the technique described in previous publications. The animals usually were given injections on three successive days and were allowed to live from 1 to 6 weeks. During the experiments we discovered, as Cecil had discovered in exper-

Fig. 1. Empyema of the gall bladder of a rabbit 7 days after two intravenous injections with 4 and 5 cubic centimeters respectively of a 24 hour glucose brain broth culture of streptococci obtained from a surgically resected gall bladder.

ments on animals with arthritis that repeated injections even though small over a longer period of time, produced better results in many instances. In our experience pure cultures of staphylococci never produced cholecystitis, neither did cultures of so called diphtheroid organisms unless the diphtheroid organisms were streptococcus variants as evidenced by subcultures. In practically every culture of a gall bladder that had been the site of empyema and that had markedly thickened walls and in cultures of hemorrhagic, gangrenous gall bladders a gram negative bacillus was isolated sometimes in pure culture and often mixed with a streptococcus. When such freshly isolated cultures were injected into rabbits in small doses (bacilli of the colon group are quickly fatal to rabbits) they sometimes also tended to produce hemorrhagic gangrenous cholecystitis. In the rabbits that received injections of cultures of the streptococcus, focal lesions of the gall bladder often developed within 24 hours. However, in order to produce chronic indurated lesions, or cholelithiasis, 3 to 5 weeks were needed. In this respect, the colon bacillus differs from the streptococcus be-

Fig. 2. a. Section of the wall of the gall bladder shown in Figure 1. There is swelling and necrosis of the cells of the tips of the villi (hematoxylin and eosin $\times 1,300$). b. Streptococci in the necrotic tip of the villus (Gram Weibert stain $\times 1,000$).

cause the colon bacillus usually produced mucopurulent bile with necrosis of the wall, in a shorter time.

Altogether 72 strains were injected into rabbits. Forty-one strains contained the streptococcus in large numbers and 28 (68 per cent) of these localized in the gall bladder of the rabbit. In contrast none of the strains of staphylococcus albus and only 5 of the 31 strains in which the streptococcus was absent or present only in very small numbers localized in the gall bladder of the rabbit. Seventy-eight rabbits were given injections of these 41 strains containing the streptococcus and in 35 (45 per cent) lesions of the gall bladder developed. In contrast 34 rabbits were given injections with the 31 other strains and in only 5 (9 per cent) lesions of the gall bladder developed. Altogether 137 rabbits were given injections of cultures obtained from the surgically resected gall bladders and in 40 (30 per cent) lesions of the gall bladder developed. The highest incidence of localization elsewhere in the body was in the joints (2 per cent). These percentages are comparatively low but it must be remembered that the majority of such experimental lesions are self healing. Consequently, in our endeavor to produce marked and more chronic evidence of cholecystitis as well as of cholelithiasis the animals were allowed to live for a long time and during this time the more

Fig 3 Hemorrhagic empyema of the gall bladder of a rabbit with adherent necrotic omentum 8 days after two intravenous injections of 5 and 6 cubic centimeters of a 24 hour culture of a mixture of streptococci and colon bacilli isolated from a surgically resected gall bladder

superficial and acute lesions healed. Notwithstanding this, including all the strains injected, some of which undoubtedly were contaminants the percentage of specific localization in the gall bladder was approximately ten times that obtained when specific strains isolated from patients with other diseases were employed.

The following results illustrate the various types of experimental lesions obtained

A married woman aged 41 years with a history of cholecystitis of 19 years duration with recent exacerbations was operated on. A cholecystogram had not been made. At operation subacute cholecystitis was found implanted on chronic cholecystitis and there were multiple stones. Cultures made from the wall of the gall bladder and from the bile contained green producing streptococci. Cultures of the central portion of the stones were sterile.

Two rabbits were each given intravenous injections on 2 successive days of 4 and 5 cubic centimeters respectively of a glucose brain broth culture of this streptococcus. Six days later the rabbits were definitely ill and were dispatched. One rabbit had empyema of the gall bladder and slight perihepatitis. Sections of the wall of the gall bladder revealed numerous streptococci in places and coexisting coccidial infection of the gall bladder. Cultures of the bile contained numerous green producing streptococci whereas all other cultures were sterile.

Fig 4 a Section of the wall of the gall bladder shown in Figure 3. The wall is thickened and there is marked cellulitis with necrosis of the infiltrated tissue (hematoxylin and eosin $\times 80$). b colon bacilli and streptococci found in the necrotic area shown in a (Gram Weigert stain $\times 1000$)

There were no gross lesions in the other rabbit except those found in the gall bladder which was distended and the wall of which was edematous and thickened with irregular white confluent areas (Fig 1). Adherent to the mucosa were numerous tiny grayish white phlebolith like bodies there were also a few of these bodies free in the bile which was watery and pale grayish green but which otherwise was grossly unchanged. Cultures of the blood spleen and joints were sterile. Those of the bile and wall of the gall bladder consisted of countless green producing streptococci.

Sections of the wall of the gall bladder (Fig 2 a) showed evidence of destruction of the raised portions of the mucosal folds with round cell infiltration many of the cells were leucocytes. Figure 2 b shows the streptococci in the necrotic areas shown in Figure 2 a.

The following results were obtained with a mixed culture of streptococci and bacillus coli.

A woman aged 61 years had been operated on previously for empyema and fistulas of the gall bladder at which time approximately two thirds of the gall bladder had been removed. She returned 3 years later with a recurrence of symptoms. At operation chronic catarrhal cholecystitis was found the walls of the gall bladder were thickened. Cultures made from wall of the resected gall bladder consisted of a mixture of green producing streptococci and bacillus coli.

Two rabbits were each given injections on 2 successive days of 5 and 6 cubic centimeters respectively of a glucose brain broth culture of this mixture. One of these rabbits died 63 days later. The body was emaciated but there were no gross changes except those found in the gall bladder which consisted of definite empyema with tiny stone like

Fig. 5 Stones in the gall bladder of a rabbit 44 days after two intravenous injections of 4 and 5 cubic centimeters respectively of a 24 hour glucose brain broth culture of streptococci and staphylococci obtained from a surgically resected gall bladder

bodies free in the bile. The other rabbit was despatched 28 days after the first injection. Necropsy did not reveal gross lesions except that the gall bladder was distended and the walls were white and thickened (Fig. 3). The bile was replaced by a seropurulent fluid in which were many small white flakes. Direct smears of this material revealed gram negative bacilli and streptococci.

Sections of the wall showed it to be markedly thickened and infiltrated throughout with leucocytes; the mucosa was destroyed (Fig. 4 a). Figure 4 b shows the bacilli and streptococci scattered throughout the necrotic and seminecrotic tissues.

In order to suggest the probable relation of bacteria to formation of gall stones the following experiment is recorded.

Cultures were made from a surgically resected gall bladder in which subacute slightly hemorrhagic cholecystitis was implanted on chronic cholecystitis. There was one fairly large stone in the lumen of the gall bladder. A rabbit was given an intravenous injection on two successive days with 5 and 4 cubic centimeters respectively of a glucose brain broth culture of green producing streptococci and staphylococcus albus obtained from the wall of the surgically resected gall bladders. The rabbit remained apparently well and was despatched 43 days later. Necropsy revealed a distended gall bladder the wall of which was thickened throughout but was markedly thickened in places so as to form small sessile nodules 2 to 5 millimeters in their greatest diameter attached to the tips of the folds of the mucosa (Fig. 5). There were also two such nodules free in the

Fig. 6 a Section of the wall of the gall bladder shown in Figure 5 at the juncture of the stone with the villus. Strands of viable connective tissue run for varying distances into the dark necrotic (stone) portion (haematoxylin and eosin $\times 3,500$). b streptococci in the living part of the villus. c myriads of streptococci and staphylococci in the necrotic (stone) portion of the villus.

bile which was abnormally viscid and pale gravisish green. Touching and cutting these nodules revealed them to be firm putty like masses containing some gritty or calcareous substance. Cultures of the bile and of portions of these 'stones' consisted mainly of green producing streptococci with staphylococcus albus.

Sections of the wall through such areas revealed it to be markedly thickened and oedematous. The mucosa was largely necrotic and was absent in places. The nodules were situated at the former site of the tips of the folds of the mucosa which they replaced. There was a sharp line of demarcation between the wall and the nodules. The nodules consisted of a homogeneous firm pink mass of eosin staining material containing myriads of bacteria. In the nodules near the attachment to the wall of the gall bladder were strands of apparently viable connective tissue that so far had resisted the action of the bacterial products. These connective tissue strands were continuous with the connective tissue of the wall of the gall bladder (Fig. 6 a). The streptococci and staphylococci were most numerous at the distal end of the nodules (Fig. 6 b) and they decreased in number as one approached the juncture of the nodule with the wall of the gall bladder. Streptococci also were found for some distance in the grossly unchanged tissue beneath the nodules (Fig. 6 c).

These experiments re-emphasize the fact that in certain forms of cholecystitis pathogenic organisms are present especially green producing streptococci and gram negative bacilli. On the contrary when the pathological diagnosis is 'strawberry gall bladder', cultures from such tissues are usually sterile.

unless there are complicating factors such as hepatitis or stones in the ducts

By classifying the patients according to symptoms, we were better able to determine the relationship of bacteria to cholecystitis. For example, in a patient with a stone in the common bile duct, one would hardly expect to find pathogenic bacteria in the wall of the gall bladder unless it also was diseased or unless the bacteria had entered the gall bladder during stasis of its content. Likewise, one would not expect to find bacteria very frequently in gall bladders from patients in group 3 whose symptoms were not typical of cholecystitis. In some of the patients in group 3 gross evidence of cholecystitis could not be found at operation. Instead, there was found in some cases, hepatitis, duodenal ulcer, or an inflamed appendix, whereas in others various adhesions were found by which the symptoms could readily be explained. In such instances, without gross evidence of cholecystitis, one would not regularly expect to obtain pathogenic bacteria from the wall of the gall bladder.

Patients in group 2 had a rather chronic condition, and unless exacerbations occurred at various times, the chances for obtaining a positive culture here also were minimal. On the other hand, the majority of cultures from patients in group 1 should be positive if bacteria are associated with the cholecystitis and this seems to have been our experience. The majority of positive cultures containing streptococci especially were obtained from patients in group 1, whereas the majority of sterile cultures were obtained from patients in the other groups. We had hoped that there might prove to be a much longer interval of time between the giving of the dye and the cultures of the wall of the gall bladder in those cases in which the cultures were positive, in contrast to the cases with negative cultures. In accordance with our hopes there was a difference of 2 and 3 days between the cultures that were sterile and those that were positive for the cocci. Perhaps this was sufficient to account for the difference in the cultural results. If so it may help to explain why cultures of resected gall bladders made recently contained streptococci less often than the cultures obtained 4 or

RESULTS OF BACTERIOLOGICAL INVESTIGATION OF SURGICALLY RESECTED GALL BLADDERS

Group	Symptoms of disease of the gall bladder	Cultures			Predominant organism isolated per cent

4	Stone in gall bladder or common bile duct	6	3	50	67	33
	Total	300	150	50	44	36

more years ago, such as Rosenow's. It may show, moreover, that the dye is endowed with therapeutic value.

There is another reason why Rosenow's results are higher than ours. His work was done years ago, when surgical measures were postponed until definite disease of the gall bladder was found. Then, too, he worked with selected cases in which gross pathological states of the gall bladder were marked, and he resected those gall bladders that were grossly unchanged.

That streptococci became localized in a gall bladder previously infected with coccidial cuculi illustrates that places of lowered resistance may be more susceptible to infection. It does not necessarily vitiate the factor of elective localization, because in many instances streptococci obtained from cases other than those of cholecystitis and injected into rabbits the gall bladders of which were infected with coccidial cuculi, did not localize in such previously infected gall bladders but produced lesions elsewhere.

Most of our experimental data in rabbits are in accordance with those of other similar studies. However, the production of cholecystitis with organisms other than streptococci, namely, gram negative bacilli, is of significance because it implies that the bacilli are not merely secondary invaders, a point originally mentioned by Rosenow. It also strengthens the idea of many that typhoid bacilli, apparently quiescent for a time in the gall bladder, may give rise to disease of

the gall bladder, and that, therefore, the gall bladder may act as a focus of infection. Our inability to produce lesions with pure cultures of staphylococci strengthens the idea that they are relatively unimportant.

At the time of the writing of this paper the report of Branch was noted. His results compare very closely with ours, even as regards the bile in the media. He found the following organisms in cultures and they are listed in the order of their frequency: bacilli, streptococci and staphylococci. Our results would place the streptococci first and the bacilli second. His conception of the bacterial content in various types of gall bladders is similar to ours and is aptly expressed in the following statement: "As for the relative frequency of the types of cholecystitis from which we recover organisms, the disconcerting consistency of positive cultures from the acute cases is only equalled by the persistent lack of growth from the chronic cases."

CONCLUSIONS

1. The majority of surgically resected gall bladders from patients with acute or subacute cholecystitis contain pathogenic bacteria, whereas the majority from patients who have chronic cholecystitis are sterile. The organisms isolated are, according to their frequency, green producing streptococci, gram negative bacilli and staphylococci.

2. Cultures from "strawberry" gall bladders are usually sterile unless there is a complicating factor.

3. There is a longer time interval between the giving of the tetrathalein sodium NNR and the making of cultures from the gall bladders in those cases in which the gall bladders were found to be infected than in those that were sterile.

4. Streptococci isolated from grossly diseased gall bladders are of etiological signifi-

cance, since they tend to reproduce the cholecystitis and cholelithiasis in experimental rabbits when injected intravenously. The colon bacillus also may have a selective action for the gall bladder. It is usually found together with the streptococcus and is found frequently in relatively acute cases or in cases in which there are stones in the common or cystic duct. Staphylococci also are encountered, but we have found them to be non-pathogenic for the gall bladders of rabbits when injected in pure culture.

PSEUDOTUBERCULOUS SALPINGITIS

JAMES DENTON M.D. AND GILBERT DALLDORF M.D. BROOKLYN
From the Departments of Pathology of The Brooklyn Hospital and The New York Hospital

THIS report is concerned with a foreign body type of inflammatory process in the oviduct which simulates tuberculosis histologically and which we believe has frequently been confused with tuberculosis of the oviduct.

Tuberculosis salpingitis, according to current conceptions, constitutes about 10 per cent of chronic adnexal disease. As gauged by statements in commonly recognized reference works on surgery, gynecology and pathology, it is usually regarded as the common form of genital tuberculosis in the female. Numerous authors state that it is benign in course in contrast to many forms of surgical tuberculosis and that following salpingectomy recovery is prompt and permanent in a large share of the cases.

Clinicians have naturally distinguished between cases in which tuberculosis is apparent elsewhere or widespread in the abdomen and those in which it is limited to the tubes. It is quite likely that the favorable course in cases of the latter type is largely responsible for the benign reputation of the disease.

Our attention was attracted to the disease by observation of 3 cases in current pathological material, of large, irregular, ring like masses of some foreign substance in sections of oviducts, which though much enlarged and patently diseased had some of the gross features of tuberculosis. The histological details in these cases showed clearly that the foreign material was not a residuum of previous caseation. They were generally enclosed in the bodies of large giant cells and there was usually associated a granulomatous reaction with extensive endothelial hyperplasia, tubercle like focal lesions and in some instances limited anemic necrosis. These interesting cases were long the subject of study and from the appearances of the rings of foreign substance it was suggested that they might be the shells of dead parasites possibly oxyuris vermicularis as the worms are reported to have been found in the tubes by several observers. Further

observations made this explanation of the nature of the substance appear incorrect but also prompted a critical review of the available cases classified as tuberculous salpingitis. Thirty four specimens containing this foreign material have been found in a total of 78 cases previously diagnosed as tuberculous salpingitis. A review of these specimens made apparent the fact that the foreign material was present in cases in which the lesions were least typically tuberculous and not discoverable in those cases in which there was more satisfactory histological evidence of tuberculosis.

PATHOLOGY

Gross pathology. A review of the operation notes of the surgeons who had cared for the 78 patients showed that the existence of tuberculosis in the pelvis was suspected in only about one third of the cases on examination of the organs *in situ*. In about the same number of the cases pinhead size gray bodies were visible on the serous surfaces of the tubes and occasionally on the surfaces of contiguous viscera. Free fluid was present in the pelvis in about one sixth of the cases and in a few of these it was blood stained. The degree of enlargement of the tubes varied somewhat but they were not usually more than 1.5 to 2 centimeters in diameter. In several cases there was complicating secondary infection with puriform material in pockets between adhesions. Adhesions in the pelvis were usual but did not differ from the adhesions in chronic pelvic disease. They were usually formed by simple, not tuberculocaseous granulation tissue.

After removal the oviducts were enlarged and firm and tubercle like bodies were more commonly visible than at operation. On section they were gray or pinkish gray, sometimes with softened centers. In only one third of the cases was there gross caseation. With but 4 exceptions the tubes on section were of essentially normal shape and the increase in size was due mainly to increase in bulk of the mucous membrane. In a large number of the

Fig. 1 Cross section of oviduct. The outlines of most of the mucous folds are still visible. The muscle coat is not thickened. The outlines of five or six small foreign body tubercles can just be made out at this magnification.

cases the site of the lumen was filled with a solid red core. The ovaries were not usually involved unless incorporated in the adhesions or inflammatory tissue about the tubes. In brief, the tubes on section usually had neither the appearances of a chronic suppurative process nor of frank caseation.

Microscopic pathology. In the 57 cases in which we considered that the morphological changes were deficient in important characteristics of tuberculous lesions including the 34 cases in which the collections of foreign material were found, the lesions were limited to the serous and mucous coats. The lesions of the serous coats were of two types: small tubercle like nodules which formed in or about subserous lymphatics, and simple granulation tissue. Many of the small, gray bodies visible grossly were not tubercles but small collections of lymphoid cells, some even having germinal centers. Most of the subserous nodules were of foreign body tubercle type with a delicate reticulum and numerous small giant cells.

The increase in bulk of the mucous membrane was mainly due to the following basic lesions: focal collections of small giant cells; nodular and diffuse endothelial hyperplasia; fibroblastic reaction on the part of the sub

Fig. 2 Cross section through an oviduct bent on itself. There is great increase in thickness of the mucous membrane. The outlines of some mucous folds are visible. There are no lesions in the muscle coat or subserous tissue.

epithelial stroma, and proliferative reaction in the epithelium.

The most frequent lesions were the small giant cell and endothelial nodules. They formed in the substance of the folds of mucous membrane either near the tips or down close to the internal muscle layers. While they produced some distortion of the mucous membrane, the general outlines of the mucous folds were generally fairly well retained. Particles of foreign material have been found in approximately half of these nodules.

Fibroblastic proliferation was extensive in some cases and either limited to the peripheral portions of nodular lesions or more diffuse. It was usually accompanied by endothelial proliferation and infiltration by lymphocytes.

Epithelial proliferation was extensive in some cases. If marked, the projections of the mucous membrane were broad and bulbous and covered with several layers of epithelium. There was a tendency to fusion of mucous folds with the formation of irregular epithelial lined canals or islets of atypical epithelium.

In some specimens there was limited central softening. This was usually associated with excessive mucous secretion, not only into the lumen and epithelium lined canals but also into the stroma of the mucous membrane. There was often scanty hæmorrhage. As a consequence the lumina were often filled with a mixture of mucus, red corpuscle and epithelial cell debris.

Fig 4 Two masses of foreign material in the bases of mucous folds. The foreign body tubercle at the left contains material in the form of fine particles

DIFFERENTIATION FROM TUBERCULOSIS

Through the courtesy of Dr Douglas Symmers, director of laboratories at Bellevue Hospital, we have had the opportunity of comparing the lesions in this surgical material with those in 10 autopsies in cases of disseminated tuberculosis in which the oviducts were involved. In the autopsy specimens the tubes were larger, they could not usually be separated from the tuberculous granulation tissue about them, caseation was extensive and usually extended into and through the muscle coats, and the tubercles on the surfaces were frequently confluent and caseous.

In the surgical cases none of the recent accessions have had typical tuberculous lesions and it therefore happens that the 14 cases in which there was reserve material for the application of stains for tubercle bacilli have been among those which we regard as pseudo-tuberculous. We have been unable to find tubercle bacilli in these and although failure to demonstrate tubercle bacilli has only negative value, it is pertinent to state that the lesions in these cases were not of such type as to suggest the presence of acid fast or other bacteria.

CLINICAL ASPECTS

An analysis of the clinical records of the total series of cases has been made, and there

appear to have been consequential differences in the clinical manifestations in the 21 cases in which the lesions are comparable to the lesions in the postmortem material reviewed and those in which we are inclined to believe the lesions are of foreign body type. The patients gave more evidence of being seriously ill. In 9 cases there was adequate evidence

Fig 5 Larger foreign body tubercles. Additional foreign substance visible with polarized light.

Fig 6 The foreign material in identical fields when examined with natural and polarized light

that there was tuberculosis in other organs. Three had definite signs of pulmonary tuberculosis. Two of these died within a year of tuberculosis. Two had extensive tuberculosis of the peritoneum and chronic obdurate sinuses persisted after operation. One patient had previously had a tuberculous kidney removed. She died a little more than a year after operation. In 3 cases there were definite lesions in the endometrium. In the 12 remaining cases in which the histological evidence of tuberculosis appeared sufficient the subsequent course of the disease is not satisfactorily known.

In the larger group in which we regard the histological evidence of tuberculosis as inconclusive or inadequate the presenting symptoms were decidedly less severe. They generally sought relief from a troublesome, but not alarming condition in the lower abdomen or pelvis. A presumptive diagnosis of genital tuberculosis was not made in any of the cases before operation, and in many cases the oviducts were not suspected of being the site of the trouble. The patients were, practically without exception, described as being well nourished and in fair to good general health. In several instances the diseased oviducts were discovered in the course of operations for

other gynecological conditions, as myomata uteri, ovarian cysts, uterine cancer, etc. Our information as to the eventual outcome of these cases is extremely meager. The immediate outcome was favorable with but one exception and in this case the patient died as the result of a surgical accident.

THE NATURE OF THE FOREIGN MATERIAL

After the group of cases in which the histological evidence of tuberculosis appears adequate is set aside, the tuberculous nature of the process in the remaining cases in which the foreign material was and was not found seems about equally uncertain. Since the foreign material appears to be responsible for the formation of the giant cells in many cases, considerable interest attaches to its nature.

When examined with natural light in stained preparations the substance most readily visible is that forming the irregular basic staining rings. These masses vary in size from 15 or 20 micra up to collections 60 to 80 micra in diameter. When hematoxylin has been briefly applied they may fail to stain and appear yellowish brown and slightly refractive. The material consistently gives a strongly positive von Kossa's reaction for calcium. They fail to react to this reagent

after brief treatment with weak acids, hydrochloric and nitric, or with acid salts, as copper acetate. They are fast to fat solvents, hot alcohol, ether, and xylol. After treatment with acids they are still stainable with ordinary histological dyes. Calcium sulphate crystals can be observed in formation microscopically when sulphuric acid is drawn under the cover slip.

Examination with polarized light gives additional information as to the amount and nature of the material. When observed with crossed Nicol prisms, great numbers of refractive, crystalloid clusters become visible in the centers of the basophilic masses and in the bodies of giant cells and endothelial nodules. All the material appears to be anisotropic. The individual crystals vary greatly in shape, many forms probably being abortive or imperfect crystal formations. The crystalline material is partially soluble in acids, forms calcium sulphate crystals and does not form gas bubbles when treated with hydrochloric acid. It does not reduce silver nitrate (von Kossa's reaction), probably on account of its relative insolubility.

Several unstained preparations were referred to Dr. Emil M. Chamot, professor of microscopic chemistry at Cornell University. He was able to extract the material from the preparations and to identify calcium phosphate and considerable amounts of ammonium magnesium phosphate. He suspected small amounts of calcium oxalate but was unable to assure himself on this point.

The more minute deposits in the nodules of endothelial hyperplasia are too small to permit of isolation and identification, but it appears likely that they are of similar composition and that the three forms in which the material is visible represent accretion stages.

Since it has taken many years for this considerable number of cases to accumulate fresh tissues for the application of fat stains have not been available. In several cases the cover glasses of frozen section preparations were soaked off and in this way small amounts of amorphous and crystalline fatty acids have been identified. This finding suggests that the ring formed bodies have their origin in deposition of fatty acids saponification, and

calcium absorption. It is clear that further observations with fresh tissue are necessary in this connection.

THE SIGNIFICANCE OF THE FOREIGN MATERIAL

Our studies convince us that the peculiar lesions in the oviducts in nearly half of the cases are caused by the formation of foreign bodies in the tissues. We are certain, from reading the reports of the pathologists by whom the diagnoses of tuberculous salpingitis were made, that they were all greatly influenced in their decisions that the lesions were tuberculous by the presence of the giant cells. The view that this foreign substance is not a natural product of a tuberculous inflammatory process is supported by the fact that it is absent in the more typically tuberculous lesions. Calcium and magnesium phosphate are natural products of tissue and tissue juices but their presence in crystalline form in so many similar lesions requires explanation. Possibly in the course of an inflammatory reaction in the oviduct pathological metabolites, in the form of crystalline material persist as foreign bodies and cause lesions simulating those of tuberculosis. This view certainly offers some explanation of the benign character of the disease.

SUMMARY

In a strict sense we have presented no conclusive evidence that the reaction in these cases is not a peculiar reaction to the tubercle bacillus. The absence of definite tuberculous granulation tissue, an obvious alternative cause for the formation of the giant cells, and finally, the lack of any clinical evidence of tuberculosis in other organs are cogent reasons in favor of our contention. It is clear that the problem requires further investigation. There are numerous instances in pathology in which it has been necessary to separate pseudotuberculosis from genuine tuberculosis as in the mammary gland, thyroid, ischio-rectal tissue, etc. At least, it is reasonable to insist that suspected cases of tuberculous salpingitis should be subjected to rigid bacteriological tests and that personal opinion as to the nature of histological lesions should be supported by animal inoculations.

SOLITARY CYSTS OF THE KIDNEY

A REPORT OF SEVEN CASES AND OBSERVATIONS ON THE PATHOGENESIS OF THESE CYSTS¹

ALLANDEK B. HILFER, M.D., F.A.C.S., SEATTLE, WASHINGTON

IN no other phase of renal pathology has there been so much fascinating speculation as to etiology, uncertainty as to pathogenesis, and lack of adequate classification as in the so called solitary cysts of the kidneys. The term "solitary" has been used to distinguish the large cysts of adult life from congenital polycystic kidneys and from the multiple small retention cysts of chronic nephritis. Yet the assumption that these cysts are an entity with a common origin on the basis of number and size alone does not seem justified from a review of the reported cases.

Many cysts have been recorded under the title of solitary that vary widely in their pathological features. Although they are defined as voluminous cysts, occurring singly in a kidney otherwise normal, a review of the cases which have appeared in the literature under this generic term shows that in many instances they were multiple and in some bilateral, that a large number were associated with definite and marked pathological conditions in the same kidney, and that many were indistinguishable from the larger nephritic cysts. Quite frequently hemorrhagic cysts have been included in the tabulation of solitary serous cysts.

From a study of the reported cases it is evident that this lack of conciseness is caused by the fact that large cysts in the kidney are not a distinct entity with a common histogenesis but that their direct etiology varies and because of this they may differ as to number, size, contents, sac wall, and associated renal pathology. It is my contention, however, that the mechanism of their production is essentially the same.

The same confusion exists in the classification of hemorrhagic cysts. Leopold suggested that they are a result of bleeding into a serous cyst. Some of them are. But there is a great difference between the thin walled cyst with serosanguinous contents, which evidently arise on this basis, and those whose thick walls

contain large amounts of fibrous tissue, atrophic renal parenchyma, at times remnants of tumor tissue, and an inner layer of organized blood clot arranged in superimposed lamellae of various ages. It has been suggested that they arise from hemorrhagic infarcts or encapsulated hematomata. Others contend that all these hemorrhagic cysts develop in neoplasms which have been destroyed in the growth of the cyst and the cells of which are left as remnants in the sac wall. Judd and Simon reported two cysts which they felt had their origin in aneurysms because of elastic tissue, intima, and endothelium in the wall. They feel that this is the most likely cause of hemorrhagic cysts.

So we find that there is a tendency for each author to describe the origin of this condition on the basis of his own particular case, being careful to exclude from his classification others with a definite etiology and with slight pathological differences, and losing sight of the fact that these cysts may not be a distinct entity with a common origin. The direct cause may vary and with it the pathological features, but the mechanism of the cyst formation is essentially the same.

The object of this paper is to report 7 cases of large solitary cysts of the kidney, 4 serous and 3 hemorrhagic, to present a review of the reported cases with particular reference to the etiology, and to describe the experimental reproduction of a solitary cyst which substantiated a new conception of their pathogenesis.

REVIEW OF THE REPORTED CASES

I have been able to collect 249 cases, 12 of which were large serous cysts and 37 hemorrhagic (Table I). Seven personal cases, 4 serous and 3 hemorrhagic, bring the total to 216 serous and 40 hemorrhagic. Cunningham has 79 cases of small solitary cysts associated with nephritis from the autopsy records of the Boston City and Long Island Hospitals, are not included in this study.

¹Read before the Clinical Society of Genito-Urinary Surgeons, San Francisco, July 15, 1930; also Chairman's address, Symposium on Surgery of Kidneys and Bladder, Pan-Pacific Surgical Congress, Honolulu, July 15, August 25, 1930.

Fig 1 Roentgenogram of barium enema showing displacement of cecum and ascending colon by large cyst of right kidney (Case 1)

Fig 2 Pyelogram showing deformity produced by large cyst of right kidney (Case 1)

The difference in the number of collected cases of hemorrhagic cysts in this report and in that of Judd is caused partly by the fact that he excluded all cases associated with tumor and partly because quite a few cases of simple hemorrhagic cysts have not been reported under that title but have been included in tabulations of simple serous cysts.

The increasing number of case reports of solitary cysts indicates that this condition is not as rare as was formerly supposed. This

opinion is held by Branch (189), who says that although they are comparatively rare clinically, because many of them do not grow sufficiently large to cause symptoms, they are not a rarity to the pathologist and occur in 3 to 5 per cent of all autopsies.

A careful review of each case in which data was available has brought out the following pertinent facts with particular reference to etiology (Table II). The average age incidence for the serous was 45, for the hemorrhagic 48 years. Females were affected about twice as frequently as males.

In many instances a comprehensive clinical history was not given. When it was, it is of some significance that in quite a few the onset

Fig. 5 Large solitary hemorrhagic cyst arising from the lower pole of the left kidney (Case 2)

Although solitary cysts are defined as occurring in a kidney otherwise normal, in 82 instances there was definite renal pathology in the same kidney (Table IV). This is a higher percentage than the figure indicates because of the frequent lack of any pathological report and of careful histological study of the kidney. It will be noted that chronic nephritis was present 31 times. This does not include the degenerative and sclerotic changes in the vicinity of the cyst which have been attributed to pressure. In 12 instances the kidney was definitely arteriosclerotic. In 3 the cyst arose from an infarct. Eighteen of the hemorrhagic cysts were associated with other conditions, 12 of which were tumors.

CASE 1 A woman aged 50 years was admitted to the Seattle City Hospital, February 28, 1926 complaining of pain and soreness in the lower right quadrant of the abdomen. This had come on suddenly 2 days previously, and was accompanied with nausea, vomiting and diarrhoea.

The temperature on admission was 100 degrees F. There was no leucocytosis and the urine was normal except for a 0.7 per cent sugar and large amounts of acetone and diacetic acid. The blood sugar was 133 milligrams per 100 cubic centimeters.

Examination showed a mass in the lower right abdominal quadrant freely movable, not tender and with no overlying muscular rigidity. A diagnosis was made of fibromyoma of the uterus, diverticulitis of the colon and diabetes. The last condition was treated by diet and insulin and the patient's general condition improved.

On April 3 patient was referred to the urological service. The renal function as measured by phtha-

Fig. 6 Kidney after removal of the cyst showing its point of attachment to the lower pole and the small nodule of tumor tissue at this point (Case 2)

lein was 60 per cent the first hour and 10 per cent the second. The urine was normal except for sugar, acetone and diacetic acid. Plain X-ray pictures showed a faint irregular shadow about the size of a grape fruit in the right lumbar region, just above the iliac crest and after a barium enema a sharp displacement of the caecum and ascending colon inward and upward as if by a large, retroperitoneal tumor (Fig. 1).

On cystoscopic examination nothing abnormal was found in the lower urinary tract. The ureters were catheterized with no obstruction and the urines from both sides were normal. The function of the right was one half that of the left. Pyelo ureterograms showed a marked deformity on the right characteristic of tumor (Fig. 2). A tentative diagnosis was made of, first hypernephroma, second, monocystic kidney.

Operation April 5, 1926 Because of the possibility of hypernephroma, Cabot's incision (transverse lumbo-abdominal meeting a vertical mid rectus) was used and the right kidney exposed extraperitoneally. The perirenal veins were markedly dilated. There was a large thick-walled cyst on the external border and because of the impossibility of a resection a nephrectomy was done. The patient's recovery was uneventful.

Pathological report The right kidney was enlarged and elongated and the external border replaced by a large thick-walled cyst (Fig. 3). There was a reversal of the usual shape of the kidney, the internal border being convex with a resulting distortion of

Fig. 9

Fig. 9 High power photomicrograph of the tubules in the cyst wall showing the compressed atrophic tubular epithelium structure (Case 2)

the pelvis. The blood supply was abnormal (Fig. 4). The cyst had extremely dense thick walls with areas of calcification and contained a thick grumous material. Microscopically section from the wall showed dense fibrous connective tissue with occasional areas of calcification. Section from the kidney showed a patchy atrophy and sclerosis with atherosclerosis of the larger vessels characteristic of the atherosclerotic kidney of Ziegler.

CASE 2 A woman aged 36 years a patient of Dr. Homer Dudley was admitted to the Swedish Hospital November 16 1925 complaining of a dull aching pain and a mass in the left side of abdomen.

In the spring of 1922 she had had an attack of painful urination with frequency and burning. This was followed by a dull aching pain in the left lumbar region accentuated by walking and by lying on the left side. One month later there was a painless hematuria followed by chills and fever and some pain in the left loin.

Examination by physician showed blood and pus in the urine. A plain X-ray picture was negative for tumor or stone in the kidney. After 2 months all the symptoms disappeared until 2 years later when the dull ache in the back returned. This gradually increased until 1 year later the patient noticed a lump in the left side. There was no nausea or vomiting but some slight dysuria. The physical findings were essentially negative except for a large symmetrical freely movable firm painless mass in the left abdomen extending from beneath the border of the twelfth rib to the level of the crest of the ilium. The urine showed a trace of albumin many pus and red blood cells and bacteria.

Cystoscopy showed a normal bladder many pus cells in the left kidney urine as compared to a few in the right and a zero phthalein in 25 minutes from the left as compared to a 25 per cent output in the same time from the right. The left pyelogram showed a slight distortion of the lower calices but there was a large rounded shadow of the same density as the kidney shadow and apparently connected with the lower one half of the kidney. A diagnosis was made of solitary cyst of the kidney and pyelonephritis.

Operation January 13 1926 The left kidney was exposed through a left lumbar oblique incision. A large thick walled cyst arose from the lower pole. It was firmly adherent to the surrounding tissue. A nephrectomy was done without rupture of the cyst. The specimen (Fig. 5) consisted of a flattened kidney arising from the lower pole of which was a thick walled cyst about the size of a grape fruit. Its contents were hemorrhagic. The inner surface was roughened from attached fibrin and small masses of old blood clot. The cyst arose from the medulla near the tip of a pyramid (Fig. 6). At its deepest point of attachment was a small mass of yellowish friable tissue which microscopically proved to be hypernephroma. The kidney tissue immediately surrounding the cyst showed some atrophic changes. The cyst wall was one quarter centimeter thick and made up of fibrous connective tissue with some round cell infiltration (Fig. 1). There were areas containing atrophic dilated renal tubules (Figs. 8 and 9) and several atrophic glomeruli scattered throughout the wall were small masses of hypernephroma cells in strand between the fibrous con-

Fig 10 (left) Strands of tumor tissue such as were found in numerous areas in the cyst wall (low power photomicrograph) (Case 2)

Fig 11 High power of tumor tissue in the cyst wall showing the cellular arrangement typical of hypernephroma (Case 2)

nective tissue (Figs 10 and 11) The cyst had no epithelial lining

It is interesting to note that there was nothing in the gross specimen to suggest the presence of hypernephroma. The cyst was indistinguishable from any large, simple cyst. The presence of hypernephroma was demonstrated only after careful microscopic examination of the cyst wall.

CASE 3 A man aged 60 years, a patient of Dr R Mosiman, was admitted to the Seattle General Hospital February 28 1927 complaining of hematuria and a large mass in the right side of the abdomen. For the past 2 years there had been a painless hematuria. Just recently he noticed a mass in the right side of the abdomen which increased in size. It was not tender and there was no lumbar pain.

The examination showed nothing of importance except a large smooth mass in the right side of the abdomen extending from the inferior costal margin to the iliac crest. It moved on respiration and was not tender. On bimanual palpation it gave the definite impression of a kidney tumor. The urine contained a trace of albumin a few pus cells and a few hyaline and granular casts. A diagnosis was made of hypernephroma.

Operation March 1 1927 Because of the enormous size of the tumor the kidney was exposed transperitoneally. A large cyst almost completely replaced the right kidney. The remaining parenchyma was elongated and spread out over the external border of the cyst. There was a marked enlargement and engorgement of the venous collaterals. A nephrectomy was done without opening the cyst. The patient was alive and well 1 year after operation.

The specimen showed a large cyst 15 centimeters in diameter over the outer side of which were stretched the remains of the kidney measuring 7 by 4 by 3 centimeters (Fig 12). The contents were hemorrhagic. At the middle point of the cyst's attachment to the kidney was a yellowish nodule of tumor tissue which on microscopic section proved to be an adenocarcinoma (Fig 13). The parenchyma in the vicinity of the cyst showed atrophic changes. The cyst wall was thin and showed a complete connective tissue replacement (Fig 14). In numerous areas in the wall small strands of tumor tissue were found with the cellular arrangement of an adenocarcinoma (Fig 15).

Here again as in Case 2 we find a large, solitary cyst with remnants of tumor in the walls but indistinguishable on gross inspection from the simple, large hemorrhagic cysts not associated with tumors.

CASE 4 A woman aged 38 years a patient of Dr W Lippincott was admitted to the Seattle General Hospital December 13 1926 complaining of diarrhoea of 2 months duration. Three weeks ago there was a sharp colic like pain in the lower left abdominal quadrant associated with nausea and vomiting.

The general examination was essentially negative except for a firm smooth freely movable mass in the left upper quadrant. There was no rigidity or tenderness. The blood and urine were normal.

Cystoscopy showed the lower tract to be normal. The ureters were catheterized with no difficulty and the separate urines were normal and the divided functions equal and good. Control X-ray plates showed a shadow the size of a large orange continuous with the left kidney shadow. Pyelograms showed the left pelvis to be slightly enlarged. The

Fig 1. Large solitary hemorrhagic cyst of right kidney. Note the nodule of tumor tissue at the deepest point of the cyst's contact with the kidney. (Case 3)

lower major calyx was flattened and the entire pelvis pushed upward and inward. A diagnosis was made of simple cyst of the left kidney.

On February 11, 1927, a transperitoneal left nephrectomy was done through a rectus incision. A large cyst was attached to the lower one half of the internal border. It was impossible to excise it because of its intimate association with the renal pedicle (Fig 16).

The specimen showed a kidney 9 by 5 by 4.5 centimeters to the inner border of which was attached a thin-walled cyst 7 by 5 by 6 centimeters with serous contents. The cut surface of the kidney appeared normal. Microscopic section showed considerable edema and tubular degeneration. The cyst wall was thin and made up of fibrous connective tissue with some round cell infiltration.

CASE 5. A woman aged 59 years referred by Dr. M. W. McKinney was admitted to the Seattle General Hospital April 18, 1926, complaining of a dull pain and tenderness in the right upper abdominal quadrant with occasional attacks of nausea and vomiting. These attacks started 10 years ago and occurred about every 3 to 4 months.

The general examination was essentially negative except for marked tenderness below the right inferior costal margin. The urine was normal. There was a leucocytosis of 19,400 with 89 per cent polynuclears.

A diagnosis was made of cholelithiasis and an exploratory laparotomy done April 19, 1926. The gall

bladder was found to be normal. There was a cyst the size of a large lemon, attached to the lower pole of the right kidney. A transperitoneal nephrectomy was done. There was an anuria and the patient died of uremia on the seventh postoperative day.

The specimen was a kidney 10 by 5 by 4 centimeters attached to the lower pole of which was a thin-walled serous cyst 5 by 3. The walls showed a complete connective tissue replacement. There was no epithelial lining. The kidney showed atherosclerotic changes with glomerular obliteration, scar tissue, and endarteritis in some areas.

CASE 6. A man aged 66 years was admitted to the King County Hospital March 3, 1919, with third degree burns of both legs and feet. He developed a severe infection and toxemia and died April 16, 1919.

Autopsy report. Chronic myofibrosis, parenchymatous degeneration, arteriosclerosis. The left kidney had a large solitary serous cyst 7.5 by 5 by 6 centimeters on the middle of the external border (Figs 17 and 18).

CASE 7. A man aged 64 years was admitted to the King County Hospital August 8, 1928, complaining of a pain in the epigastrium. A diagnosis was made of carcinoma of the prostate, renal calculus, and chronic nephritis. The urine showed albumin, red blood cells, casts, and 10 to 12 pus cells to the high dry field. The phenolsulphonphthalein was 20 per cent in 1 hour and 1 month later 10 per cent in 2 hours. The urea nitrogen was 88 milligrams per 100 cubic centimeters and the creatinin 4.8 milligrams per 100 cubic centimeters. He died of uremia September 17, 1928.

The clinical diagnosis was confirmed at autopsy. In addition, a large serous cyst associated with several smaller ones was found in an arteriosclerotic left kidney (Fig 19). It is the same sort of cyst that has frequently been reported under the title of solitary cyst. Yet it is unquestionably a nephritic cyst in an arteriosclerotic kidney. In size, gross appearance, and histologically it resembles in every detail the cyst shown in Figure 17 and differs from it only in that the etiology here is evident. In Case 6 it is not. It does not seem reasonable to exclude it from classification under the generic term solitary cyst simply because we know its origin.

THEORIES OF ETIOLOGY

Numerous explanations of the origin of these cysts have been given (36 and 200). In the more recent literature, opinions are divided between the congenital theory and the idea that they are acquired retention cysts. The work of Kampmier (196) and of Reinhold (199) on the embryology of the uriniferous tubules is quoted in support of the contention that they develop from embryonic rests, persistent cystic tubules in the embryo, or from the failure of union of the glomeruli and tu

bules and that they are genetically related to polycystic kidney

There are various discrepancies in this theory. The disease is one of late adult life, the average age incidence being 45, and it is frequently found in the sixth and seventh decades. It is contended by supporters of the congenital theory that the cysts are slow growing and are not of sufficient size to cause symptoms until middle life, yet in a large percentage of cases considering the absence of clinical history in many the very rapid growth of the cyst over a period of a few weeks or months has been noted. It is not unusual to find a history as follows:

A sudden onset of symptoms referable to the kidney followed by a period of quiescence for a few months, a return of the symptoms, and the appearance of a small mass which increases rapidly in size. For example, in one case a cyst the size of a cricket ball was palpated and in 9 months it completely filled the abdomen. In another a cyst the size of a grapefruit increased to that of a full term pregnancy in 2 months. In another a movable kidney of normal outline was palpated. Three months later there was a cyst three or four times the size of the kidney.

This idea of the rapid growth of these cysts is contrary to the generally accepted opinion although Braasch (108) has referred to it. He

states "The rapidity with which these cysts grow is interesting. Patients not infrequently claim that they have noticed that the tumor which may be the size of an orange or larger, has appeared and grown to its present size within a few months. The etiology has not been determined and would make an interesting problem for someone."

In children these cysts are rare, both clinically and at autopsy. It is hard to reconcile these facts—that is, the age incidence of 45, the rarity in children at autopsy, the sudden onset of symptoms, and, in many instances, the comparative rapidity of growth with a theory which assumes that they start in early life, grow slowly, and therefore do not manifest themselves until the fourth or fifth decade. It would seem more reasonable to suppose that they were related in some way to the acquired renal lesions which are more common in middle life.

Many investigators support the theory that they are retention cysts and are due to some undiscoverable obstruction in the tubules with active renal secretion continuing distal to the lesion. The commonest obstruction is assumed to be a localized inflammation with peritubular sclerosis and contraction. This is, of course, recognized as the origin of the small, retention cysts of nephritis, but it is considered inadequate by many as an explana-

Fig. 12. Large solitary hemorrhagic cyst of right kidney. Note the nodule of tumor tissue at the deepest point of the cyst's contact with the kidney (Case 3).

lower major calyx was flattened and the entire pelvis pushed upward and inward. A diagnosis was made of simple cyst of the left kidney.

On February 11, 1927, a transperitoneal left nephrectomy was done through a rectus incision. A large cyst was attached to the lower one half of the internal border. It was impossible to excise it because of its intimate association with the renal pedicle (Fig. 16).

The specimen showed a kidney 9 by 5 by 4.5 centimeters to the inner border of which was attached a thin walled cyst 7 by 5 by 6 centimeters with serous contents. The cut surface of the kidney appeared normal. Microscopic section showed considerable edema and tubular degeneration. The cyst wall was thin and made up of fibrous connective tissue with some round cell infiltration.

CASE 5. A woman aged 59 years referred by Dr. M. W. McKinney was admitted to the Seattle General Hospital April 18, 1926, complaining of a dull pain and tenderness in the right upper abdominal quadrant with occasional attacks of nausea and vomiting. These attacks started 10 years ago and occurred about every 3 to 4 months.

The general examination was essentially negative except for marked tenderness below the right inferior costal margin. The urine was normal. There was a leucocytosis of 19,400 with 89 per cent polymorphonuclears.

A diagnosis was made of cholelithiasis and an exploratory laparotomy done April 19, 1926. The gall

bladder was found to be normal. There was a cyst the size of a large lemon attached to the lower pole of the right kidney. A transperitoneal nephrectomy was done. There was an anuria and the patient died of uræmia on the seventh postoperative day.

The specimen was a kidney 10 by 5 by 4 centimeters attached to the lower pole of which was a thin walled serous cyst 5 by 3. The walls showed a complete connective tissue replacement. There was no epithelial lining. The kidney showed atherosclerotic changes with glomerular obliteration, scar tissue and endarteritis in some areas.

CASE 6. A man aged 66 years was admitted to the King County Hospital March 3, 1919, with third degree burns of both legs and feet. He developed a severe infection and toxæmia and died April 16, 1919.

Autopsy report. Chronic myofibrosis, parenchymatous degeneration, arteriosclerosis. The left kidney had a large solitary serous cyst 7.5 by 5 by 6 centimeters on the middle of the external border (Figs. 17 and 18).

CASE 7. A man aged 64 years was admitted to the King County Hospital August 8, 1928, complaining of a pain in the epigastrium. A diagnosis was made of carcinoma of the prostate, renal calculus and chronic nephritis. The urine showed albumin, red blood cells, casts and 10 to 12 pus cells to the high dry field. The phenolsulphonphthalein was 70 per cent in 2 hours and 1 month later 10 per cent in 2 hours. The urea nitrogen was 88 milligrams per 100 cubic centimeters and the creatinin 4.8 milligrams per 100 cubic centimeters. He died of uræmia September 17, 1928.

The clinical diagnosis was confirmed at autopsy. In addition a large serous cyst associated with several smaller ones was found in an arteriosclerotic left kidney (Fig. 19). It is the same sort of cyst that has frequently been reported under the title of solitary cyst. Yet it is unquestionably a nephritic cyst in an arteriosclerotic kidney. In size gross appearance and histologically it resembles in every detail the cyst shown in Figure 17 and differs from it only in that the etiology here is evident. In Case 6 it is not. It does not seem reasonable to exclude it from classification under the generic term solitary cyst simply because we know its origin.

THEORIES OF ETIOLOGY

Numerous explanations of the origin of these cysts have been given (36 and 700). In the more recent literature opinions are divided between the congenital theory and the idea that they are acquired, retention cysts. The work of Kampmier (196) and of Reinhoff (199) on the embryology of the uniferous tubules is quoted in support of the contention that they develop from embryonic rests, persistent cystic tubules in the embryo or from the failure of union of the glomeruli and tu-

FIG. 20 Progressive development of hydronephrosis in direct proportion to the duration of the obstruction after complete ureteral block. The specimens at left represent a 7 day a 14 day a 28 day and a 56 day hydronephrosis in dogs after ligating the right ureter. At right normal kidneys.

permanent, uniform, partial constriction of the renal artery was produced by a small piece of rubber tubing which was split and fastened about the artery (Fig. 21). This reduced the blood supply to the kidney to a degree, which, although it permitted urinary secretion to continue evidently at a greatly diminished rate produced rather a marked anemia.

When these dogs were sacrificed at varying periods and the hydronephrosis that followed ligation of the ureter was compared with control hydronephroses for the same period, it was found that there was a constant progressive increase in the rate of development that is despite anemia and evident reduction of urinary secretion when the artery was compressed the dilatation was much greater than when the blood supply was not disturbed. Figures 22 to 25 illustrate this variation.

It will be noticed that this increased rate of development was not occasional but was con-

stant and progressive throughout the series. This variation was accounted for by assuming that the anemia produced by the arterial compression resulted in a parenchymal degeneration which weakened resistance in the kidneys and permitted a more rapid process of distention. In other words, the anemia reduced tissue tone and favored relaxation to back pressure from ureteral obstruction.

Group II—Arterial ligation plus ureteral obstruction (194) The importance of blood supply to dilatation after ureteral obstruction was further demonstrated in another group of animals in which, in addition to tying off the ureter one branch of the renal artery was ligated. The renal artery is divided into anterior and posterior branches. They are end arteries in the true sense of the word, so that ligation of either branch will result in infarction in the area which that branch supplies. Figures 26 and 27 demonstrate the area of distribution of the anterior and posterior branches

FIG. 16 Simple serous cyst of left kidney encroaching on the hilum and renal pedicle (Case 4)

tion of these larger cysts. Apparent discrepancies have been first that there is no evidence of any obstructive factor in many cases second that pathological lesions so situated as to block large groups of tubules are common yet solitary cysts are comparatively rare third that obstruction to the tubules at the papilla has been produced experimentally and that although there was dilatation which in some instances persisted no definite cysts were produced. In other words group tubular obstruction alone cannot cause these enormous dilatations which might be compared to

FIG. 18 Section of cyst showing the loss of kidney substance in its formation (Case 6)

FIG. 17 Solitary serous cyst of left kidney (Case 6)

blowouts of the parenchyma. There must be another constant factor.

I wish to review some experimental work on hydronephrosis, done in collaboration with Dr. Frank Hinman and published in 1923, which demonstrated a fundamental principle in the mechanism of renal dilatation following urinary obstruction. I feel that this principle can be applied to an explanation of the origin of large cysts of the kidney. For the sake of clearness it will be necessary to give here some of the details of this work (101, 192, 193 and 194).

THE CIRCULATORY FACTOR IN RENAL DILATATIONS

In a study of the development of hydronephrosis it was found that if a ureter is completely obstructed the degree of hydronephrosis which develops is in direct proportion to the duration of the obstruction (Fig. 20). With a standard uniform rate of development as a control it was possible to test the effect of various modifications of the renal secretion, such as diuresis, oliguria, splanchnotomy, compression of the renal vein, ligation of the vena collaterals, etc. on this rate. The most interesting and unexpected results were obtained in those experiments in which we directly modified the renal circulation by interference with the renal artery.

Group I—*Arterial compression plus ureteral obstruction* (192). For example, in one group of dogs after ligation of the ureter a

Fig. 23 Lower 21 day hydronephrosis in dog following complete ureteral block and partial compression of the renal artery upper kidney is used for comparison and represents the degree of hydronephrosis following simple ureteral block alone for the same period

These experiments established the importance of blood supply and local nutritional disturbances in the mechanism of renal dilations from urinary obstruction and also in the process of repair, which follows relief of obstruction. I feel that the principle involved can be applied to our understanding of the mechanism of the production of these large solitary cysts.

APPLICATION OF THIS PRINCIPLE TO THE PATHOGENESIS OF SOLITARY CYSTS

I was struck by the similarity not only of the gross appearance but of the histological structure of these experimental diverticula to the first case of solitary cyst which I have reported. This gave rise to the idea that the important factor, disturbance of blood supply in the mechanism of the production of the former might be concerned in the origin of the cysts.

Although group tubular block alone cannot produce them, it is conceivable in the light of the experimental work that if the same condition which produced the tubular obstruction interfered with the arterial supply to the same segment of the kidney introducing the factor

Fig. 24 Lower 28 day period hydronephrosis in a dog with partial compression of the renal artery, upper, simple hydronephrosis for the same period

of parenchymal anemia and degeneration, which favors tissue relaxation and rapid dilatation, then a cyst might form.

Fig. 25 Lower 56 day period hydronephrosis with partial compression of the renal artery, upper, simple hydronephrosis for the same period used for a control.

Fig. 21 Roentgenographic appearance of arterial barium sulphate injection of 7 day hydronephrosis of the left kidney of a dog with partial compression of the left renal artery. Thinning out of the arterial tree of the left kidney as compared with the right due in part to the compressing tube T which can be seen in place at the hilum.

in a rabbit's kidney. The pathological changes are those of anemic infarction, with cloudy swelling, hyaline degeneration followed by fibrosis and atrophy (Fig. 28).

When the ureter was ligated and the posterior branch of the renal artery tied off, the unique condition shown in Figure 29 was found after 14 days. The posterior one half of the kidney, which had been infarcted, ballooned out into an enormous diverticulum which communicated by a small opening with the hydronephrotic pelvis in the anterior one-half of the kidney, the blood supply of which had not been disturbed.

Figure 30 shows a section of the sac or diverticulum and the fenestrum which opened into the pelvis of the anterior one half of the kidney. The same result was obtained in nearly all the rabbits on whom the combined operation was done. Figures 29 to 35 show the specimens for varying periods of obstruction.

That the location of these diverticula is dependent on the area of infarction is beautifully illustrated in the specimen shown in Figure 35. In this experiment, in addition to

Fig. 22 Lower 14 day period hydronephrosis in a dog with partial compression of the renal artery. Upper kidney is used for comparison and represents the degree of hydronephrosis seen with simple ureteral obstruction for the same period. Remarkable acceleration in the rate of hydronephrotic atrophy when the artery is compressed.

the ureteral block, only a small arterial branch to the lower pole was sectioned, and the urinary back pressure besides producing a hydronephrosis in the normally vascularized portion of the kidney caused a blow-out which was limited exactly to the area which had been deprived of its blood supply. The sac wall in all instances was made up of fibrous connective tissue which was formed by the compression of the infarcted parenchyma by the urinary back pressure (Fig. 36).

What has happened in this group is that the urinary back pressure produced by ureteral ligation is exerted equally in all directions in the kidney and meets little resistance from the degenerated area, which has been deprived of its blood supply. As a result this balloons out into these enormous sacs, which can be compared with blow-outs.

In the first group, where the artery was compressed the anemia was uniform and the increased rate of dilatation general. In the second group where the one branch of the artery was ligated, the anemia was localized and complete (infarct), and the dilatation was correspondingly localized and extremely rapid.

Fig. 29 Gross specimen *in situ* 14 days after ligation of left ureter combined with ligation of posterior branch of renal artery. anterior half of kidney embedded in the large saccular dilatation of posterior half which has been deprived of its blood supply

weight unless it could be backed by experimental proof. Two investigators, Peterson (198) and Tollens (201), have attempted to produce cysts by obstructing the tubules, one with a silk suture about a papilla and the other by cauterizing the tip of a papilla. They obtained definite dilatation of the tubules but nothing which resembled a cyst.

If our conclusions are correct and if a localized arterial disturbance or parenchymal anamia is a factor in the formation of these cysts then its introduction is a simple matter by ligating one small branch of the renal artery in addition to blocking the tubules.

The rabbit's kidney is especially well suited for this type of experiment because it is a one lobed kidney and therefore has but one papilla (Fig. 38). It would be difficult in a multilobed kidney similar to the human to pick out one papilla for obstruction and then be sure in ligating one branch of the artery that the infarct would be in the same segment of the kidney. In the rabbit all the collecting tubules can be blocked at one time and when a branch of the artery is ligated urinary back pressure is sure to be exerted on the infarcted area. The following experiment was done.

Protocol - July 19 8 The kidney in a rabbit weighing 3 kilograms was exposed through a lumbar incision. The papilla was everted through a small incision in the renal pelvis and was fulgurated thoroughly to block the tubules. This incision was

Fig. 31 Same condition as illustrated in Figure 30 for a 21 day period of obstruction. Saccular dilatation of infarcted posterior one half of kidney. 1 Opening which communicated with the hydronephrotic pelvis of the anterior one half, upper control 21 day hydronephrosis

Fig. 26 Roentgenogram of a barium sulphate injection of the renal arteries in a rabbit. The anterior branch of the left artery has been divided between ligatures at A. The injection demonstrates the usual area of distribution B of the posterior branch.

In the experimental condition the urinary back pressure is produced artificially by ligating the ureter and the parenchymal anastomosis.

Fig. 28 Margin of infarct 7 days after ligation of posterior branch of renal artery. Lighter area to the right represents the infarct. Degenerative changes are marked.

Fig. 27 Sagittal section of injected kidney shown in Figure 26 demonstrating the relative distribution of the anterior and posterior branches of the renal artery. The posterior branch is injected.

by ligating a branch of the renal artery. In the cysts the intrarenal urinary back pressure is produced by group tubular obstruction and the parenchymal anastomosis by the implication of an arterial branch in the region of the block in the process (Fig. 37). With active glomerular function continuing distal to the lesion rapid dilatation takes place. The surrounding kidney undergoes a compression atrophy and produces the connective tissue wall of the cyst. In some instances the fibrous tissue substitution is complete; in others there are still remnants of parenchyma in the sac wall. The obstructive factor, whether it be obliterating endarteritis with peritubular sclerosis, atherosclerosis, infarct, tumor, or what not is involved in the process; hence all gross evidence that it was concerned in the formation of the cyst is eventually lost.

It is of course understood that the conditions mentioned are fairly common with well recognized pathological sequences. These lesions will produce a cyst only when they are so located as to cause group tubular obstruction with active glomerular function distal to the lesion and when because of them there is nutritional disturbance in the same segment of the kidney.

EXPERIMENTAL PRODUCTION OF SOLITARY CYST

An hypothesis of this kind, no matter how much the clinical features or pathological findings may support it, would carry little

Fig 36 Photomicrograph of wall of a diverticulum produced by infarcting portion of kidney and then blocking the ureter. There is a complete connective tissue substitution. Compare with wall of solitary cysts. Figures 7 and 42.

atherosclerosis, infarct, tumor, etc., which we assume could be etiological factors, might cause the combination of circumstances essential to cyst formation.

There is no question but that the mechanism described is operative on a small scale in the formation of the multiple small cysts in the arteriosclerotic kidney. The following is paraphrased from Mallory (197): "There is an obliterating endarteritis with sclerosis of the groups of arterioles and glomeruli and as a result nutritional disturbances of the adjoining parenchyma. The subtending tubules atrophy, and there is a connective tissue substitution. Small groups of tubules, the glomeruli of which are not involved become occluded by the peritubular sclerosis and there is dilatation with cysts." They are multiple because the process in the arteriosclerotic kidney is diffuse and small because the smaller vessels are involved. Hence the nutritional disturbance is confined to small area and the tubular obstruction to small groups.

It is conceivable that with occlusion of larger vessels large cysts might form on the same basis. This would be especially likely in the focal form of atherosclerotic nephropathy (atherosclerotic kidney of Ziegler) in which the process is not diffuse, involves only certain of the renal vessels, often those of large caliber.

Fig 37 Diagrammatic comparison of mechanism of production of experimental diverticula and of solitary cysts. A Experimental diverticula. Urinary back pressure produced by ligating ureter and parenchymal anemia by sectioning one branch of renal artery. B Solitary cysts. Urinary back pressure (intrarenal) produced by group tubular block and parenchymal anemia by implication of an arterial branch in the same process which produced the tubular block.

The relationship of at least some of these large, serous cysts to nephritis cannot be denied. In 28 of the reported cases, there were definite nephritic changes, chiefly vascular. In 25, the larger cysts, reported as solitary, were associated with smaller ones, similar in every detail except size and indistinguishable from those seen in nephritis.

It is not contended that all large serous cysts arise on this basis, but it does not seem that size should preclude the possibility of some of them at least having this origin.

It is also conceivable that a single infarction from embolus or thrombosis might produce a cyst. In the majority of instances such a lesion results in a wedge shaped infarct with subsequent scarring and contraction. However, if one of the smaller vessels of the corticomedullary zone were involved and the lesion so situated as to have distal to it active, functioning glomeruli, then a cyst might form. The area of infarction undergoes a compression

Fig 38 Illustrates an unlobed kidney. Section shows single papilla at P.

Fig. 32 Section of anterior one half of kidney the blood supply of which has not been disturbed showing hydronephrotic pelvis which communicates with vascular dilatation of the infarcted posterior one half of kidney seen behind Twenty-one day period of obstruction

closed with a fine silk suture. The posterior branch of the renal artery was ligated and the lumbar wound was closed. The rabbit was sacrificed after 18 days. Figures 39 to 41 show the condition found.

A cyst was produced similar in every way to the ordinary solitary cyst of the kidney. It did not communicate with the renal pelvis. The ureter passed behind it. It arose from the infarcted area. Figure 40 shows another view of the cyst with the ureter running behind it and the infarcted area.

A sagittal section of the kidney (Fig. 41) showed the normal pelvis, the place where the papilla was fulgurated and the thick walled cyst. The wall was made up of fibrous connective tissue (Fig. 42).

The confirmation of this theory of the mechanism of cyst formation is contained in the photomicro-

Fig. 33 Same condition as illustrated in Figures 29 to 32 for a 28 day period of obstruction. A Opening into the hydronephrotic anterior portion

graphs shown in Figure 43. It shows the normal parenchyma with dilated tubules for it must be remembered that all of them were obstructed in the papilla. There is also the area deprived of its blood supply with hyaline changes and degeneration and then the cyst wall arising from this area with a complete connective tissue substitution.

Let us briefly consider how the lesions obliterating endarteritis with peritubular sclerosis

Fig. 35 Twenty-eight day hydronephrosis with ligation of anterior branch of lower pole effect of the increasing pelvic pressure on the infarcted area in this case limited to the lower one third of posterior one half of kidney. A Communication between dilated pelvis and diverticulum. B

encapsulated, and a small cyst form, but with such lesions as aneurisms, angioma and hybernephroma, frequently associated with these cysts, the bleeding would tend to be repeated and furnish the intrarenal pressure

SUMMARY

This conception can be briefly summarized as follows. These large, usually solitary cysts of the kidney are acquired. They are not a distinct entity with a common etiology but the mechanism of their production is essentially the same. Recognized pathological conditions of the kidney cause them but only when so situated as to produce a combination of group tubular obstruction and anæmic degeneration of the parenchyma from circulatory disturbances in the same segment of the kidney. In some instances an additional factor is repeated prolonged hemorrhages into the same area.

This conception explains the variation in size, number contents cyst wall, and associated renal conditions on the basis of variation of the direct etiological factor—the amount of group tubular obstruction and the area of nutritional disturbance depending on the size and distribution of the vessels involved. It also explains the apparent absence of a direct etiological factor in some instances for the original lesion may become so involved in the

process that all evidence of its presence is eventually lost.

Among the clinical and pathological features of large, renal cysts which lend support to this hypothesis are

1 The average age incidence of 45 years, a period when vascular lesions as arteriosclerosis, endarteritis, aneurisms, infarcts, and acquired lesions, such as tumor are common.

2 The rather frequent association of these cysts with lesions, which might produce the conditions assumed to be necessary for their formation.

3 The frequent presence in the kidney containing a so called solitary cyst of smaller cysts similar to the larger in every detail except size and indistinguishable from nephritic cysts.

4 The presence in the sac wall of groups of atrophied glomeruli and tubules indicating its origin from renal parenchyma, which has undergone a compression atrophy with a connective tissue substitution.

5 The presence of remnants of neoplasm in the walls of many of the hemorrhagic cysts as the only indication that tumor was concerned in their formation.

6 In many instances the sudden onset of symptoms, comparatively short clinical course,

Fig. 39 Solitary cyst produced experimentally in rabbit's kidney

Fig. 40 Photograph illustrating *I* infarcted area from which arises *C* cyst *U* ureter passing over cyst

atrophy and becomes together with the compressed surrounding parenchyma the connective tissue wall of the cyst. Hence all evidence that it was concerned in its formation is eventually lost.

The same holds true for tumors. Neoplasms arising in the medulla might produce the combination of tubular block and arterial occlusion. When this occurs the area blows out into a large cyst, usually hemorrhagic because of the tendency for tumors to bleed. What would have been a hypernephroma or an angioma becomes a large solitary hemorrhagic cyst with barely discoverable remnants of tumor tissue in the walls. These are the only evidence of its origin because the original tumor became involved in the compression atrophy and together with the compressed surrounding parenchyma forms the wall of the cyst. The character of hemorrhagic cysts would suggest that in many, in addition to the tubular block, the intrarenal pressure is furnished by repeated hemorrhages into the parenchyma. A primary simple hemorrhage might become absorbed or if fairly large

and rapid growth of the cysts which can be easily understood in the light of the experimental work in which the enormous diverticula formed in a few days.

Finally by creating experimentally the conditions assumed to be necessary for cyst formation, we have been able to reproduce a large solitary cyst similar in every detail to those found in the human kidney.

Since the completion of this paper solitary cysts of the kidney have been reported by Cubert Hucper Lewis and Carroll Lucin Reluzzi Salleras and Secretari.

I wish to express my thanks to Drs Dudley Mosiman Lippincott and McKinney for permission to study their specimens and to report their cases (Cases 2 3 4 5).

Fig. 14 A normal squamous epithelial covering (cervix) Total depth small. Relatively wide depth of compressed surface cells. Lack of intermediate semiaactive cells. Lowermost layer low columnar in type. Complete lack of inflammatory reaction. A thin layer of cells corresponding to stratum granulosum beneath superficial cells.

Fig. 15 Squamous epithelium showing first an excessively thickened and keratinized superficial layer and second a definite stratum granulosum. Photomicrograph of section which was taken from a hypertrophied cervix which possessed an excessively thickened skin like covering.

say that it is made up of cells which are distinct morphologically from those of the malpighian layer, and are of the columnar type, though often cuboidal in shape, a fact which I attribute to an excessive degree of pressure.

The cervical squamous epithelium occasionally shows a well marked stratum granulosum running between the flattened superficial cells and the malpighian layer. This is, however, but poorly marked in the majority of cases, as compared with that observed in the squamous epithelium of normal skin, and if as according to Ranvier the granules of eleidin which these cells contain are used for transference into the keratin of the more superficial strata, it would appear that their function is not so necessary in the case of the cervix which has a relatively soft surface, as it is in the case of skin. In Figure 14 one may observe a thin line of cells in this position which stain rather more deeply than do the cells of the malpighian layer immediately below them.

Figure 15 is taken from a hypertrophied cervix possessing an excessively thickened surface, the superficial flattened cells of which have more right to the term *stratum corneum* than have those of the vast majority of cervixes. Here one may observe a very definite stratum granulosum, activity on the

part of which has evidently been called for in the supply of keratin for the excessively thickened and horny superficial layers. I consider however that activity on the part of the cells of the stratum granulosum is largely functional in this way, and I do not believe that they are concerned in any way with the cancerous reactions of this epithelium as a whole.

The basal columnar cells of the malpighian layer however react by proliferation to irritative stimuli. An inflammatory reaction in association with these cells produces multiplication of them by cell division. A percentage of the cells thus produced become displaced from immediate contact with the irritant and revert to passivity. New basal cells continue to proliferate. The thickness of the epithelial covering is increased and the new cells out of contact with the irritant take up an intermediate position between the stratum granulosum and the lowermost layers. These newly formed cells possess nuclei and cytoplasm which stain deeply. They are polyhedral in shape and have relatively thin walls. These new cells, now intermediate in position are seen to be undergoing gradual flattening as they near the surface, i.e., as they become relatively old. Their walls become gradually thicker and their nuclei and cytoplasm gradually diminish in amount.

AN INQUIRY INTO THE BASIC CAUSE AND NATURE OF CERVICAL CANCER¹

II THE RELATION BETWEEN CERVICITIS (EROSION OF THE CERVIX) AND CERVICAL CANCER

A. A. BAILEY M.C. M.D. CH.B. MANCHESTER ENGLAND

THE RELATIVE AGE, FUNCTION AND STABILITY OF SQUAMOUS AND COLUMNAR CELLS—METAPLASIA

THERE is no doubt that epithelial cells concerned in the covering of tissue surfaces, being produced at varying stages in the formation of the structure to which they belong may be said to possess a certain age relation to one another—a distinction by no means as definite as that existing between true embryonic cells and adult tissue cells but analogous to that represented by the distinction between say spindle cells and adult muscle fibers often observed in association. For instance it is obvious in dealing with squamous epithelium that the upper and outer layers of cells are older than the lower and deeper ones. In the cervix uteri the outer layers of squamous cells are progressively flattened until those at the surface have become compressed into a thick protective covering of toughened tissue composed of the membranes of the cell walls concerned and containing scattered compressed nuclei. The surface of the cervix however usually remains smooth and fleshy, and in this way is distinctive from a tissue such as the skin which is similarly covered histologically but which possesses a hardness to its surface due to the keratin in the stratum corneum which is present in very minor degrees in the superficial cells of the cervix. Immediately below this outer covering there is a layer varying in depth consisting of semi flattened cells possessing thick walls no protoplasm and ill defined nuclei. This layer merges insensibly into the polyhedral type of cell which makes up the bulk of the epithelial structure. The protoplasm and nuclei of these cells stain well. The lowermost layer, one cell in thickness, immediately abutting on to the subjacent tissues is columnar in type, though often cuboidal in shape. The

most active cells of this epithelial structure are those of this deepest layer. It is from these columnar cells that new polyhedral cells are produced in the event of proliferative activity. The nuclei of the lowermost polyhedral cells stain more deeply and sharply than the more superficial ones. The same may be said of their protoplasm. These facts are indicative of youth on the part of these cells. The nearer the polyhedral cells are to the basal columnar layer, which is a primary layer, the newer or younger they are. As one proceeds toward the surface one observes the fading of the protoplasmic contents of the cells, together with the diminution in density and distinctness of this nuclei. This aspect is tantamount to the passage from activity to passivity and proves the fact that the polyhedral cells possess only the mechanical protective function. Eventually these cells merge into the flattened type above mentioned. Cell production is carried on at the base of the epithelium the former basal cells being forced upward toward the surface.

A normal epithelial covering one which has not been called upon to exert cell activity, should therefore consist of a narrow band of cells a relatively wide portion of which should be composed of extremely flattened surface cells—significant of long standing quiet on the part of the deepest layer—and no intermediate newly formed cells of the type just described.

Figure 14 shows a normal unaffected squamous covering to the cervix. The superficial compressed or semi horny layer occupies approximately half of the total depth of the epithelium and abuts directly on to the cells of the malpighian layer, the lowermost layer of which is composed of cells of a low columnar type. This is often the case though by no means always is the lowermost layer definitely of a columnar type. One might, however,

Fig 14 A normal squamous epithelial covering (cervix) Total depth small. Relatively wide depth of compressed surface cells. Lack of intermediate semiactive cells. AN INQUIRY INTO THE BASIC CAUSAL AND NATURE OF CERVICAL CANCER¹

II THE RELATION BETWEEN CERVICITIS (EROSION OF THE CERVIX) AND CERVICAL CANCER

R. A. BAILEY M.C. M.D. CH.B. MANCHESTER ENGLAND

THE RELATIVE AGE, FUNCTION, AND STABILITY OF SQUAMOUS AND COLUMNAR CELLS—METAPLASIA

THEIR is no doubt that epithelial cells concerned in the covering of tissue surfaces being produced at varying stages in the formation of the structure to which they belong may be said to possess a certain age relation to one another—a distinction by no means as definite as that existing between true embryonic cells and adult tissue cells, but analogous to that represented by the distinction between, say spindle cells and adult muscle fibers, often observed in association. For instance it is obvious in dealing with squamous epithelium that the upper and outer layers of cells are older than the lower and deeper ones. In the cervix uteri the outer layers of squamous cells are progressively flattened until those at the surface have become compressed into a thick protective covering of toughened tissue composed of the membranes of the cell walls concerned and containing scattered compressed nuclei. The surface of the cervix, however, usually remains smooth and fleshy, and in this way is distinctive from a tissue such as the skin which is similarly covered histologically, but which possesses a hardness to its surface due to the keratin in the stratum corneum which is present in very minor degrees in the superficial cells of the cervix. Immediately below this outer covering there is a layer varying in depth consisting of semi-flattened cells possessing thick walls no protoplasm, and ill defined nuclei. This layer merges insensibly into the polyhedral type of cell which makes up the bulk of the epithelial structure. The protoplasm and nuclei of these cells stain well. The lowermost layer one cell in thickness, immediately abutting on to the subjacent tissues is columnar in type, though often cuboidal in shape. The

most active cells of this epithelial structure are those of this deepest layer. It is from these columnar cells that new polyhedral cells are produced in the event of proliferative activity. The nuclei of the lowermost polyhedral cells stain more deeply and sharply than the more superficial ones. The same may be said of their protoplasm. These facts are indicative of youth on the part of these cells. The nearer the polyhedral cells are to the basal columnar layer, which is a primary layer, the newer or younger they are. As one proceeds toward the surface one observes the fading of the protoplasmic contents of the cells, together with the diminution in density and distinctness of this nuclei. This aspect is tantamount to the passage from activity to passivity and proves the fact that the polyhedral cells possess only the mechanical protective function. Eventually these cells merge into the flattened type above mentioned. Cell production is carried on at the base of the epithelium the former basal cells being forced upward toward the surface.

A normal epithelial covering, one which has not been called upon to exert cell activity, should therefore consist of a narrow band of cells, a relatively wide portion of which should be composed of extremely flattened surface cells—significant of long standing quiet on the part of the deepest layer—and no intermediate newly formed cells of the type just described.

Figure 14 shows a normal unaffected squamous covering to the cervix. The superficial compressed or semi-horny layer occupies approximately half of the total depth of the epithelium and abuts directly on to the cells of the malpighian layer the lowermost layer of which is composed of cells of a low columnar type. This is often the case though by no means always is the lowermost layer definitely of a columnar type. One might however,

Fig 18 High power view of the primary cell division among the basal columnar cells. One may observe the process of nuclear division. The basal layer has begun to divide into two over a limited area

surface infection, with failure to respond to the irritative stimulus. Desquamation results, due to maceration of sensitive cells beneath them. The younger cells however, react in various ways according to the stimulus imposed. They are therefore unstable by comparison, and their instability to a given stimulus appears to be the greater the younger they are.

The all important layer from the functional point of view, is the lowermost, that composed of the columnar type of cell. As I have previously said, the actual height of the cells composing this layer may vary enormously. It is to be readily understood that a columnar cell situated between an epithelium many layers in thickness and dense mesoblastic tissues is subjected to varying degrees of pressure along its length and this fact no doubt plays an important part in the determination of the actual height of the cells concerned. In any case however there is no doubt but that the cells concerned in this basal layer one cell in thickness are of the columnar type even though many instances may show them to be of a low columnar variety or even cuboidal. A very large percentage of cases however show regular and very definite columnar cells in this situation though of a small and closely packed type.

I say that this is the all important layer functionally because I believe that it is di-

Fig 19 The low columnar cells of the basal layer of adjoining squamous epithelium encroaching by extension on to the old erosion area. Commencing regeneration of squamous epithelium originating from the basal layer

rectly concerned in the production of the new (young) cells of the malpighian layer (rete mucosum). The study of my cases has shown me that it is by a primary cell division of these columnar cells that the proliferative changes are instituted in that region of the epithelium affected by the irritant stimulus. Active and repeated cell division on the part of these columnar cells leads to the production of cells of the polyhedral type which go to the formation of the new lower layers of the rete mucosum.

Figure 17 shows a case in which an other wise perfectly normal squamous epithelium one that has hitherto been unaffected by irritative stimuli and which exhibits histological characteristics similar to that described in Figure 14, is subjected to an inflammatory reaction of low degree, as evidenced by a relatively loose leucocytic infiltration immediately in contact with its basal layer. In the area shown one may observe the very beginnings of proliferative cell division taking place in the columnar cells of this layer. Under the low power the basal layer is seen to present a localized thickening and 'double' appearance due to the primary division of the columnar cells. Under the high power magnification (Figure 18) one may definitely observe the process of nuclear

Fig. 16 The effect of a low grade irritant on the epithelial covering. The epithelium is much thickened. The superficial compressed layer is relatively thin. The new intermediate cells of the malpighian layer are very well marked.

Fig. 17 A low grade infection irritating the basal layer of a normal squamous epithelium. Proliferative cell division among columnar cells leading to formation of new cells of rete mucosum. A low leucocytic infiltration beneath epithelium. A localized doubling of basal layer.

and concentration the farther they are situated from the basal cells from which they have sprung. Obviously a gradual retrogression due to advancing age in association with entire lack of function.

A squamous epithelial covering, therefore which exhibits these intermediate cells in fair degree, thereby lessening the relative thickness of the superficial compressed layer shows histological proof of its having been subjected at one time or another to an irritative reaction affecting its basal layers. The greater the thickness occupied by these intermediate cells the more the proliferation that has occurred from the basal layer and consequently the longer has the irritation been continued. Examples of this type of mild reaction are to be found in long standing hypertrophies of the cervix in the causation of which a low grade infection has played a part.

Figure 16 is taken from a case of this type. The squamous epithelium here shows its reaction to a low grade infection which has become subdued and the evidences of which are now extinct. One observes the increased thickness of the covering epithelium. This is almost entirely due to the intermediately placed relatively young cells which can be seen to change gradually as they near the surface from possessing the histological fea-

tures of the new cell to that of the older surface cell. It will be noticed that during the course of this change the cells lose their cytoplasm much more readily than their nucleus which still remains even in certain of the cells which have passed to the stage of almost total compression. The thickened epithelium is again lined basically with a low columnar type of cell, quite distinct from those in immediate contact with it showing that this primary layer reasserts itself as such after activity ceases.

In any given squamous epithelium therefore the youngest or most recently produced cells are those situated at the base of the malpighian layer or rete mucosum in contact with the basal columnar layer. The nearer the surface a squamous cell is the older it is. A young or recently produced cell is relatively rich in the density of its cytoplasm. Its nucleus stains deeply and appears to be large on account of the relative smallness of the newly produced cell. Moreover we shall see that the younger a cell is the less stable it is. The older cells toward the surface of the epithelium those that have lost their cytoplasm and whose walls are becoming thickened are incapable of reactive changes. Their nuclei if still present are inert. One may frequently observe instances in which these older cells are in contact with

Fig. 22 (left) An irritant of first virulence attacking squamous epithelium. Relative depth of the infiltration is shown together with the slight reaction on the part of the adjacent epithelium.

Fig. 23 Contact site between squamous epithelium and irritant. Rupture of the basal columnar layers by the irritant. Local destruction of cells without reaction. Masses of macerated epithelial cells in the inflammatory exudate.

cells of the columnar type which first form the contact. These are primarily derived from the columnar epithelial cells of adjoining cervical glands by extension (see Fig. 4 low power, and Fig. 18) which are even more resistant to maceration than the columnar cells of the squamous basal layer but are later replaced by these basal cells which extend from the base of the adjoining squamous epithelium and always precede the reformation of the new squamous covering. This fact is exemplified in Figure 19. Here one may observe this basal layer growing upward to the surface of the old erosion. It maintains its morphological character in so doing although the height of the cells is not quite equal to that which normally appears. There is a complete absence of surface inflammatory reaction in this case, so that the new columnar epithelium has been allowed to travel a relatively long distance without reacting to an irritative stimulus. A long strip of cells, therefore, has thus grown out from the adjoining squamous epithelium. The furthestmost cells consist of only the one layer, basal cells themselves but as one approaches nearer to the original epithelium this layer becomes two or three cells in thickness and there are isolated regions in which this thickness is locally increased to four or five cells. It is noticeable that the columnar

type of the cell is definite where the layer is only one cell in thickness, but that the base of the thickened regions is composed of cells which are more cuboidal in shape. This I consider is undoubtedly due to the phenomenon of cell division having taken place in the basal layer with the consequent reproduction of polyhedral shaped cells which are extruded to the surface to become squamous

Fig. 24 The edge of an active ulcer. Old squamous epithelium. Subepithelial acute inflammatory infiltration of approximately one third the density of the destructive force. Sharp epithelial downgrowths. Intact basal columnar layer showing metaplastic activity and protective function.

Fig. 20 (left) The normal junction between squamous and columnar epithelia at the region of the external os

Fig. 21 The external os. A junction between the squamous and columnar epithelia. A subepithelial inflammatory reaction causes reactive thickening of the squamous but no change in the columnar epithelium

division in many of the primary cells. The nuclei of these primary columnar cells are elongated in shape. After division the nuclei of the resultant cells are still elongated but it is possible to observe a rapid transition on the part of the newly produced cells to the polyhedral type after complete separation from the parent cells with a consequent rounding of the nucleus. This phenomenon takes place in the cells produced away from the base of the parent cell. The new basal cell retains its columnar shape definitely if the irritation to which it is subjected is very slight and its reactive activity consequently slow, not so definitely if the irritation is intense, thus calling for rapid metaplastic activity. In this case the new basal cells tend temporarily to lose their definite columnar shape in the stress of severe involvement but in all cases the true histological nature of this layer can be traced in lesser involved areas, and in all cases the type is definitely resumed on the cessation of activity. I will therefore, assert that irritation below that of a destructive virulence affecting the columnar celled basal layer of the squamous epithelium as evidenced by an inflammatory reaction in the vicinity, results in a true metaplastic activity on the part of these cells whereby they progressively produce new cells of the

polyhedral type which are themselves physiologically inert but which, on account of their youth are highly unstable in their powers of resistance to irritation. The proof of this assertion I hope to show as we proceed.

With regard to age of the cells entering into the composition of the squamous epithelial covering therefore, one may say that the basal columnar layer is the primary layer—that from which the epithelium is produced and hence its cells are the oldest. Moreover they possess a physiological function, that of cell production by metaplasia. For the rest the oldest squamous cells are those at the surface—the youngest at the base, and these are as yet polyhedral. Squamous and polyhedral cells have no physiological activity. Their function is purely mechanical—a protective one.

Like all cells however, they exhibit the phenomenon of proliferation as a response to irritation and this phenomenon is more readily observed in the newly formed cells of the squamous epithelium than in the older ones—a fact which demonstrates the relative instability of the youthful cell.

In the commencement of healing of an erosion or even of ulceration of the cervix when the elements of epithelium again begin to cover the erstwhile inflamed zone, it is

Fig 27 Long bulbous downgrowths resulting from continued irritation of the squamous epithelium from below by an irritant of the third degree of virulence

Fig 8 Large irregular bulbous downgrowths some resulting from the filling of gland spaces. An appearance which might be mistaken for malignancy

In examining large numbers of sections one is frequently struck by the fact that an inflammatory reaction of a density¹ which is always sufficient to call forth strong reactive changes in connection with squamous epithelium effects no reaction when in contact with the normally situated original columnar epithelium. Figure 21 again shows the junction between the squamous and columnar epithelia. There is a subepithelial inflammatory reaction present which has had the effect of thickening the squamous epithelium (by the process already discussed) but has had no effect upon the high columnar cells which maintain their evenness of continuity.

This distinction in reactive qualities between these two types of epithelium is not so obvious in a section such as this which shows the two in contact as it is in others where the effect of the same irritant can be observed but in different areas. We shall however, meet with such instances later. My object however in this section is to show the great distinction in stability or resistance to irritation that exists between these two types of epithelium. It will be seen throughout that an irritant the action of which will produce destruction of the squamous epithelium will only produce a proliferative reaction in the columnar epithelium of the canal and glands.

and that one which can produce proliferative changes in the squamous epithelium has no effect upon the columnar. The distinction goes much further than this, as we shall see, but thus far we are able to exemplify these two dissimilarities which will suffice in the attainment of the object in view.

In dealing with a structure one cell in thickness the relationship in age of the cells does not enter as it did when dealing with the squamous epithelium, but the function of these columnar cells is obviously that of a

Fig 29 The more regular and shorter downgrowths associated with transient erosion

¹ And later discuss the question suggested by this term

Fig. 25 Old squamous epithelium affected by an irritant of the first degree of virulence from below—being an increase from an irritant of the second degree. Dense acute inflammatory infiltration in contact with terminations of downgrowths

Fig. 26 Local destruction without cell reaction of terminal portion of cell downgrowth. Basal epithelial activity is present in the superficial rarefied zone. Columnar cell division is well shown

in shape. This fact is in accordance with what we have seen when the basal cells react to irritation. When actively functioning they temporarily lose their definite columnar quality—a fact which is easily understood when one realizes that the cell function necessitates cell division. I therefore believe that during the process of repair in old erosions the new squamous epithelium is produced by the active physiological activity of these primary basal cells and not by direct growth extension from adjoining squamous cells. Indeed as I have said before I consider these cells to be physiologically inert having owed their inception to the basal cells themselves and being capable only of direct proliferation under stimulus as behooves cells the function of which is a purely mechanical one.

The question of the age function and stability of the elements of the squamous epithelium is now complete but we must still consider in this section the same factors with regard to the columnar cells which line the cervical canal and glands. These cells differ morphologically from those just discussed in that they are of the high columnar type possessing well marked nuclei at the base and are ciliated. Normally their junction with the squamous epithelium in the region of the external os is abrupt and serial sections of

this region fail to show any definite continuity between them and the basal columnar cells of the squamous layer.

Figure 20 shows this normal junction. At its termination the squamous epithelium tapers either abruptly or gradually the basal columnar layer growing upward to meet a descending surface. The columnar cells of the canal join this termination abruptly, and there is no impression of continuance between them and adjoining cells.

We have already seen in discussing the pathology of erosion that the columnar epithelium is the most resistant to infection and irritation. This is exemplified by the fact that this epithelium is the first to proliferate to the surface of the affected area, which it covers while still proliferating in the primary effort to effect repair (see Fig. 4). These cells are thus in actual contact with an irritant the virulence of which is sufficient utterly to destroy the original squamous epithelium *en masse*. We have seen moreover that it is not until this virulence is considerably diminished that the basal layer of the squamous epithelium again grows out on to the surface held by the columnar epithelium (see Fig. 6). The columnar epithelium, therefore is much more resistant to maceration and hence more stable than any of the elements of the squamous epithelium.

Fig. 27 Long bulbous downgrowths resulting from continued irritation of the squamous epithelium from below by an irritant of the third degree of virulence

Fig. 28 Large irregular bulbous downgrowths some resulting from the filling of gland spaces. An appearance which might be mistaken for malignancy

In examining large numbers of sections one is frequently struck by the fact that an inflammatory reaction of a density¹ which is always sufficient to call forth strong reactive changes in connection with squamous epithelium, effects no reaction when in contact with the normally situated original columnar epithelium. Figure 21 again shows the junction between the squamous and columnar epithelia. There is a subepithelial inflammatory reaction present which has had the effect of thickening the squamous epithelium (by the process already discussed) but has had no effect upon the high columnar cells which maintain their evenness of continuity.

This distinction in reactive qualities between these two types of epithelium is not so obvious in a section such as this which shows the two in contact as it is in others where the effect of the same irritant can be observed, but in different areas. We shall however, meet with such instances later. My object however, in this section is to show the great distinction in stability or resistance to irritation that exists between these two types of epithelium. It will be seen throughout that an irritant the action of which will produce destruction of the squamous epithelium will only produce a proliferative reaction in the columnar epithelium of the canal and glands,

and that one which can produce proliferative changes in the squamous epithelium has no effect upon the columnar. The distinction goes much further than this as we shall see, but thus far we are able to exemplify these two dissimilarities which will suffice in the attainment of the object in view.

In dealing with a structure one cell in thickness the relationship in age of the cells does not enter, as it did when dealing with the squamous epithelium, but the function of these columnar cells is obviously that of a

Fig. 29 The more regular and shorter downgrowths associated with transient erosion

¹ I shall later discuss the question suggested by this term

Fig. 30 Squamous downgrowth filling a gland space. New cell production laterally and old cells forced downward.

secreting epithelium, so that in all cases in which this epithelium is stimulated to the extent of proliferation, its resultant activity is always toward the formation of new glands. Thus we have seen to be the case when dealing with erosion.

We shall now proceed to consider the reactive changes produced in these various epithelial elements in response to the irritative stimulus, and to that end one must recognize the fact that cellular reactions will depend upon the strength or virulence of the par-

Fig. 31 A pseudo appearance of early malignancy produced by irregular bulbous downgrowths.

ticular stimulus to which they are subjected. A brief consideration of this factor must, therefore, take precedence.

THE RELATIVE VIRULENCE OF IRRITATIVE STIMULI AFFECTING CERVICAL EPITHELIUM

During the histological examination of a large number of specimens, as in this series one is constantly confronted with the fact that the irritative stimulus in contact with the epithelium, which is evidenced by the production of an inflammatory reaction in the vicinity falls for practical purposes that is according to the specific cellular reaction which results into five main degrees. The first may be called irritative stimuli of the first, second, third, fourth and fifth degree of virulence in descending order. One may safely presume that the typical inflammatory reaction which is produced in living tissues in response to the presence in them of foreign bodies, atypical cell formations (tumors), chemical irritants or infections by microorganisms varies in density directly as the degree of irritation produced by these intruders. Without going so far as to make an actual comparison by cell count of the leucocytic and lymphocytic cells in affected areas under consideration it has been quite obvious during the routine study of the 8,000 cases of my series, that from the point of

Fig. 32 The effect of an irritant of the third degree upon long standing proliferated epithelium.

Fig 33 General bulbous downgrowths

Fig 34 Irregular small epithelial nodules produced as the result of a round cell infiltration of the fourth degree. A local infiltrative concentration can be seen. No sub-epithelial rarefaction. Narrow zone of newly produced cells.

view of cellular density in the inflammatory infiltration produced, the tissues under consideration have been subjected to irritations (no matter from what cause) which may be divided into five main degrees of virulence, and it is a fact that the resultant epithelial reactions correspond to a great degree of accuracy with the density of the infiltration which is in immediate contact.

One recognizes, of course, the fact that the reaction on the part of the tissues of the body, which is itself the instigator of these histological evidences, is governed by the resistance of these tissues to invading irritants—and hence is necessarily a varied factor even as the actual degree of irritation is varied. The action of an irritant of known virulence upon the tissues of one particular person will result in the production of an inflammatory reaction of a density differing from that produced by the same irritant in another host. These reactions would, of course, be regulated by the affected persons' powers of resistance, and histologically the cellular densities of the associated inflammatory reactions will differ in the two cases in either one of the innumerable (presumably) minor degrees, or even sufficiently to warrant placing this known irritant in separate main categories of virulence in each case such as has been described. It will thus be seen that, owing to the presence of the varied factor of

the patient's resistance, it is compatible with sound reasoning to suppose that a given irritant may produce tissue reactions in different hosts, the histological examination of which would place that irritant in different main categories of virulence. The five degrees of virulence therefore, into which I have divided the irritants affecting cervical epithelium are purely relative—relative to the

Fig 35 Uniform epithelial thickening in response to an irritant of the fifth degree of virulence. The columnar nature of the basal layer is well seen. A loose epithelial lymphocytic infiltration.

Fig. 36 High power view to show the definite columnar character of the basal layer and the process of cell production from this by metaplasia

Fig. 37 General view of the effect of an irritant of the third degree of virulence upon new squamous epithelium (see The Cancer Phase—Squamous Epithelium)

resistance of the host. Theoretically each degree might be produced by the same irritant. Again any one degree might be produced by irritants varying in actual virulence. I have said above however that the effect of these five degrees of irritant upon the affected epithelial structures is constant to a high degree of accuracy as nearly as one can

speak of constancy in connection with the human subject and without absolute mathematical accuracy of detail.

We have therefore two varying factors (1) the actual virulence of the irritant and (2) the host's resistance combining to the production of a definite histological phenomenon which I will treat as a constant factor, on account of the constant effect produced by it—an inflammatory reaction of either of five cellular densities—to which a relative term in irritative virulence is applied indicative of the relationship of the varying factors mentioned and these relative degrees of irritation have a constant effect upon cervical epithelium.

To complete this chain as it were it would appear that one must expect the individual cells of cervical epithelium to react constantly to minute variations in the degree of irritative stimulus and therefore to maintain themselves as constant factors in the scheme. Whether this be so it is of course impossible to say but in any case the absolute constancy of this terminal factor is not a necessity in so much as their type of reaction to irritation is histologically uniform and as the main degrees of irritative virulence are alone able to effect the important and constant distinctions in cellular change one may safely presume that the included minor degrees are similarly uniformly reacted to.

Fig. 38 The cancer phase—squamous epithelium. The earliest evidence of the inception of cancer change. Perforation of the basal layer by inflammatory exudate. A typical cell proliferation on the part of the new polychoidal cell. Typical blurring of general cell mass (see text). The spasmodic and localized metaplastic response on the part of the basal layer.

Fig 39. Destruction of the new squamous epithelium without reaction by contact with a localized increased density of the subepithelial infiltration corresponding to the first degree of virulence (see Figs 22 and 23)

While recognizing, therefore that the degrees of density of inflammatory reaction in the human body are infinite, I have preferred here to divide them into five main degrees on account of the fact that cellular reactions as I have observed them throughout the whole of my series, fall into five main types and these correspond accurately to the main degree of irritation in contact

THE EFFECT OF THE ACTION OF AN IRRITANT OF THE FIRST DEGREE OF VIRULENCE UPON OLD SQUAMOUS EPITHELIUM

The picture here is one of complete and rapid destruction of the epithelial elements. The densest type of inflammatory reaction consisting of masses of closely packed leucocytes and lymphocytes envelopes the remains of the epithelial cells in the affected area. Destruction by maceration and liquefaction is carried out, without any effort to respond on the part of the epithelium. This type of reaction takes place in Stage 1 of so called cervical erosion. An acute irritant is in contact with an unprepared epithelium. Rapid destruction results. Among the masses of infiltrated leucocytes one may observe numerous areas of partially destroyed cells of the polyhedral type formally belonging to the deeper layers of the squamous epithelium.

Fig 40. The cancer phase—squamous epithelium. A somewhat farther advanced stage (see text)

The infiltration penetrates relatively deeply from the affected surface, and quantities of dislodged squamous cells come to occupy positions at a much deeper level than they did originally since they are carried inward by the fluid exudate excited by the irritant. They are, however, at this stage partially destroyed and totally inert.

Figure 22 shows the type of density of the inflammatory reaction associated with an irritant of the first virulence and the depth to which the infiltration penetrates relative to the pre existing epithelium.

Fig 41. The cancer phase—squamous epithelium. Another instance (see text)

FIG. 42 The cancer phase—squamous epithelium. A more advanced phase bordering upon developed cancer

One may observe in such a case that the epithelium adjacent to the affected zone shows only slight reaction. There is but a slight increase in its thickness showing that there has been no long continued action of the irritant upon it. What reaction there is, since such action is due to the increased production of new polyhedral cells by the stimulated basal layer and these are plainly visible, corresponds accurately to that expected when this layer is in contact with the looser inflammatory infiltration, which is here observed as a prolongation from the main mass. There has been no time for epithelial reaction to take place to any extent

Fig. 43 A very early developed squamous cancer (see text)

FIG. 44 High power view

along this lesser involved line. The transition between the denser infiltrative zone, in which the epithelial elements are destroyed and the relatively unaffected areas is abrupt. That the squamous epithelium here has as yet been unaffected by previous irritants is shown by its total thinness, the relative scarcity of polyhedral cells, and thickness of its superficial flattened layers, combined with the lack of subepithelial rarefaction, a legacy of previous erosion. The density of the subepithelial tissues here is such that the cells of the basal layer of the epithelium are largely cuboidal in type. There is also no evidence here of old cervical glandular proliferation. We are dealing, therefore, with the effect of the most virulent irritant upon old, original, squamous epithelium, the composing cells of which should possess the highest degree of resistance to maceration possible to this type of cell.

At the very point of contact however, between the denser inflammatory infiltration and the adjacent epithelium the basal columnar layer is broken through and inflammatory cells infiltrate to some extent between the squamous cells. There is no reaction on the part of the superficial epithelial cells which are inert and purely protective. The lower polyhedral cells show abortive attempts at proliferation but the irritant is too strong and its action too rapid at this site to allow

Fig. 43. The slight cellular reaction produced in glandular epithelium by contact with an irritant of the first degree of virulence

Fig. 46. The cancer phase—columnar epithelium. The cell reactions immediately preceding malignant change in young gland epithelium (see text)

resistance and local destruction is again observed here

Figure 23 shows this area, which is of course, common to all this type of case. Inflammatory infiltration into the substance of the squamous layers can be seen and the ruptured basal columnar layer is easily discernible. The lack of epithelial reaction to the irritant is definite. In this section one may also observe the isolated areas of half destroyed squamous cells at various levels in the densest part of the exudate. These cells are changed and varied in shape but tend to cling together for the most part in small groups.

Such is the effect therefore, of an irritant of the first degree of virulence upon squamous epithelium. The picture is one of total and rapid destruction, and the cellular reactions conform in detail to this process. The reactions here described are observed in the first stage of so called cervical erosion. In this condition the full effect of the irritant is relatively transient. The resistance of the affected tissues is such that the process of cell destruction is soon stayed and the phenomenon of repair commenced. The adjacent epithelial structures, therefore undergo little or no reactive change but constitute the basis from which the ultimate repair cells emanate as previously described.

THE EFFECT OF THE ACTION OF AN IRRITANT OF THE SECOND DEGREE OF VIRULENCE UPON OLD SQUAMOUS EPITHELIUM

The cellular reactions involved in this instance are observed in cases of true active ulceration of the cervix. The base of the ulcer consists of squamous epithelial elements destroyed by maceration in consequence of their contact with an irritant of the first degree of virulence. In the case of true ulceration the resistance of the tissues is

Fig. 44. The cancer phase—columnar epithelium. A slightly more advanced stage. The earliest evidence of definite cancer change in new gland epithelium

Fig. 48 Direct malignant proliferation from old gland elements in response to local and prolonged severe irritation

relatively poor. The process of invasion of the destructive irritant is inadequately stayed. The phenomenon of ultimate repair is delayed. The result is therefore, that the zone of destruction is more permanent and pending the advent of the repair it becomes gradually transformed, by organization of the inflammatory elements into one of chronicity, its composition being chiefly that of granular tissue in which are embedded scattered areas of semi liquefied polyhedral cells remnants of the primarily affected squamous lining which are carried far down into the depths by the destructive exudates.

Meanwhile the adjacent squamous lining is in contact with an inflammatory infiltration of a density distinct from that just discussed yet possessing equal activity since polymorphonuclear leucocytes are present in relatively equal quantity. The area now under consideration is, of course the extreme edge of a zone of acute inflammation the area at which tissue resistance is attempting to assert itself, or at which there is a falling off in the full force of the irritant. Irritation of the second degree, therefore is a transient

Fig. 49 Advanced cancer. The contact between the benign and malignant tissues can be observed

and relatively rapid phase between the destructive and milder types and its action upon old squamous epithelium is observed only in connection with the active stage of true ulceration. It is the degree of non destructive but most irritative type and is characterized by a typical reaction on the part of epithelial cells in contact with it. At either edge of a most active ulcer, the under surface of the adjacent squamous epithelium is in contact for a short distance with an inflammatory infiltration, of the same active nature as that which has destroyed a section of it, but of a density approximating to about one third. The cellular reaction in this region is most intense. The basal columnar layer is irritated to such an extent that its most active degree of metaplastic activity is called forth. Long sharp pointed downgrowths are quickly produced as the result. The central cells of these downgrowths are of the new polyhedral type (as previously described) resulting from division of the basal columnar cells but the cells lining the sides are of the low cuboidal or columnar type true basal cells. It is at the extreme point of the downgrowth that the greatest activity exists and here a small localized bulging may be brought about. The columnar cells can here be seen in the state of active division newly separated cells being extruded upward to the interior of the downgrowth. The true columnar character of these basal cells can well be made out in most cases, but such is

their activity at this region that the height of the lowermost cells is often considerably diminished. The transition from the columnar to the polyhedral type is well observed in the recently produced cells as they recede farther from the base. The tremendous activity of these basal cells acts as a protection to the central cells. Even in contact with this degree of irritation, the basal layer remains functionally intact. In the most irritated cell downgrowths a small abrasion of this layer may occasionally occur, with local cell destruction beneath, but that the external irritant does not tolerate irritative reaction on the part of the central cells, is shown by their lack of, or negligible, proliferation. Such a breach in this protective and functional layer is but a momentary in the case of epithelium, the reactive powers of which are capable, if only just, of combating the irritation inflicted upon them. This is so in the instance under consideration. In such a case the more acute stage of ulceration will be overcome and the condition will pass into chronicity and thence to healing.

Figure 24 shows the phenomenon here described. The type of cervix subject to ulceration is one that has undergone some previous hypertrophy. The squamous covering in this case is already thickened by the slow process of cell production under the lowest grade of irritative stimulus. The epithelial cells as a whole, however, may be said to be relatively old (although not as old as those comprising the original covering) on account of the extreme slowness with which this thickening has taken place and the length of time which it has been present. These facts are proved by the relative thickness of the superficial flattened cells of the stratum corneum, and the relative paucity of recently produced cells in the malpighian layer, which is almost entirely composed of vacuolated cells of the long standing type. The squamous covering shown in Figure 24, therefore, is of the type common in long standing hypertrophy. The basal columnar cells, therefore, are now functionally old cells. There is now no subepithelial rarefaction. Fibromuscular elements about on to the epithelial. Regenerative vitality must have

been acquired as the result of long continued rest. This type of epithelium then must be considered old.

It will be seen when old epithelium is in contact with an irritant, such as in this case, that the dense subepithelial fibromuscular tissues exert a protective effect of their own. The inflammatory cell exudate can be seen to occupy positions between the muscle bundles, which themselves serve as a partial barrier between this and the epithelium. There is obviously much greater difficulty in the irritant making contact with epithelial cells which are closely supported by dense mesoblastic structures than with those unprotected in this respect.

I consider that the importance of the cell reactions involved by contact with this grade of irritant lies more in the remote effect produced than in the immediate one. The immediate effect shows a great tribute to the manifold activities of the cells of the basal layer. The complete reaction is quite distinct from anything else seen in epithelial activity, and it is for this reason that I have nominated the causal agent to a degree of virulence of its own, namely, the second degree. The reaction is, however, a definitely localized one and, notwithstanding the angry nature of it, is not one of immediate danger, from the point of view of malignancy. This is the most rapidly produced epithelial reaction possible. The thinner and more pointed the downgrowths, the more rapidly they have grown, the greater the proportion of proliferative to metaplastic activity on the part of the basal layer. There is no danger of malignancy at this stage. If a point is reached at which the basal cells fail temporarily or permanently in their function, a breach is made in this layer and the central cells are locally destroyed. There is little or no reaction on their part. The irritant in contact is of too active a nature to permit of irritative proliferation in cells of the passive type. The importance of this phase lies in its remote effect. The most active new cell production is combined with an extensive subepithelial rarefaction. At the close of this phase, one is left with the most highly sensitive epithelium possible, composed both in the basal and

other layers of very young cells and totally unprotected from below by supporting mesoblastic structures

The effects of irritants of the first, second, and third degree of virulence upon old epithelium are the effects of different degrees of the same type of inflammatory reaction namely, acute inflammation as evidenced by the polymorphonuclear character of the exudate. The three degrees differ only in the density of the infiltration. The three reactions are distinct. The type of irritant is, however, the same and its function, in sufficient concentration, is to destroy epithelium. This it does in the first degree but not in the second or third. An irritant of the first degree nearly always attacks the epithelium from the surface aspect and it is as one of the second degree that its effect upon subepithelial contact is observed, thus resulting in the reaction just described. However, proof of the consequent destruction which would result from an increase in the virulence of a subepithelial irritant is shown by a study of Figure 25. According to my series, this is the rare condition in which an acute inflammatory exudate corresponding to the density of the first degrees of virulence is in contact with the squamous epithelium from below and along a wide area. The old nature of the epithelium can be observed as well as the strength of the deep supporting tissues. There is rarefaction, however in the more superficial zones. The inflammatory infiltration is extremely dense and highly polymorphonuclear. It is obvious here that the cell reaction similar to that provoked by an irritant of the second degree has taken place, leaving rarefied areas between the downgrowths, and that the irritant has then increased in virulence to the first degree, either by addition to it or by diminution of the patient's resistance at this stage. The types of the cell downgrowths are now densely involved in inflammatory exudate the elements of which can be seen to have penetrated through the basal cell layer into the substance of the central cells themselves. The muscular supporting elements in this region are, however quite in evidence, but are not capable of adequate protection against

this irritant. The terminal portions of the cell downgrowths are seen to be undergoing destruction by liquefaction. There is little or no irritative proliferative reaction on the part of the passive cells. Higher up in the rarefied areas, where the infiltration in contact is relatively slight, there are local metaplastic and proliferative reactions of a typical nature on the part of the basal columnar cells involved. The true destructive effect of an acute inflammatory infiltration is demonstrated here. There is no time for pure cell proliferation. Presumably the liquefactive properties of the polymorphonuclear leucocytes take effect too quickly. The very acuteness of the inflammatory reaction is a safeguard against malignancy, so long as the acuteness lasts. As I have said above, irritants of the first, second, and third degrees of virulence belong to this type.

THE EFFECT OF THE ACTION OF AN IRRITANT OF THE THIRD DEGREE OF VIRULENCE UPON OLD SQUAMOUS EPITHELIUM

The production of bulbous downgrowths
Without doubt the most common of the cell reactions observed in connection with epithelial irritation affecting the squamous layer is that produced by irritants of the third degree of virulence. It is the reaction typically resulting from the effects of an irritant of moderate strength acting over a longer period than those just discussed. It is to be found in the regions more remote from the zone of acute destruction in so called erosions and commonly as a phase during the stages of healing. It is also seen in the more chronic or less active type of ulceration. The bulbous or blunt epithelial downgrowth is the direct outcome of the effects of an irritant insufficient to cause destruction, but of sufficient strength to stimulate the basal layer to active metaplastic and proliferative activity of a slower and more uniform nature than that observed in the case of the second degree. The rate at which cell activity is called for is such as to enable the cells of the basal columnar layer to react more constantly and, as a rule, in degrees varying directly as their distance from the apex of the downgrowth which point owes its position to a localized

increased concentration of the inflammatory reaction concerned. The infiltration produced by this particular degree of irritation is of a density distinct from that of those already discussed and approximates to half that of the second degree.

In the case of the third degree, however, a certain latitude is allowable as to the actual density of the infiltration, and the bulbous downgrowths produced vary somewhat in the degree of bluntness directly as the degree of this density. This variation, however, in no wise detracts from the definite character of the third degree as a whole, as evinced by the specific cell reactions called forth by its action. It is also distinct in every way from the preceding and proceeding degrees of irritation.

The inflammatory infiltration in question is produced on the outer zone of a focus of acute inflammation. A point is reached at which the infiltration is reduced to a stage of easy tolerance on the part of the tissues in contact with it. This process is of course gradual, the diminution in the density occurring uniformly in conjunction with the distance from the central focus. After the zone occupied by the second degree is passed, however, the irritant no longer possesses the power of destruction, and from that point down to one at which the acuteness of the reaction may be said to cease, a typical cell response is produced resulting in the formation of bulbous downgrowths, as aforementioned, which differ only in their length and bluntness according to the slight variations in the density of the infiltration which has been in contact.

Figure 27 shows an example of the more active type of bulbous downgrowth. This type, of course, is found in connection with the outer zones of active ulceration or nearer to the central zone in the case of the more chronic ulcers or healing ulcers.

It is a fact, as is natural to suppose, that the long bulbous downgrowth does not occur in connection with acute erosion as the process is far too transient to allow of their production.

A long continued irritation in contact with the basal layer of the epithelium is necessary

to the production of this type, and this can be affected only in conjunction with true ulceration (Cf. ulcers).

In Figure 27 this condition may be observed. The original squamous layer shows a condition of long standing hypertrophy. The relatively newly produced cells stain more deeply in the region of the base of the downgrowths. As they recede to the surface, the nuclear staining becomes fainter until it is gradually lost as they approach the surface. New cell production is seen to be carried out at the sides of the downgrowths in the same way, but not to quite the same extent, so that the bulbous shape is thus maintained. The depth of the newly produced cells is relatively slight, as compared with the mass of old ones, thus demonstrating the slowness of the general reaction. The inflammatory infiltration is observed to be uniform but mild as compared with that observed in the preceding degrees. Exudative cells are seen in contact with the downgrowths both at the sides and bases, and it is obvious that the relative rate of cell production by the basal layer varies as the density of the infiltration in contact. The subjacent fibromuscular elements are observed in normal density and are acting as a partial protective agent to the epithelial cells, as previously described. Of course, these bulbous downgrowths may assume great relative size, varying with the length of irritation experienced and the degree of resistance of the subjacent tissues. A large bulbous downgrowth, for instance, is likely to result from active epithelium situated at the mouth of a cervical gland. The new cells easily fill the gland lumen. Figure 28 shows an example of this. But, in all, the process is the same—that of steady, uniform, polyhedral cell production by metaplastic activity of the basal layer, combined in addition with constant proliferative activity on the part of these same cells.

The bulbous downgrowths seen in connection with transient erosions are generally of a more uniform type and smaller. They are the result of a much less prolonged irritation. Figure 29 gives a fair example of this type. In this figure the columnar character of the basal layer is well shown. The newly formed

polyhedral cells can also be seen being extruded toward the epithelial surface. The regular subepithelial infiltration is well observed.

Figure 30 shows another example of squamous cells in process of filling a proliferated gland space. It will be seen that the production of cells is from the sides of the downgrowths, which are in contact with the irritant, and that old polyhedral cells are being forced down by pressure into the gland lumen. There is no cell activity at the base of such a downgrowth.

Numerous examples of bulbous downgrowths may be observed in connection with inflammatory conditions of the cervix. The foregoing are typical examples. The depth of the downgrowth varies as the length of the irritation and the degree of resistance by subjacent tissues. The longest downgrowths are, therefore, observed in connection with the outer zone in chronic ulceration and in cases in which the cells are placed within a gland lumen which contains an inflammatory exudate. In certain cases the irregular shape of the downgrowths, together with artefact in preparation, give a pseudo appearance of early malignancy. Figure 31 shows an example of this. A few irregularly shaped downgrowths, with small areas apparently separated owing to prolongations having been cut across, present an appearance which might be mistaken for commencing malignancy by anyone not accustomed to gynecological pathology.

In all this type of case, however, it will be seen that an acute inflammatory exudate of a certain maximum density, approximating to half that observed in the second degree, is in contact with the basal layer, that new cell production takes place from this layer on all sides of the downgrowth, and that the rate of production varies directly as the local density of the general infiltration. The fact is evident, however, that the rate of new cell production called for by this third degree of irritation is not too fast to be conveniently dealt with by the metaplastic and proliferative powers of the basal layer of cells. In no area does one find a rupture of this layer with destruction of the polyhedral cells beneath. Here and there

along the edge of the downgrowth, localized increased activity is seen, but this is accompanied by adequate replacement by the basal layer, and a new bulging prolongation results. The type of cell reaction to this degree of irritant is definite. Whenever a looser subepithelial infiltration of the same nature is observed, it is merely a transient prolongation from one of this degree, and as such is not responsible for any specific reaction.

Figure 32 shows very well the effect of this degree of irritant upon an old, thickened epithelium. The squamous covering here has long ago passed through proliferative activity, so much so that its entire thickness is practically made up of vacuolated cells possessing little or no cytoplasm. In these cases of long standing hypertrophy, as before mentioned, one looks upon the epithelium concerned as relatively old.

An irritation supervenes here and one can observe the zones of newly formed polyhedral cells standing out by contrast of their cytoplasmic contents from the old squamous cells. The basal cell activity and subepithelial infiltration are well shown. The general reaction results in the production of irregular bulbous downgrowths.

Figure 33 again shows a good example of the bulbous type of downgrowth extending over a wide area.

With a consideration of the third degree of irritation, we conclude the question of the effect of acute inflammatory infiltrations upon old squamous epithelium. I find that the effect of the purely chronic type of inflammatory reaction falls into two closely approximated types, which nevertheless might be distinguished on account of a difference in density. The first or more virulent of these we will now consider under the heading of the fourth degree.

THE EFFECT OF THE ACTION OF AN IRRITANT OF THE FOURTH DEGREE OF VIRULENCE UPON OLD SQUAMOUS EPITHELIUM

Chronic inflammation. The purely chronic type of inflammatory subepithelial exudate is comparatively rare. There is no doubt that in my series this particular reaction occurs only once, approximately to every thirty

examples of the acute variety. The cell reaction produced is negligible. There is very little irritative quality associated with a pure round cell infiltration. This type, however, is worthy of note on account of the well known pathological regard for "chronic inflammation" and "chronic irritation." These, of course are terms loosely applied to inflammation and irritation of long standing and do not necessarily apply to this exact type, which, as we shall see in connection with the cervix uteri at any rate, is a factor of relatively little importance.

Pathologically the effects of the purely chronic form of irritation, as evinced by the presence of a purely round cell subepithelial infiltration, are small in comparison with those just discussed. They should, however, be divided into two degrees according to virulence. The denser form, that which forms the subject of this chapter, is observed as a fairly regular infiltration in contact with the basal layer of the epithelial covering, having a density less than that associated with the active infiltration of the third degree, but possessing irregularly scattered nodes of concentration, similar to the lymphatic nodes observed in cases of leucoplakia vulvæ.

I do not consider these to be of the same nature inasmuch as they are more intimately connected, as a rule, with the general infiltration. I regard them nevertheless as an evidence of the relative virulence of this type of irritation, such as it is, and estimate that a reaction of this character possesses an irritative power only one stage less than that described as the third degree.

The typical reaction observed is distinct from all others in so far as the general cell activity is concerned. The epithelial response is limited and stunted. The mesoblastic tissues show little or no change. The basal columnar cells react to the irritant irregularly and to a relatively limited degree. Irregular, short, and scattered cell downgrowths are produced. Small nodular protruberances form the epithelial base rather than downgrowths. The slowness with which they are produced is evidenced by the fact that the cytoplasmic staining faculty of the more recently formed

polyhedral cells differs but slightly from that of the older cells in the epithelium, and that the number of newly formed cells, even in respect of the areas of downgrowth, is small, a fact which is demonstrated by the relative narrowness of the more deeply staining zone of new cells.

Where the infiltration is somewhat diminished, an irregularly diffuse thickening of the epithelium is produced by more regular basal cell activity. The fibromuscular elements remain practically unchanged. There is no rarefaction.

Figure 34 shows this reaction and indicates the position of a localized area of concentration in the infiltration.

The epithelial reaction here agrees in detail with what one would theoretically expect by a comparison with the effect of an irritant of the third degree. There is no doubt that the squamous epithelium behaves uniformly toward external stimuli. This uniformity of behavior is a constant factor throughout. The squamous epithelium itself holds no secret.

THE EFFECT OF THE ACTION OF AN IRRITANT OF THE FIFTH DEGREE OF VIRULENCE UPON OLD SQUAMOUS EPITHELIUM

The irritant of the fifth degree is the mildest possible one and is represented by the presence of a loose, round cell infiltration in contact with the basal layer of the epithelium, of a density approximating to one half of that associated with the fourth degree.

As might be expected from the uniform and slight nature of the stimulus (there are no associated points of concentration of the infiltration), the epithelial reaction is also uniform, or nearly so, and this takes the form of a generalized thickening by new cell production from the basal layer. There are no localized cell downgrowths here because the irritant never reaches a sufficient concentration to force their production. However, wherever the density is slightly increased, one may readily observe a corresponding slight increase in the general epithelial thickness, another tribute to the extreme uniformity of the epithelial behavior. It is certainly in these lowest grades of irritation that one may

polyhedral cells can also be seen being extruded toward the epithelial surface. The regular subepithelial infiltration is well observed.

Figure 30 shows another example of squamous cells in process of filling a proliferated gland space. It will be seen that the production of cells is from the sides of the downgrowths, which are in contact with the irritant, and that old polyhedral cells are being forced down by pressure into the gland lumen. There is no cell activity at the base of such a downgrowth.

Numerous examples of bulbous downgrowths may be observed in connection with inflammatory conditions of the cervix. The foregoing are typical examples. The depth of the downgrowth varies as the length of the irritation and the degree of resistance by subjacent tissues. The longest downgrowths are, therefore, observed in connection with the outer zone in chronic ulceration and in cases in which the cells are placed within a gland lumen which contains an inflammatory exudate. In certain cases the irregular shape of the downgrowths, together with artefact in preparation, give a pseudo appearance of early malignancy. Figure 31 shows an example of this. A few irregularly shaped downgrowths, with small areas apparently separated owing to prolongations having been cut across, present an appearance which might be mistaken for commencing malignancy by anyone not accustomed to gynecological pathology.

In all this type of case, however, it will be seen that an acute inflammatory exudate of a certain maximum density, approximating to half that observed in the second degree, is in contact with the basal layer, that new cell production takes place from this layer on all sides of the downgrowth, and that the rate of production varies directly as the local density of the general infiltration. The fact is evident, however, that the rate of new cell production called for by this third degree of irritation is not too fast to be conveniently dealt with by the metaplastic and proliferative powers of the basal layer of cells. In no area does one find a rupture of this layer with destruction of the polyhedral cells beneath. Here and there

along the edge of the downgrowth, localized increased activity is seen, but this is accompanied by adequate replacement by the basal layer, and a new bulging prolongation results. The type of cell reaction to this degree of irritant is definite. Whenever a looser subepithelial infiltration of the same nature is observed, it is merely a transient prolongation from one of this degree, and as such is not responsible for any specific reaction.

Figure 32 shows very well the effect of this degree of irritant upon an old thickened epithelium. The squamous covering here has long ago passed through proliferative activity, so much so that its entire thickness is practically made up of vacuolated cells possessing little or no cytoplasm. In these cases of long standing hypertrophy, as before mentioned, one looks upon the epithelium concerned as relatively old.

An irritation supervenes here and one can observe the zones of newly formed polyhedral cells standing out by contrast of their cytoplasmic contents from the old squamous cells. The basal cell activity and subepithelial infiltration are well shown. The general reaction results in the production of irregular bulbous downgrowths.

Figure 33 again shows a good example of the bulbous type of downgrowth extending over a wide area.

With a consideration of the third degree of irritation, we conclude the question of the effect of acute inflammatory infiltrations upon old squamous epithelium. I find that the effect of the purely chronic type of inflammatory reaction falls into two closely approximated types, which nevertheless might be distinguished on account of a difference in density. The first, or more virulent of these, we will now consider under the heading of the fourth degree.

THE EFFECT OF THE ACTION OF AN IRRITANT OF THE FOURTH DEGREE OF VIRULENCE UPON OLD SQUAMOUS EPITHELIUM

Chronic inflammation. The purely chronic type of inflammatory subepithelial exudate is comparatively rare. There is no doubt that in my series this particular reaction occurs only once, approximately to every thirty

between old squamous epithelium and that which has been recently formed as the result of the reparative mechanism in dealing with the damage caused by cervicitis. The new squamous covering is always found, therefore, in conjunction with evidences of the end results of cervicitis: proliferation of the cervical glands in the region of the external os, distended gland spaces in this situation, and a certain amount of rarefaction of the subjacent mesoblastic tissues. The new epithelium itself is often fairly uniform in thickness. The cells composing it are very much more uniform in their staining properties than those concerned in old squamous epithelium. As a result the basal columnar layer is not so prominent, and in addition the cells comprising it are a little more inclined to the cuboidal on account of their recent productive activity. The nuclei of even the surface cells are still obvious, there being a relatively narrow layer of the more flattened type and these but partially flattened as yet. The entire cell content of this recently formed structure is young. The diffuse and deep cytoplasmic staining together with the large size of the cell nuclei indicate this fact. The newly produced polyhedral cells are of necessity highly unstable, not far removed from the embryonic at this stage. Until they have enjoyed immunity from external irritation for a certain minimum period as the result of complete protection by the basal layer which produced them, they will not acquire that histological proof of stability indicated by the gradual loss of cytoplasmic staining and the diminution in the size of the nucleus which is observed in their older counterpart and which is known to be the associate of complete privacy both in function and in responsiveness. These new cells have the same passive rôle to play if they are allowed to grow old enough to play it. The cells of the superficial zone are nucleated, having been rapidly extruded to the surface in the manufacture of the new covering. The basal columnar cells must necessarily be relatively unstable as such, having been called upon to exert their full metaplastic function in this production. As pure protecting cells they cannot be com-

pared with the basal cell layer seen in old and hitherto unaffected epithelium nor even that associated with a diffusely (and hence slowly) thickened epithelium resulting from the effects of low grade irritation. In these latter cases we have seen how the basal layer reacts to the varying degrees of external stimulus, but in the case of newly produced epithelium the complete destruction of this layer is much more easily accomplished, and even the destruction of the new epithelium itself. As I have said elsewhere, however, destruction of epithelium is a safeguard against malignancy. Irritation of epithelium short of the power to destroy is the danger, and especially is this the case where the young cell is the one affected, and more especially still when that young cell plays a purely passive role functionally and can react to stimulation only by active proliferation. If that young cell were allowed to age only sufficiently to lose the active elements of its protoplasmic and nuclear contents, as evinced by the deep diffuse staining properties of these constituents, and to pass into its functional and responsive inactivity, the resultant reaction to external irritation would be nil or practically so as shown by the effect of destructive irritants upon old squamous epithelia. In all our previous inquiry the basal layer has either been in a position adequately to protect its inactive progeny or this has been destroyed with little or no reaction along with the basal layer.

In a word, there are only two conditions under which an irritant can exert prolonged action upon the polyhedral cells of squamous epithelium without being strong enough to destroy them. In every other case the basal cell layer is strong enough to protect them by metaplastic activity. Penetration of this layer by destruction results in destruction of the less resistant polyhedral cells beneath *ipso facto*. It remains, therefore, for the basal layer to weaken itself out of proportion to the maximum resistance of the cells it has produced. This is the state of affairs in the case of (1) entirely new squamous epithelium, such as we have just discussed, and (2) old squamous epithelium which has undergone rapid and continued activity as the result of

perceive the true delicacy of the epithelial cell reaction. Moreover it is from a study of this type of reaction as a basis that one may come to understand the cellular upheavals associated with the grosser irritants.

Figure 35 shows an example of the reaction to this degree of irritation. Beneath the somewhat thicker epithelial covering, the lymphocytic infiltration is seen to be slightly denser. The metaplastic activity of the basal cells, which are here well seen to be of a definite columnar type, is observed to be slightly greater in connection with the slightly denser zone of infiltration. The distinction is slight, but definite, and undoubtedly proves the delicacy and uniformity of cellular response to irritation.

Under the high power one may once again observe the specific metaplastic function of the basal columnar cells. The process of cell and nuclear division may be seen—an elongated cell containing two nuclei, the upper half of this cell being destined for the passive protective role of the polyhedral type (Fig 36).

With the consideration of this lowest degree of irritation, we complete the study of the effects of irritation generally upon old squamous epithelium. The five main degrees into which irritants have been divided are based, as previously explained, upon the constancy of the associated factors in each, viz (1) the density of the inflammatory infiltration produced by the irritant and (2) the cellular reaction invoked. The histological picture in each case is constant.

THE CANCER PHASE—ITS RECOGNITION WITH REGARD TO SQUAMOUS EPITHELIUM, AND THE EFFECT OF AN IRRITANT OF THE THIRD DEGREE OF VIOLENCE UPON NEW SQUAMOUS EPITHELIUM

In the foregoing text I have attempted to stress two points particularly (1) the delicacy and constancy of epithelial cell behavior under varying conditions, and (2) the histological and physiological distinctions between old and new squamous epithelium and columnar epithelium.

To my mind, from the examination of this series, the epithelial response to an obvious

stimulus in all its varying degrees is so constant a thing that one can not for a moment credit the possibility of behavior other than constant under any other circumstances or set of circumstances, on the part of these cells which have been only too ready to disclose their methods of weathering the mildest and severest storms of irritation.

Should it not be very probable then, that the very inception of cancer change in these same cells is the result of a similarly constant phenomenon?

It remains to acquire and study examples of the very earliest evidences of malignancy in the cervix, so early that histologically it has hitherto been impossible to recognize them as such.

The cervix removed for malignancy is of course, useless in this respect, the condition being too advanced histologically, but in a long series of cases such as now under consideration, examples of the beginnings of cancer may be found. Even then, however, slight as may be the evidence, the very definite character of it may be sufficient to mark the mode of its inception. It is not sufficient to say, "This epithelium has gone to the length of cancer change." The phases immediately preceding that change must be recognized—the Cancer Phase. The reason for something distinct from the cell reactions hitherto discussed which are associated with varying stages of cervicitis and ulceration, must be elucidated. We now thoroughly understand the pathology of erosion and ulceration as also the minute reactions of the epithelia involved in these conditions. We have accepted the fact that these states are predisposing factors to cancer growth. All pathological evidence has been overwhelmingly in favor of this being the case. My pathological findings in this series support this fact.

The stepping stone between the benign and malignant must be found—the link between cervicitis (erosion) and cervical cancer.

We have previously discussed the question of the relative age of the cellular elements composing the squamous covering (Part 2, par 1) and have recognized the distinction

the tissues in which it is situated readily enable these inflammatory cells to form actual contact with the new basal layer. This fact can be observed. Localized zones are seen in which the columnar cells of the basal layer are responding nobly to this unforescen irritation and are reacting in truly typical style. The actual cell and nuclear division can be seen even under the low power. (This fact furnishes yet another proof of the nature and formation of these cells.) The under surface of the epithelium therefore bulges downward in very slight degree here and there. The irritation is obviously of very short standing as yet. The metaplastic activity of the basal cells has only just begun.

In other areas, however, it can be definitely observed that the inflammatory cells have broken through the basal layer and are in actual contact with the most recently produced polyhedral cells. The basal layer has failed at last in its protective function. Its continued and prolonged activity has weakened it out of proportion to the maximum powers of resistance of the cells it has just produced. One can make out the scattered and macerated cells of this layer in the general exudate.

The reaction on the part of the subjacent cells is that for the observation of which we have conducted this search.

In this particular case the reaction is just commencing and has only proceeded to the extent of relatively slight increase in cell formation. It is, however, definite. There is a generalized loss of cell outline due to a general protoplasmic diffusion through the cell walls. There is a generalized lack of cell individuality. Overdistention of existing cells by deeply staining cytoplasm is noted. There is loss of cell shape possibly by bursting. Already irregular shaped and mitotic nuclei can be seen. Large diffuse nuclei shade off into the surrounding cytoplasm.

The whole affected cell mass is blurred and ill defined. There is multiplication by proliferation. The depth of the epithelium is increased. The newly formed polyhedral cells, temporarily possessing in high degree the wherewithal to reproduce their kind, are

proliferating actively under stimulation, and at the expense of their own existence. Each new cell produced in this way and at this speed from a newly born (by metaplasia) cell as a base, must inevitably possess less of the characters vital to functional life than its predecessor. The exact nature of these characters does not concern us in this investigation. Enough has been written upon the subject of cell morphology in cancer to make this clear. My object is concerned solely with the recognition of the onset of this change and I believe that here, in this specimen under examination, one may perceive the earliest evidence of the incidence of cancer in the human subject.

Figure 38 shows a view of the temporary and spasmodic metaplastic activity of parts of the basal layer and also the appearance which I have described as typifying the earliest onset of cancer change. The relatively loose nature of the subepithelial infiltration, corresponding to the third degree, is seen. The atypical nature and shape of both cells and nuclei, together with the protoplasmic diffusion which results in a blurring of the affected cell mass is also observed. There is a slight increase in cell depth of the epithelium caused by the new cell production. With regard to squamous epithelium, this is the moment of change from benign to malignant—the Cancer Phase. In every way, notwithstanding the slight degree of change from the normal here produced, the histological picture conforms in detail to that present in developed cancer.

In the case under observation the subepithelial infiltration, which has brought about the specific changes just discussed, shows areas of increased density in two or three separate and distinct regions. The squamous epithelium in contact with these areas, which correspond to an irritant of the first degree of virulence, is locally destroyed with little or no reactive change, thus agreeing accurately with the behavior of old squamous epithelium in contact with a similar irritant. Figure 39 shows this phenomenon. The complete absence of cell reaction is noticed, the picture being one of rapid destruction. Naturally one expects

irritation, a condition of things observed in connection with ulceration. In this latter case, however, the resultant columnar and polyhedral cells produced are relatively more resistant and stable than those of entirely new epithelium—in so far as they have been produced by a regular, if rapid, metaplastic activity on the part of basically old and original columnar cells, in contradistinction to a new cell production from a basal layer which itself owes its presence to proliferation.

However, there is no doubt that this latter condition does present that proportional diminution in protective strength to the basal layer necessary to the inception of cancer, but, as I have stated, not in so marked a degree as in the former state, and we shall see that it is the new epithelium therefore which provides the most favorable basis for cancer growth.

Figure 37 is derived from a cervix which was removed during the routine operation for prolapse. The cervix was somewhat hypertrophied and exhibited the gross appearances associated with old erosion—a chronic catarrhal exudate, the presence of nabothian follicles, and so on.

Histological examination of this cervix however, discloses a relatively small area of the portio near to the external os, which shows evidence of a recently recovered erosion. The new epithelium is of more or less uniform thickness. The cells composing it stain fairly deeply throughout. Their nuclei are relatively prominent by reason of their size and deep staining property. The contents of these cells possess in the greatest degrees those qualities which are the birthright of the infant cell—that cell which is newly produced by the very specific activity of an older type, produced as the result of metaplasia. The cell contents show plainly the ease with which such a cell could respond to external stimulus by proliferative multiplication in the effort to reproduce its kind, an activity which must inevitably lead to the gradual retrogression of the type.

It is evident that these newly produced cells possess, for a time, an excess of the normal constituents—a protective measure

against absolute extinction at birth—which is quickly absorbed as the cell proceeds to its passive function, receiving its protection thenceforward from more recently produced cells of the same kind, if not from the basal layer itself. It is a fact that the cytoplasm and nucleus diminish in bulk and character (as evinced by the diminution in basic staining property), as the cell is extruded to the surface, that is, as it becomes older, as it recedes farther from the possibility of external stimulation, and as it becomes progressively more and more passive functionally. I cannot say that these cells, at birth, possess for a time by derivation, something of the specific metaplastic function of their forbears, except in so far as their obvious preparation for activity is concerned. The cells produced by them are of the same type though rapidly proceeding to the parasitic or malignant.

In the section under consideration, the cells even of the superficial layers show well marked nuclei. There is no horny layer of flattened, empty cells as yet. The basal layer is well seen and the columnar nature of its cells can be observed. There is a certain rarefaction of the subepithelial tissues—relatively wide spaces intervening between faintly staining muscle elements. There is no evidence in this case of hyaline deposit but this occurs in varying degree in certain other cases. I attach no great importance, however, to this factor as it in no wise affects the point at issue. I consider hyaline deposition as an occasional associated factor in subepithelial rarefaction. Proliferated and distended cervical gland spaces are present in this section and encroach to the edge of the area under examination. The whole is a picture of a recently recovered eroded zone. How recent one can only guess.

Beneath, and in contact with this new epithelium is an acute inflammatory exudate, of marked polymorphonuclear character but in no way differing from exudates of equal density observed heretofore. This exudate corresponds to that which is produced by an irritant of the third degree of virulence. Its density is not great. The cellular exudate is moderately scattered but the rarefaction of

the tissues in which it is situated readily enable these inflammatory cells to form actual contact with the new basal layer. This fact can be observed. Localized zones are seen in which the columnar cells of the basal layer are responding nobly to this unforeseen irritation and are reacting in truly typical style. The actual cell and nuclear division can be seen even under the low power. (This fact furnishes yet another proof of the nature and formation of these cells.) The under surface of the epithelium therefore bulges downward in very slight degree here and there. The irritation is obviously of very short standing as yet. The metaplastic activity of the basal cells has only just begun.

In other areas, however, it can be definitely observed that the inflammatory cells have broken through the basal layer and are in actual contact with the most recently produced polyhedral cells. The basal layer has failed at last in its protective function. Its continued and prolonged activity has weakened it out of proportion to the maximum powers of resistance of the cells it has just produced. One can make out the scattered and macerated cells of this layer in the general exudate.

The reaction on the part of the subjacent cells is that for the observation of which we have conducted this search.

In this particular case the reaction is just commencing and has only proceeded to the extent of relatively slight increase in cell formation. It is, however, definite. There is a generalized loss of cell outline due to a general protoplasmic diffusion through the cell walls. There is a generalized lack of cell individuality. Overdistention of existing cells by deeply staining cytoplasm is noted. There is loss of cell shape possibly by bursting. Already irregular shaped and mitotic nuclei can be seen. Large diffuse nuclei shade off into the surrounding cytoplasm.

The whole affected cell mass is blurred and ill defined. There is multiplication by proliferation. The depth of the epithelium is increased. The newly formed polyhedral cells, temporarily possessing in high degree the wherewithal to reproduce their kind, are

proliferating actively under stimulation, and at the expense of their own existence. Each new cell produced in this way and at this speed from a newly born (by metaplasia) cell as a base, must inevitably possess less of the characters vital to functional life than its predecessor. The exact nature of these characters does not concern us in this investigation. Enough has been written upon the subject of cell morphology in cancer to make this clear. My object is concerned solely with the recognition of the onset of this change and I believe that here, in this specimen under examination, one may perceive the earliest evidence of the incidence of cancer in the human subject.

Figure 38 shows a view of the temporary and spasmodic metaplastic activity of parts of the basal layer and also the appearance which I have described as typifying the earliest onset of cancer change. The relatively loose nature of the subepithelial infiltration, corresponding to the third degree, is seen. The atypical nature and shape of both cells and nuclei, together with the protoplasmic diffusion which results in a blurring of the affected cell mass is also observed. There is a slight increase in cell depth of the epithelium caused by the new cell production. With regard to squamous epithelium, this is the moment of change from benign to malignant—the Cancer Phase. In every way, notwithstanding the slight degree of change from the normal here produced, the histological picture conforms in detail to that present in developed cancer.

In the case under observation the subepithelial infiltration, which has brought about the specific changes just discussed, shows areas of increased density in two or three separate and distinct regions. The squamous epithelium in contact with these areas which correspond to an irritant of the first degree of virulence, is locally destroyed with little or no reactive change, thus agreeing accurately with the behavior of old squamous epithelium in contact with a similar irritant. Figure 39 shows this phenomenon. The complete absence of cell reaction is noticed, the picture being one of rapid destruction. Naturally one expects

irritation, a condition of things observed in connection with ulceration. In this latter case, however, the resultant columnar and polyhedral cells produced are relatively more resistant and stable than those of entirely new epithelium—in so far as they have been produced by a regular, if rapid, metaplastic activity on the part of basically old and original columnar cells, in contradistinction to a new cell production from a basal layer which itself owes its presence to proliferation.

However, there is no doubt that this latter condition does present that proportional diminution in protective strength to the basal layer necessary to the inception of cancer, but, as I have stated, not in so marked a degree as in the former state, and we shall see that it is the new epithelium therefore which provides the most favorable basis for cancer growth.

Figure 37 is derived from a cervix which was removed during the routine operation for prolapse. The cervix was somewhat hypertrophied and exhibited the gross appearances associated with old erosion, a chronic catarrhal exudate, the presence of nabothian follicles, and so on.

Histological examination of this cervix, however, discloses a relatively small area of the portio, near to the external os, which shows evidence of a recently recovered erosion. The new epithelium is of more or less uniform thickness. The cells composing it stain fairly deeply throughout. Their nuclei are relatively prominent by reason of their size and deep staining property. The contents of these cells possess in the greatest degrees those qualities which are the birthright of the infant cell—that cell which is newly produced by the very specific activity of an older type produced as the result of metaplasia. The cell contents show plainly the ease with which such a cell could respond to external stimulus by proliferative multiplication in the effort to reproduce its kind, an activity which must inevitably lead to the gradual retrogression of the type.

It is evident that these newly produced cells possess, for a time, an excess of the normal constituents—a protective measure

against absolute extinction at birth—which is quickly absorbed as the cell proceeds to its passive function, receiving its protection thenceforward from more recently produced cells of the same kind, if not from the basal layer itself. It is a fact that the cytoplasm and nucleus diminish in bulk and character (as evinced by the diminution in basic staining property), as the cell is extruded to the surface, that is as it becomes older, as it recedes farther from the possibility of external stimulation, and as it becomes progressively more and more passive functionally. I cannot say that these cells at birth, possess for a time by derivation something of the specific metaplastic function of their forbears, except in so far as their obvious preparation for activity is concerned. The cells produced by them are of the same type though rapidly proceeding to the parasitic or malignant.

In the section under consideration the cells even of the superficial layers show well marked nuclei. There is no horny layer of flattened, empty cells as yet. The basal layer is well seen and the columnar nature of its cells can be observed. There is a certain rarefaction of the subepithelial tissues, relatively wide spaces intervening between faintly staining muscle elements. There is no evidence in this case of hyaline deposit, but this occurs in varying degree in certain other cases. I attach no great importance however to this factor as it in no wise affects the point at issue. I consider hyaline deposition as an occasional associated factor in subepithelial rarefaction. Proliferated and distended cervical gland spaces are present in this section and encroach to the edge of the area under examination. The whole is a picture of a recently recovered eroded zone. How recent one can only guess.

Beneath, and in contact with this new epithelium is an acute inflammatory exudate, of marked polymorphonuclear character, but in no way differing from exudates of equal density observed heretofore. This exudate corresponds to that which is produced by an irritant of the third degree of virulence. Its density is not great. The cellular exudate is moderately scattered, but the rarefaction of

junction between these cell masses and those produced as the result of the activity of old epithelium is distinct. In reviewing this long series, the various distinctions in cell morphology are evidenced time and again. There is no distinction, however, so definite as that which exists between a collection of infant cells, such as occurs in the production of this phase, and all other types.

Yet another instance, and this somewhat more advanced still, can be observed in Figure 42. Here the new epithelium has produced atypical downgrowths of the type described over a minute area. The subepithelial infiltration in contact, which is responsible, is very typical and the method of production of these downgrowths from the new polyhedral cells corresponds to that already described. Here is a case which exhibits an area, totally included within the field of the low power of the microscope which is passing through the interstage between the benign and malignant. The same may be said of the case from which Figure 41 is taken. In the case from which Figure 40 is taken a greater length of epithelium is involved but this is because the process of healing has of necessity involved a larger area.

The production of the cancer phase with regard to squamous epithelium, therefore, results from the effects of an irritant corresponding to the third degree of virulence, acting in contact with the under surface of relatively new epithelium. It is, of course, impossible to say for what length of time this action must be maintained in order to produce this result. By comparison, it appears to me to be quickly produced. The important point is that the infiltration is not in sufficient concentration to destroy utterly. Only the attenuated basal layer is destroyed. Moreover, the attack is delivered from below. There is every facility for the production of a subepithelial inflammatory reaction by direct spread throughout the rarefied supporting tissues, but whether or not this is the case I am not prepared to say. Possibly the irritant is conveyed by the blood stream in this instance. However, it is necessary for a distinct recurrence of the irritation to occur

in a subepithelial situation and during the time of instability of the epithelium. Undoubtedly the cancer phase reactions described are progressive from this point. There is no doubt that these reactions must increase rapidly with each new cell produced. Moreover, as the mass of infant cells becomes larger and consequently more parasitic in type, the infiltration in contact will increase in density both by reason of the presence of an increasing "foreign" element, and of the fact of increasing tissue activity and also on account of the increasing ease of secondary involvement by septic organisms as the result of progressive surface softening in the affected area. We, therefore, see in cases of developed cancer an associated inflammatory reaction which approximates more nearly to the first degree of virulence, but we must remember that this was not the one concerned in the initial production.

Figure 43 shows one of the earliest evidences of developed squamous cancer that I have in my series. The whole affected zone can be included in the low power field. I consider, however, that the cell morphology is typical. The area involved corresponds to that of an erstwhile healed erosion. Proliferated cervical gland spaces can be seen beneath this minute cancer. The general softening, which affects the surface, can be observed and the localized dense inflammatory infiltration which surrounds the involved epithelium is undoubtedly partly derived from bacterial infection through the surface. The junction with the more normal epithelium is abrupt because of the difference in density of the adjacent tissues causing separation on cutting. Yet the distinction between the cell reaction here and that seen and described in the preceding cases is barely discernible. The transition takes place in sensibly and is now complete. Figure 44 shows the high power view at the junction of the normal epithelium.

I feel that the link between the benign and malignant is bridged by the full consideration of the cases concerned in Figures 37 to 43. There is no doubt in my mind as to the mode of transition and I trust that this has now been made clear.

this to be the case, the new squamous epithelium being less resistant in all respects than the old. It is, however, all important to observe, in the one case, the two cell reactions toward two degrees of irritation, and to compare these with those occurring in the case of old epithelium. The effect of the irritant of the first degree must necessarily be the same in each case, but that of the third degree depends upon the type of squamous epithelium involved, the cancer phase being the outcome of the effect of an irritant of the third degree upon what we now recognize to be new epithelium.

Figure 40 shows a somewhat farther advanced stage of this phase. In this specimen one may recognize the junction between the old squamous covering and the newer epithelium which has recovered an old eroded zone. The widespread subepithelial rarefaction which is present in conjunction with the line of new epithelium, which proceeds down to the region of the cervical glands, is typical. The type of new epithelium is also typical, the general thickness being in this case uniform, except where now obliterated or stimulated, and the cells composing it more nearly approximating to one another as regards age than those of old epithelium. Here in this specimen, however, there has obviously occurred a recurrence of epithelial irritation which is affecting this newly healed area, and this is evidenced by the presence of an acute subepithelial inflammatory exudate in contact. This exudate varies in density in parts of the affected area. Where it approximates to an irritant of the first degree, the epithelium in contact is destroyed wholesale without reaction. This is the case over a relatively large area in this specimen. When the density of the infiltration corresponds to an irritant of the third degree, the typical epithelial reaction is produced. In this case one may observe the contact made between the exudate cells and the polyhedral cells of the epithelium. It is possible to see small groups of faintly staining basal columnar cells scattered by desquamation but still in the region of their normal position. They are no longer functioning. Masses of irregularly shaped cells are locally produced by prolifera-

tion from the activity of polyhedral cells. The most recently produced are often grossly enlarged and engorged by their cytoplasm. Their nucleus is large and diffuse. There is no longer any base line to the squamous epithelium. Irregular perforations of it have taken place and irregular cell masses composed of infant cells, many indistinguishable from the malignant, are beginning to penetrate into the rarefied tissues beneath. In other parts the basal cells are seen to be still functioning but it is obvious that the rate of activity is great. The type of polyhedral cell produced is not normal. It is too large, too distended, too deeply staining. Its nucleus is too diffuse. In some cases nuclear division can be seen. The cell produced is too primitive. However, where metaplastic activity has for a time prevailed, epithelial downgrowths of varying degree are formed. They are nevertheless quite distinct from those brought about by the activity of old epithelium.

It is but a trivial step from the phase which we have just observed to that of developed cancer. Differences hardly perceptible would lead to a definite assertion as to the presence of cancer. There is no doubt that the rate of cell activity in the phase just observed is even increasing. Each new cell produced is more active from a proliferative point of view than its predecessor. Soon the picture will be dominated by typical cancerous activity. This crucial phase will be obliterated. The vast majority of specimens examined are typical and hence useless from our point of view. The onset of developed cancer is associated with an increase in the density of the inflammatory reaction in contact. This is only to be expected since a relatively large area is involved by the presence of foreign cells. Also the secondary infection by pathogenic organisms is immediate once access is obtained and this is simple in surface cancers.

Figure 41 shows another instance of this vital phase. Here a subepithelial inflammatory exudate approximating in density to the third degree has destroyed the basal layer and by affecting the polyhedral cells directly, has produced atypical downgrowths consisting of typical primitive cells. The dis-

cells, morphologically similar to those produced by the columnar cells of the squamous basal layer. Prolonged stimulation of these cells, therefore, results in the production from them of a different type of cell, a process of delayed metaplasia analogous to but much less easily provoked than that seen in connection with the basal squamous layer. In other cases they may react by sudden and irregular gland multiplication, a process which proceeds directly to the malignant. Both these reactions, where truly original gland elements are concerned, are extremely rare. With regard to the former reaction, there is always some associated gland proliferation, which occurs in the presence of irritation, *ipso facto*, so that one may practically assert that direct cell change does not occur from original gland epithelium.

Indeed, it is only in the relatively rare cases of localized acute intracervical irritation, which occurs in the absence of surface erosion, that the original gland epithelium is affected in this way. In the vast majority of cases surface irritation involving the squamous epithelium is present, and in these the deeply placed gland elements show no cell reaction. It is left, therefore, to the newer gland elements, those resulting from direct proliferation in cases of surface irritation, to exhibit that type of change which proceeds inevitably to the malignant.

Figure 45 gives a good instance of the tremendous resistance of this type of epithelium. Here recently produced glandular elements are surrounded by an inflammatory infiltration of great density—equal to the first degree of irritative virulence. Little or no reaction results, however, in the cells themselves. The inflammatory exudate does not penetrate the basement membrane—which I consider to be extremely resistant—and the glandular epithelial cells are, therefore, out of actual contact with this exudate. I believe that this fact plays the same important part in the production of individual cell stimulation with resultant change that has been seen in the case of squamous epithelium. Figure 45 merely emphasizes a point that we have observed in many previous instances during our routine study of this series.

Occasionally localized cell downgrowths of minor degree are seen to originate from isolated areas of the surface epithelium of the canal. For the most part these are due to the stimulation of isolated prolongations of the squamous epithelium. Small strips of this epithelium occasionally encroach beyond the normal squamous columnar junction and remain as minute surface patches on the surface of the canal. I have not attached any special importance to these areas and have always found the epithelium concerned in them to react identically with adjacent and more normally situated epithelium of the same kind. In this connection I do not necessarily agree with Moench and other authors as to the excessively sensitive nature of squamous epithelium in this region. Although its presence has been frequently demonstrated in my cases, there has never been any definite evidence of untoward activity associated with it. Neither, indeed, would I expect such to be the case, in view of the normal morphology of its constituent cellular elements.

The new glandular elements, rapidly produced by proliferation, however, cannot possibly possess the resistance of their parent cells. It is in connection with these that we see the eventual degeneration of the glandular epithelium by enforced individual cell multiplication. There is no doubt that the high columnar cells which line the new gland spaces in the region of the surface erosion though morphologically similar, are much less adult than those from which they have originated. If proliferative activity has been rapid, there must be many of these cells which possess little or no further activity in this respect. The normal reaction to irritation is exhausted, just as it eventually is in the case of the basal layer cells of squamous epithelium. Further stimulation results in the direct production from these cells of polyhedral type cells, as the result of a metaplastic activity analogous to that possessed by basal columnar cells. Whereas, however, in the case of basal columnar cells this process can proceed at length by virtue of the specific function of these cells, in the case of these attenuated columnar gland cells this reaction marks their ultimate

I have previously explained that the activity of the basal layer in true ulceration may be such as to weaken locally and temporarily its component cells out of proportion to the maximum power of resistance of the polyhedral cells which it has produced, but that this is not nearly so probable as in the case of entirely new epithelium which owes its existence to recent manufacture by basal cells themselves produced by great proliferation.

Moreover, in the case of true ulceration there is not that transient phase of quiet which allows of the devitalizing specific metaplastic activity of the basal layer. The cellular downgrowths occasioned by active ulceration are controlled for the most part as already explained, and if as rarely is the case, but as Figures 25 and 26 show, there occurs a temporary increase in the virulence of the irritant in contact with these downgrowths, the new polyhedral cells are destroyed without reaction along with the cells of the basal layer. The irritant in contact is too strong to destroy the basal cells and stimulate the polyhedral cell without destruction. For this reason the true ulcer is much less liable to malignancy than the proliferative erosion. As I have said previously, cell destruction is a safeguard against malignancy.

In this respect, therefore, it would be necessary for the adjacent epithelium of a long standing ulcer, one which has passed the active stage, to be re-stimulated by an irritant corresponding to the third degree of virulence, and thus to be done in connection with prolonged downgrowths which have taxed the proliferative and metaplastic powers of the basal cells to the full, and before recuperation on their part has been effected. It would then be possible, but not as probable as in the case of new epithelium, that the basal layer cells in the region of the apices of the downgrowths, that is, the most recently produced, might be locally destroyed, thus allowing direct contact between the irritant and the subjacent polyhedral cells. It is a clinical fact that the development of cancer in connection with ulcers takes place in the long standing chronic type, such as we have

observed in this series, and not in the truly active ulcer.

THE CANCER PHASE—ITS RECOGNITION WITH REGARD TO COLUMNAR EPITHELIUM AND THE EFFECT OF AN IRRITANT OF THE FIRST DEGREE OF VIRULENCE UPON NEW COLUMNAR EPITHELIUM

In the chapter dealing with the relative age and function of columnar and squamous cells, I have indicated the extreme distinction which exists in the matter of resistance to irritative stimulus between these two types. The columnar epithelium of the cervical glands is extraordinarily resistant to maceration. This fact has been shown in dealing with the proliferative activity of these cells in response to stimulation by an irritant which is sufficient to destroy with ease, and without reaction the squamous epithelium. The columnar cells of the basal layer of the squamous epithelium, we have seen to possess a degree of resistance relative to their specific function, but in so far as they are a smaller type and functionally much more active, their resistance cannot be nearly so great as that possessed by the large, relatively empty and thick-walled cells the function of which is largely of a secreting nature, and not in any way connected with new cell production.

I regard these columnar cells, which line the normal non-proliferated glands of the cervical canal, as practically immune from malignant change. Cell change in them occurs only as a response to the most prolonged and virulent form of irritation. Their normal reaction, as we have seen, is by direct proliferation and new gland formation. The cells lining the old gland spaces for the most part remain unchanged.

Even gland proliferation, of definite degree, is not provoked by irritants of less than the first degree of virulence. We have seen elsewhere instances of the resisting power of these older gland spaces to irritants of the lesser degrees. When, however, the irritant in contact is prolonged in action and of extreme virulence certainly of the first degree columnar cells very occasionally show a direct reaction by the local production within the gland space of typical large polyhedral

cell production and malignant degeneration. The gland space here shown is similarly surrounded by an inflammatory exudate of the first degree, much of which has penetrated into the lumen. Direct contact is made, both from without and within, with the gland cells. These are now seen to be transformed over the greater part of the circumference of the space, into a mass of ill defined but typical cells of the malignant type. The process here has only as yet just begun. The rapidly multiplying polyhedral cells are seen to conform still to the original outline of the epithelium from which they have sprung. The basement membrane has disappeared. New cells have encroached beyond the normal boundaries. A typical mass of blurred and deeply staining cells in intimate contact with a dense infiltration results. Part of this single gland space is as yet unaffected. The inflammatory infiltration in contact with this part is locally very slight. The columnar cells here have not been stimulated, hence they still remain normal. Here is yet another proof of the necessity of direct contact between exudate and cell to produce cell reaction.

In Figure 47 we see the earliest evidence of definite cancer in glandular epithelium. The two gland spaces shown in Figure 46 and Figure 47 are the only ones in the whole specimen which are affected in this way. Here again one sees the necessity for absolute contact between the inflammatory exudate cells and the epithelial elements before cell reaction takes place. Figure 47 demonstrates this fact well. Without contact there is no reaction.

Figure 48 demonstrates the relatively rare reaction of direct malignant gland proliferation, resulting in the production of a true adenocarcinoma. This reaction invariably takes place in association with the deeply placed and original gland elements and is provoked by their direct contact with a dense inflammatory exudate corresponding to an irritant of the first degree. My cases show that it is rare to find these old glands involved by direct contact with an irritant in the absence of a surface erosion. Even in the presence of this latter condition, the vast

majority of cases show a relatively slight degree of direct involvement of the glands situated high in the cervical canal. The inflammatory exudate, in practically all the cases, is, for the most part, in association with the newly proliferated elements. An active irritant of the greatest virulence, involving the glands of the cervical canal locally, there being no spread to the portio or to the uterine cavity, is a very rare condition. A scrutiny of the cases of this series bears this out. I have said elsewhere that I believe these old glandular elements to be practically immune to cancer change. Their natural reaction to irritation is by direct proliferation. Very rarely is any other reaction required. Direct contact irritants are nearly always of a minor degree. The only irritant capable of calling forth an alternative reaction is one of the greatest virulence prolonged in its attack, that is, one acting directly upon these gland elements and analogous, either by reason of its own inherent virulence or by reason of the state of the patient's resistance, to that observed in the production of true surface ulceration. Under these conditions it is readily understandable that the natural and initial reaction of these gland elements to irritation will be provoked suddenly and continuously and out of proportion to their productive power, with the result that true glandular malignancy will be produced. I therefore regard these old gland elements as indestructible by pathological irritants.

The condition of solid alveolar carcinoma, resulting from the malignant production of polyhedral type cells from new columnar epithelium, as already described, is, however, the condition of importance, in so far as its occurrence is greatly in excess of true adenocarcinoma. We have completed our study of the incidence of the cancer phase in this respect. From this point it is but an insignificant step to that of developed cancer. My object in this instance therefore ends with the observation of this all important phase.

Developed cancer. I have only one thing to say with regard to developed cancer. It is necessary for me to emphasize my firm belief in the origin of carcinoma from pre-existing

response to the contact irritant and results in the inevitable and rapid extinction of these cells, which at last have been forced to the production of a type lower in the scale than themselves. This process, therefore, soon negatives the remaining resisting power of the young columnar cell which is soon destroyed and thenceforward, direct cell multiplication by proliferation with consequent inevitable degeneration in type, proceeds from the newly produced polyhedral cells. The hitherto well marked basement membrane, upon which the columnar gland cells rest, is broken, and encroachment by the now potentially malignant cells proceeds beyond the normal confines. Moreover, the inflammatory exudate, hitherto mainly located outside the gland space, penetrates within the lumen and establishes direct contact with these cells, thereby increasing the rate of production and ensuring the onset of malignant change. The type of polyhedral cell produced from the columnar gland cell is seen to approximate rapidly to that produced by direct proliferation of squamous polyhedral cells. It is infantile in type and distended by deeply staining protoplasm. It possesses an ill defined and large nucleus and ill defined and large cell walls. A collection of these cells present the typical blurred appearance noted in connection with the cancer phase in squamous epithelium.

Whereas, however, the cancer phase is produced in squamous epithelium by the action of an irritant of the third degree of virulence in direct contact with otherwise normal if young polyhedral cells, it is necessary for an irritant of the first degree to penetrate the basement membrane of attenuated gland epithelium or, even if in direct contact with the cells from within the lumen, to stimulate this type of cell to its last response.

We have seen in the case of squamous epithelium that an irritant of the third degree stimulates without destroying—a necessity in the production of malignant change. An irritant of the first degree destroys the young polyhedral cells of the squamous layer. These are, however, very different in type from those produced by the young gland cell. They are normal cells in themselves, produced

by the normal specific function of the basal layer, and for the purpose of a normal function when necessary (protective). On the onset of the cancer phase, we have seen that the density of the associated inflammatory exudate increases to that corresponding to the first degree, but cells potentially malignant or developed in malignancy are not now affected by this contact.

The cancer phase with regard to squamous epithelium, therefore, is developed from these young polyhedral cells, after destruction of the extremely attenuated basal layer. The cancer phase with regard to columnar gland epithelium is developed directly from the youngest proliferated cells—of similar morphology and function to that possessed by the highly resistant parent cells. The strongest irritant is, therefore, still necessary in its production. Cells, potentially malignant, are almost immediately produced there being no true metaplastic function possessed by these gland cells, and the rapid and progressive degeneration in type proceeds in the presence of this irritant, which, in this case, is similarly inadequate to destroy cells that have definitely embarked upon the malignant course.

Figure 46 demonstrates the cell reactions which immediately precede the onset of malignant change in young columnar gland epithelium.

Here, one may observe a newly produced gland space, situated deeply. It owes its presence to proliferation from older gland elements in response to the presence of a surface ulcer. This gland space is surrounded by, and is in intimate contact with an inflammatory exudate of a density equal to an irritant of the first degree of virulence. The basement membrane is seen to be perforated from without and a quantity of inflammatory cells are observed to have penetrated, via this perforation, into the gland lumen. In another area the commencement of direct cell stimulation by polyhedral cell formation can be seen. This gland space is about to exert its final cell response prior to the inevitable onset of malignancy.

Figure 47 shows an adjacent gland space in the same section. Here the process has advanced to the definite degree of irregular

cell production and malignant degeneration. The gland space here shown is similarly surrounded by an inflammatory exudate of the first degree, much of which has penetrated into the lumen. Direct contact is made, both from without and within, with the gland cells. These are now seen to be transformed over the greater part of the circumference of the space, into a mass of ill defined but typical cells of the malignant type. The process here has only as yet just begun. The rapidly multiplying polyhedral cells are seen to conform still to the original outline of the epithelium from which they have sprung. The basement membrane has disappeared. New cells have encroached beyond the normal boundaries. A typical mass of blurred and deeply staining cells in intimate contact with a dense infiltration results. Part of this single gland space is as yet unaffected. The inflammatory infiltration in contact with this part is locally very slight. The columnar cells here have not been stimulated, hence they still remain normal. Here is yet another proof of the necessity of direct contact between exudate and cell to produce cell reaction.

In Figure 47 we see the earliest evidence of definite cancer in glandular epithelium. The two gland spaces shown in Figure 46 and Figure 47 are the only ones in the whole specimen which are affected in this way. Here again one sees the necessity for absolute contact between the inflammatory exudate cells and the epithelial elements before cell reaction takes place. Figure 47 demonstrates this fact well. Without contact there is no reaction.

Figure 48 demonstrates the relatively rare reaction of direct malignant gland proliferation, resulting in the production of a true adenocarcinoma. This reaction invariably takes place in association with the deeply placed and original gland elements and is provoked by their direct contact with a dense inflammatory exudate corresponding to an irritant of the first degree. My cases show that it is rare to find these old glands involved by direct contact with an irritant in the absence of a surface erosion. Even in the presence of this latter condition, the vast

majority of cases show a relatively slight degree of direct involvement of the glands situated high in the cervical canal. The inflammatory exudate, in practically all the cases, is, for the most part, in association with the newly proliferated elements. An active irritant of the greatest virulence, involving the glands of the cervical canal locally, there being no spread to the portio or to the uterine cavity, is a very rare condition. A scrutiny of the cases of this series bears this out. I have said elsewhere that I believe these old glandular elements to be practically immune to cancer change. Their natural reaction to irritation is by direct proliferation. Very rarely is any other reaction required. Direct contact irritants are nearly always of a minor degree. The only irritant capable of calling forth an alternative reaction is one of the greatest virulence prolonged in its attack, that is, one acting directly upon these gland elements and analogous, either by reason of its own inherent virulence or by reason of the state of the patient's resistance, to that observed in the production of true surface ulceration. Under these conditions it is readily understandable that the natural and initial reaction of these gland elements to irritation will be provoked suddenly and continuously and out of proportion to their productive power, with the result that true glandular malignancy will be produced. I therefore regard these old gland elements as indestructible by pathological irritants.

The condition of solid alveolar carcinoma, resulting from the malignant production of polyhedral type cells from new columnar epithelium, as already described, is, however, the condition of importance, in so far as its occurrence is greatly in excess of true adenocarcinoma. We have completed our study of the incidence of the cancer phase in this respect. From this point it is but an insignificant step to that of developed cancer. My object in this instance therefore ends with the observation of this all important phase.

Developed cancer. I have only one thing to say with regard to developed cancer. It is necessary for me to emphasize my firm belief in the origin of carcinoma from pre-existing

epithelium Wilson has pointed out the frequent histological demarcation which exists between the carcinomatous cells and those of the adjacent epithelium, and has suggested that the direct origin of the one from the other is not yet proved. More recently Schiller has noted this appearance and speaks of an "oblique groove" which runs between the benign and malignant tissues.

The cases of developed cancer in this series have also shown a distinct demarcation line in practically every case. I regard this, however, as an artefact, and produced in cutting the sections. The density of the normal epithelium and its subjacent tissues is much greater than the loose, semi-liquefied and almost entirely cellular malignant tissue which itself extends to a relatively great depth. There is a great difference in consistency between these two adjacent tissues. On cutting thin sections therefore it is almost impossible to prevent separation at their junction—especially at the surface.

Figure 49, however, shows a developed cancer and demonstrates the contact between the benign and malignant cells.

THE BASIC CAUSE OF CERVICAL CANCER

From the foregoing it will be seen that my endeavor, in attempting to elucidate the problem of the relationship between cervicitis (erosion of the cervix) and cervical cancer, and incidentally to acquire a knowledge of the nature of cancer inception, has been to place these conditions as a whole upon a common basis. A study of my cases has shown that the one phenomenon common to all is the associated presence of an inflammatory exudate. Also that epithelial reaction, no matter by what type of epithelium, depends entirely upon intimate contact between the cells of the exudate and the epithelium concerned. One has also learned that the type of epithelial reaction produced depends directly upon the nature and function of the epithelium, and also upon the density and accessibility of the inflammatory exudate in contact with it.

There has been no exception to these rules throughout this long series of cases. Epithelial activity has never occurred in the

absence of a contact exudate. The type of reaction, under the various conditions, has been so constant as to impress me, beyond any doubt whatever, with the fact of the constancy of cell behavior. Once the relative values, in terms of age, function, and type, of these cells are understood, and the associated external factors taken into true account one might almost evolve the histological picture which would result from any given combination. There is nothing atypical in cell behavior in response to irritation until malignancy is reached. Even then, the "anaplastic atypia" is merely a matter of the phenomenon of malignancy itself, and is in no wise concerned with the factors which produced it. Once the border line is crossed the causal agent plays no further part. The stimulus has been given. What proceeds thereafter does so, in spite even of many additional external factors which thenceforward are present, and is, in itself, progressive and inevitable. That, however is not part of our concern. Our inquiry ends at the inception of this phase, which is brought about as the result of direct contact between inflammatory exudate cells and certain types of epithelial cells.

The inflammatory exudates observed throughout the whole of this series, and including those concerned in the production of the cell changes referred to, are typical and identical. There is no variation in type as far as the component cells are concerned. The relative numbers alone vary according to the degree of acuteness of the inflammation produced.

As previously explained I have preferred to use the word "irritation" in preference to 'infection' in dealing with these exudates, in so far as it is presumably possible for them to be produced by the action of purely chemical irritants as well as by bacterial organisms. The concentration of either of these agents however, is in the immediate vicinity of the exudate produced and there is no histological distinction in type resulting from their action, except, as I have said in the matter of degree. These exudates therefore may result from the action of either of these agents. In the case of the cervix uteri, however, there

is no doubt that septic organisms (including the gonococcus) are very frequently concerned, and, in my opinion, it is impossible to ignore the fact that organisms of this kind are directly responsible in the production of most, if not all, of these exudates. The discovery of the exact organism or chemical does not concern us. There is no reason to disagree with Gye's theory of a filtrable virus in this respect. He has concentrated upon the recognition of the initial causal factor in the production of cancer.

The nature of cancer, when produced, also forms no part of this work. Blair Bell and others have probed deeply into that aspect. Blair Bell regards the initial causal factor as unimportant in comparison with the nature of cancer itself, from the point of view of treatment. It is toward the recognition of an *intermediate causal factor* that this work has been directed. Whatever the initial cause be it is its direct expression which acts upon epithelial cells eventually to produce cancer change, and thus—a typical inflammatory exudate—is a constant factor toward this phenomenon.

I have divided the exudates concerned into 5 types according to relative concentration (Part 2, par 1), thus representing irritants of five degrees of virulence. I have avoided a definite cell count in connection with this division on account of its arbitrary nature, as explained. Nevertheless I believe that in each individual case the actual cell concentration of this exudate marks the degree of irritation exerted by it upon epithelium in contact. The fact that exudates of equal density may be produced in different cases by organisms or chemical irritants of varying virulence according to the resistance of the patient concerned is of importance, in so far as it increases the value—as the causal agent—of this intermediate factor, which alone acts constantly. The same initial factor acting in a number of cases, might result in the production of exudates of varying density in each. The cell reactions would therefore also vary. Cancer may be produced in one and not in another.

The densities of the two chief exudates, those corresponding to irritants of the first

and third degrees, are distinct. It has been seen that the action of an exudate corresponding to an irritant of the first degree of virulence is necessary to the production of cancer from columnar epithelium, and that one equal to an irritant of the third degree is sufficient in the case of squamous epithelium. In the latter case direct contact is assisted by subepithelial rarefaction. The exudate is in contact from below, but there has always been evidence of a surface gap from which direct subepithelial spread has undoubtedly been effected. I do not therefore consider this phase to be due to a secondary subepithelial irritation, emanating possibly from the blood stream.

I would, therefore, assert that the basic cause of cervical cancer is the effect of an inflammatory exudate (being the visible sign of an irritant of bacterial or chemical nature), acting directly upon epithelial cells, and of a density varying in accordance with the type of epithelium involved.

The nature of cancer inception is that of a pure cell reaction on the part of pre-existing but newly produced epithelial cells.

I do not believe that a single initial cause can produce this effect, constantly and in all cases, in connection with epithelium of one type alone, much less in connection with epithelia of different types. I do not therefore believe that there is one great initial cause concerned in cancer production, but that a variety of initial causes actually conduce to this end—through the agency of this single intermediate cause which alone is constant.

Cancer change in squamous epithelium is provoked by a re-irritation of new epithelium, in columnar epithelium, by a prolonged and constant irritation of great intensity, which is probably repeated many times.

As we have seen, the distinction between "new" and "old" squamous epithelium is arbitrary and not absolute. Epithelium of this type may be said to be "new" so long as the resistance of the columnar cells of the basal layer is less than the maximum resistance of the subjacent polyhedral cells. At the moment that the resistance of the basal layer becomes greater than that of the subjacent cells, in consequence of freedom from irritation or metaplastic activity over a period of

time, the epithelium concerned may be said to be "old"

In this respect, therefore, the phenomenon of cancer inception is a cell reaction which depends as much upon the time of its onset, within arbitrary time limits, as it does upon the factors which conduce to it

CONCLUSION

Without further repetition, I have little to say in conclusion except that

1 Cervicitis, erosion of the cervix, is definitely related to cancer of the cervix

2 This relationship is effected through the agency of a factor common to both—an associated inflammatory exudate in contact with epithelium. This is the intermediate causal factor and is constant

3 The basic cause of cervical cancer is to be found in this constant factor which is associated with all cell reaction, including that of cancer inception

4 The phenomenon of the action of contact inflammatory exudates of varying degree upon epithelia varying in type, forms this intermediate causal factor, or basic cause, in the production of cancer

5 There is no one great initial cause of cervical cancer

6 In the case of squamous epithelium the change is produced as the result of a re-irritation of minor intensity affecting newly produced cells. In the case of columnar epithelium it is produced by a prolonged and intense irritation affecting new epithelium—probably recurrent

7 As far as the cervix uteri is concerned, I am inclined to the belief that the initial causal factor concerned in the production of the intermediate causal factor is bacterial, and is moreover concerned to a large degree with the well known septic organisms. Recurrent attacks of specific intensity, from the epithelial standpoint, involving epithelium during the danger period, result in the production of cancer. The question of the time

at which this attack is made, therefore, plays its part, and this fact is undoubtedly instrumental in minimizing this catastrophe

Whatever initial causes there are in the production of cancer growths, whether bacterial or chemical, the effect is produced through the agency of this constant intermediate factor. The result is the production of the cancer process, which again may be variable in its intrinsic nature, although in relation to the epithelia of the cervix uteri this phenomenon shows a rare degree of consistency

I wish to emphasize, therefore, that whereas there may be, and in my opinion undoubtedly are, many initial causes in the production of cancer, and the nature of the growth itself may even be atypical, nevertheless there is always one factor concerned in this process which remains constant in type for all epithelia, and, moreover, constant in degree according to the nature of the epithelium concerned. It is this, therefore, the intermediate causal factor which I have described, which in my opinion is of such great importance in association with the phenomenon of cancer inception

As I have said elsewhere, the nature of cancer inception is that of a pure cell reaction, dependent alike upon the type of epithelium involved, the span of time during which the young cells are affected and the degree of intermediate causal association with them at that time

6 Alterations in the densities of contact inflammatory exudates results in alterations in the cell reactions produced, *ipso facto*. An alteration in the density of the exudate concerned during the epithelial danger period, whether pathological or therapeutic, would result in an altered cell reaction. Involved epithelium at this stage must frequently just escape cancer change through pathological means, resulting from coincident changes in inherent resistance. Is it possible to effect the same result by therapeutic means?

SPASTIC ILEUS

LEO M ZIMMERMAN M D CHICAGO

Instructor in Surgery Northwestern University Medical School

IN the final decade of the last century the idea became current that spasmodic contraction of the intestinal musculature might obliterate the lumen of the bowel for a varying period of time and lead to the picture of intestinal obstruction. Israel speculated on the phenomenon of obturating gall stones which became fixed after having traversed a portion of the intestinal tract without difficulty, and he attributed part of the occlusion to contraction of the bowel wall about the concretion. Koerte, too, was impressed by the fact that small stones not infrequently gave rise to intestinal obstruction. He hypothesized that the stone delayed the passage of intestinal contents without actually obstructing them. Fermentation then occurring in the stagnant contents released irritating substances which provoked exaggerated peristalsis and spastic contraction of the bowel about the stone. It remained for John B. Murphy, however, to demonstrate a spastic occlusion of the intestine at laparotomy in a patient suffering from lead poisoning. In 1897, the year following, Haidenham, in a paper read before the German Surgical Society, presented spastic ileus as a clinical entity and reported 3 cases in which the enterospasm was demonstrated at operation. There was considerable opposition to the statements of Haidenham at that time but, in the 30 years that have followed, the existence of a spastic or dynamic form of ileus has become established beyond reasonable doubt. The total number of reported cases, however, is not large. Fromme, in 1914, collected 20 cases in which the diagnosis was confirmed at operation. In 1920 the number according to Sohn had reached only 30. The following year Nagel gathered from the literature 51 cases which had been proved at operation or autopsy. I have collected 157 cases from the literature, in which the condition has been adequately demonstrated on either the operating or postmortem table or both, and to this number have added two

observations of my own. The reported cases probably constitute only a small percentage of the total number occurring, as is evidenced by the fact that Koerte was able to report 28 of his own cases, all of which were confirmed at operation or autopsy. It is highly probable that many of the cases of intestinal obstruction which have responded to treatment with antispasmodics, heat, or other non operative measures were really spastic in origin.

Spastic ileus has been defined as an intestinal obstruction the origin of which depends solely on a persisting contraction of the intestinal musculature. According to an excellent description by Freeman, "Spastic ileus is due to a spasmodic muscular contraction of a portion of the intestinal tract. It may affect either the small or the large bowel or both, in one place usually, or possibly in many places. It generally includes a few inches of the gut only, although at times a considerable length is compromised. A common location is the lower portion of the ileum. The typical appearance is striking and unmistakable. A section of gut a few inches in length is contracted to the limit, rendering it white, bloodless, and so firm that it often may be picked up by one end and held horizontally without bending. The contracted part does not merge gradually into the adjacent bowel, but stops abruptly at either end, the rest of the intestine remaining normal, but if the trouble lasts long enough the proximal bowel dilates as in any other form of obstruction. The spasm frequently persists after the abdomen is opened, although it may disappear, and it is sometimes found even at autopsy." It might be added that often the manipulation incident to laparotomy and exploration is sufficient to cause the spastic portion of bowel to relax, and the collapsed segment has frequently been observed to fill out under the hand of the surgeon.

Because its clinical picture lacks exact definition spastic ileus does not lend itself well to statistical study. It is difficult to establish

a positive pre-operative diagnosis and often impossible to rule out mechanical factors. It has, therefore, been correctly stipulated that only those cases in which the diagnosis has been verified at operation or autopsy should be tabulated. Many cases which occur and subside spontaneously or with conservative treatment would be omitted in such a study. Nor will the operative or postmortem findings include all cases. Although the spasm often persists in spite of general anæsthesia, it is probable that it sometimes yields in narcosis, and though spastically contracted bowel has been found at necropsy, it is to be assumed that in some instances the contractions will have relaxed in death. On the other hand, it is possible that spasms found at autopsy may have been agonal rather than factors in the cause of death. Furthermore, there is no sharp limitation as to what shall be included under the term *spastic ileus*. The clinical picture of enterospasm varies from the acute, severe cases, which simulate acute mechanical obstructions, through the subacute and chronic forms, to the mild spasms which cause simple constipation or slight discomfort suggestive of gall bladder or appendiceal disease. Again, if spasm plays a part in obturating obstructions, as Israel and Koerte have suggested, which cases shall be ascribed to the foreign body and which to the spasm? Finally, it has been claimed that intussusception often begins as a spasm, and localized spastic contractions have been seen accompanying or following the reduction of invaginations. A sharp differentiation between these two conditions is, therefore, often very difficult.

Spastic ileus, like other functional disorders, may result from a wide variety of different conditions, and considerable discussion has arisen as to the mechanism of the contraction. Frequently, several factors seem to be present, and various writers differ as to the relative importance of the individual components. There are those who see local irritation of the bowel or of its adjacent structures as the dominant cause. Some ascribe the greatest importance to changes in the vagus nerve or the retroperitoneal plexus, and others lay the condition essentially to psychic disturbances. Pototschnig assumes the presence of

a "tendency to spasm" of the autonomic system as a necessary prerequisite of spastic ileus. Steindl has found organic changes in the medulla of patients dying of spastic obstructions and believes that such occurrences are due primarily to a pathological condition of the central nervous system. Payr, on the other hand, has succeeded in demonstrating spasm of the intestinal musculature from experimental occlusion of the mesenteric vessels and would explain the phenomenon on a circulatory rather than on a nervous basis at least in the traumatic forms. Obviously, no one explanation is adequate to account for all of the observed cases.

The innervation of the bowel is very complicated and not entirely understood. According to Mueller, it seems that most of the motility is controlled by the intrinsic nervous plexus—the plexus of Auerbach and Meissner. In addition the function of the bowel is under control of the vagus and sympathetic systems by way of the celiac and inferior mesenteric plexus. And over all, exerting some measure of control, is the central nervous system. From the great diversity of causes of spastic ileus described, it would seem that stimuli arising in any portion of this nervous apparatus may produce the spasm that interferes with the passage of intestinal contents. The causes of spastic ileus, therefore, fall into three groups, corresponding to the three major divisions of the nerve supply to the bowel.

SPASTIC ILEUS FROM STIMULI ACTING ON THE BOWEL AT THE SITE OF SPASM

Every surgeon has seen transient spasms of the intestine from pinching or squeezing during the course of abdominal operations, and contractions of longer duration have been produced experimentally by the use of stronger stimuli. Thus mechanical thermal or electrical irritation, the injection of physostigmin into the lumen, or the painting of adrenalin or barium chloride solution on the serosa have all been found to give rise to such spasms. Moreover excised portions of bowel (Magnus) will respond in the same way to these stimuli, indicating that the reflex is an intrinsic one, by way of the Auerbach and Meissner plexus. Clinically, cases of spastic ileus have fre-

quently been reported due to local irritants analogous to the experimental ones mentioned

Foreign bodies Israel and Koerte, as stated before, both described intestinal obstruction from small gall stones which had traversed part of the intestinal tract without difficulty, and they ascribed the occlusion to spastic contraction of the bowel about a stone. Similar spastic segments, due to scybala, have been seen by Schloffer and Sohn, Vogel has reported a case of spastic ileus due to fruit seeds which produced a picture as threatening as one of mechanical obstruction. The foreign body was pushed into the cæcum at laparotomy, and the patient recovered. There is probably an element of spasm in most cases of obturating obstruction. It is difficult to explain why such objects as fecaliths, gall stones, or fruit seeds, which so frequently form part of the intestinal content with no untoward effect, should, in the exceptional case, lead to severe enough irritation to cause spastic occlusion of the bowel. Perhaps the assumption of Koerte that irritating substances develop in the stagnating contents behind the obturating body will account for it, or it may be, as Florack suggests, that decubitus ulceration from the pressure of the foreign body gives rise to the spastic reflex.

Intestinal worms An interesting group of cases due to the presence of foreign bodies is the one caused by intestinal parasites. Two types of intestinal obstruction due to worms have been described: an obturating ileus from massed clumps of parasites and a spastic ileus about one or several worms. Even in the former group, an element of spasm may play a part in the final obstruction. Cases of the second type have been reported by Haidenhain, Hagedorn, Kiesselbach, Kuester, Rost, and Schulhof, in which the spasm was due to ascaria, Barth's case was due to tapeworm, and Dmitreff's case resulted from oxyuria. Rost observed in 1 year 4 cases in which operation was performed, and he attempted to determine experimentally the cause of the spasm. In testing the effects of extracts of various portions of round worms on the musculature of excised intestine of the cat he found that extracts of the digestive and gen-

ital organs increased the tonus while that of the skin depressed it. He, therefore, concluded that living worms could produce intestinal obstruction by forming large obturating masses, and that spasm was due to death and disintegration of the parasite. Sohn, however, maintains that the irritation is a mechanical one, and his view is supported by the instructive observation of Kuester, who found enterospasm due to a worm at laparotomy and could make the spasm travel up and down as the parasite was pushed to and fro in the intestine. In the case due to oxyuria (Dmitreff), an ulcer had been produced by the worm, which had perforated to the serosa. It is possible that some of the cases in which no cause for the spasm could be found at operation may have been due to intestinal parasites. Nordmann operated upon a child 2 years old under the diagnosis of strangulation ileus and found spasm. No cause was discovered, and only after the child passed a clump of worms a year or so later was the etiology of the attack explained. Barth's patient developed spastic ileus following colporrhaphy. At laparotomy enterospasm was found without attributable cause, and only autopsy revealed the tapeworm in the contracted portion of the bowel.

Undigested food Several cases are on record in which no other cause for the enterospasm could be found than indigestible foodstuffs. Engstad recently reported one in which the patient gave a history of having eaten at least twelve ears of sweet corn on the preceding day, and another in which excessive intake of ice water on a very hot day seemed to be the sole cause of the attack. The latter case has its counterpart in the "heat cramps" frequently observed in industry, which rarely come to operation and which are not, as a rule, thought of as potential spastic obstructions. Kelly and Pototschnig have each reported a fatal case of spastic ileus, in which no other factor than undigested food or excessive intake could be found at operation or autopsy. Intestinal spasms and intussusceptions in infants may well be on the basis of the ingestion of irritating foods.

Bleeding into the intestine The escape of blood into the gastro intestinal tract often

acts as an irritant, as is witnessed by the frequent vomiting and diarrhoea following massive gastro intestinal hemorrhages. Jenczel describes spastic ileus following resection of a carcinoma of the colon. Laparotomy revealed massive hemorrhage from an overlooked duodenal ulcer, with extreme contraction of the entire small intestine. Franke reports two similar cases, one of which was likewise demonstrated at operation.

Ulceration As mentioned before, decubitus ulceration may be the immediate cause of enterospasm in the presence of foreign bodies or intestinal worms, just as ulcers elsewhere in the alimentary tract often give rise to spasms at their sites. Strehl has had a case of ileo caecal tuberculosis with increasing obstruction. At operation, fifteen segments of spastically contracted bowel were seen, corresponding to which were the multiple tuberculous ulcers found at autopsy.

Hernias One of the most frequently observed local causes of spastic ileus is strangulation in a hernial sac. The spasm persists after spontaneous or operative relief and is due, apparently, to damage to the bowel during the period of strangulation. Brunzel has observed 3 such cases, 1 of which followed strangulation of an umbilical hernia. Similar observations are reported by Barth, Brunn, Melchior, Florack, Reiss, and Kessler. Wilms has called attention to the fact that strangulation of a Littre hernia also may be followed by spastic occlusion of the bowel. This group of cases suggests that some of the mishaps following taxis or reduction of strangulated hernia may have been due to persisting spasm at the site of strangulation.

Circulatory disturbances Payr has shown that the injection of solid particles into the mesenteric vessels, producing artificial emboli and local anemia, causes maximal contraction of the affected portion of bowel and he has reported a case of spastic ileus due to torsion of the omentum with thrombosis of the veins. Mueller states that arteriosclerosis of the mesenteric vessels may give rise to enterospasm, and Lecene reports one such case in which no cause other than sclerosis of the vessels supplying the spastic segment of the bowel could be found. Some of the cases

following operation or intestinal strangulation may have their origin in disturbances in the blood supply of the affected portions of the intestine.

REFLEX SPASTIC ILEUS DUE TO DISTANT LESIONS

The occurrence of spastic ileus from intrinsic reflexes as described above is readily understood. Less clear are those cases which seem to arise from irritants acting at a distance, the effect of which must be by way of an extrinsic reflex. While it is true that most of the control of the motility of the bowel is effected by the myenteric plexus of Auerbach and Meissner, the coeliac and inferior mesenteric plexus, made up of sympathetic and vagus elements, do exert some control. Talma demonstrated experimentally that vigorous stimulation of the coeliac ganglion resulted in active motility of the intestine, chiefly in the form of spasmodic contractions. There are on record several clinical cases of spastic ileus, which were due to inflammatory or cicatricial processes involving the coeliac plexus. Maier and Mosse have demonstrated changes in the coeliac ganglion in experimental lead poisoning, to which they attribute the colics and spasms accompanying this condition. Recent observations with regional and spinal anesthesia have given further support to the assumption that irritants at a distance, acting by way of the extrinsic reflexes, may cause spastic ileus. Denk states that, with satisfactory injection of the splanchnic plexus (by the Kappis method), he often notices moderate cyanosis and definite spasms of the bowel. Wagner found that spinal anesthesia was frequently sufficient to initiate peristalsis in paralytic ileus, and his observations have been confirmed experimentally and clinically by Markowitz and Campbell, and Ochsner, Gage, and Cutting. Mayer made similar observations and noted further that spastic ileus could also be relieved by intraspinal anesthesia. French surgeons in particular, have adopted spinal anesthesia as a treatment for ileus, and Duval has collected 400 cases in which it has been used. Of this number 8 were said to have been cases of spastic ileus, and in every instance the condition was defi-

nately relieved by the spinal injection. The relief of obstructions due to atony and spasm by the same measure would appear scarcely credible, but Colmers explains the apparent contradiction as follows. Normal tonus of the intestine depends upon a balance between the pressor effect of the vagus and the depressor influences of the splanchnics. Should the balance be disturbed by excessive stimuli from either of these systems, interruption of the abnormal impulses by spinal anaesthesia would promptly restore the normal status. Granting that the action of stimuli by way of the vegetative nervous system may lead to the picture of spastic ileus, it will be seen that these stimuli may be direct, acting on the nerves or ganglion cells themselves, or indirect, acting by way of reflex irritation.

Lesions involving the coeliac plexus. Exner and Jaeger report a case of spastic ileus due to an inflammatory lesion of the posterior wall of the pylorus, with involvement of the retro-pentoneal nerve plexus. Klett's case was due to carcinoma of the pancreas with retro-pentoneal extension, and Prader's to acute pancreatitis. Koennecke saw two such patients, one with an inflammatory tumor of the pancreas and one with an ulcer which penetrated into the pancreas. Although changes in the coeliac ganglion have been described in experimental lead poisoning, the evidence has been held inadequate to warrant placing the cases of spastic ileus due to plumbism in this group.

Spastic ileus following contusions to the abdomen. While spastic ileus occurring after blunt contusions to the abdomen may be the result of injury to the bowel itself, it more often appears to be reflex from trauma to pentoneal surfaces. Several cases of this type are on record. Rehn operated upon a patient 9 hours after a severe contusion, with diagnosis of ruptured bowel. A portion of the sigmoid, corresponding in position to the site of the traumatism, was found contracted down to the diameter of a finger. Beyond this there was nothing, and recovery followed the simple laparotomy. Trendelenburg has opened the abdomen twice, following contusions, to find localized spasm of the bowel. Often the injury which gives rise to the spasm

is not severe. Fromme reports a case in a child, aged 11½ years, who was running on a springy wooden floor, and another in which the patient fell and fractured several ribs. I have seen a case very similar in its etiology to this last one.

CASE 1. The patient J. H., a male aged 27 years, fell from a scaffold about 25 feet high while at work on the morning of December 10, 1927. He was admitted to Wesley Hospital about an hour later in a state of moderate shock (blood pressure 90-60) and complaining of pain in the back. The X-ray picture revealed an oblique fracture of the right transverse process of the first lumbar vertebra, all other bony structures being normal. The temperature was subnormal, and the pulse rate was 80. The abdomen was diffusely and uniformly rigid but was neither tender nor painful and there were no external evidences of injury to the abdomen. No neurological findings were elicited. During the ensuing 24 hours the patient recovered from his shock and the abdominal rigidity relaxed somewhat. About 28 hours after admittance he began to complain of severe intermittent, cramp-like pain referred to the region of the umbilicus which soon became so acute as to cause him to cry out with each paroxysm. Vomiting occurred twice. The pulse rate rose rapidly to 122, and the abdomen became slightly distended but the temperature remained normal. Some of the rigidity was still present and there was very slight tenderness in the right lower quadrant. Peristaltic sounds were increased and vigorous peristaltic waves were heard to accompany the paroxysms of pain. Because of the picture of mechanical ileus the abdomen was opened under nitrous oxide anaesthesia. Exploration of the entire abdominal cavity revealed no evidence whatsoever of trauma. A segment of ileum about 3 feet long was found to be collapsed, empty, and ribbon-like. At either end the collapsed portion merged with normally distended bowel. There was no obstruction or other abnormality at these points. During the manipulation incident to the examination, the contracted segment was seen to relax and resume the appearance and caliber of the rest of the bowel. The abdomen was closed without drainage. On the following day the patient had several paroxysms of abdominal pain which responded readily to opiates, atropin, and external heat. Convalescence was rapid, and there were no other symptoms attributable to his injury or operation.

Reimer lays great stress upon the irritating action of extravasated blood in the pentoneal cavity on the production of spastic ileus. He cites 3 cases following abdominal contusions, 2 of which were operated upon, in which the spasms persisted until the hamoperitoneum was evacuated. A series of patients with

acts as an irritant, as is witnessed by the frequent vomiting and diarrhoea following massive gastro intestinal hæmorrhages. Jencel describes spastic ileus following resection of a carcinoma of the colon. Laparotomy revealed massive hæmorrhage from an overlooked duodenal ulcer, with extreme contraction of the entire small intestine. Franke reports two similar cases, one of which was likewise demonstrated at operation.

Ulceration. As mentioned before, decubitus ulceration may be the immediate cause of enterospasm in the presence of foreign bodies or intestinal worms, just as ulcers elsewhere in the alimentary tract often give rise to spasms at their sites. Strehl has had a case of ileo cæcal tuberculosis with increasing obstruction. At operation, fifteen segments of spastically contracted bowel were seen, corresponding to which were the multiple tuberculous ulcers found at autopsy.

Hernias. One of the most frequently observed local causes of spastic ileus is strangulation in a hernial sac. The spasm persists after spontaneous or operative relief and is due, apparently, to damage to the bowel during the period of strangulation. Brunzel has observed 3 such cases, 1 of which followed strangulation of an umbilical hernia. Similar observations are reported by Barth Brunn, Melchior, Florack, Reiss and Kessler. Wilms has called attention to the fact that strangulation of a Littre hernia also may be followed by spastic occlusion of the bowel. This group of cases suggests that some of the mishaps following taxis or reduction of strangulated hernia may have been due to persisting spasm at the site of strangulation.

Circulatory disturbances. Payr has shown that the injection of solid particles into the mesenteric vessels, producing artificial emboli and local anæmia, causes maximal contraction of the affected portion of bowel, and he has reported a case of spastic ileus due to torsion of the omentum with thrombosis of the veins. Mueller states that arteriosclerosis of the mesenteric vessels may give rise to enterospasm, and Lecene reports one such case in which no cause other than sclerosis of the vessels supplying the spastic segment of the bowel could be found. Some of the cases

following operation or intestinal strangulation may have their origin in disturbances in the blood supply of the affected portions of the intestine.

REFLEX SPASTIC ILEUS DUE TO DISTANT LESIONS

The occurrence of spastic ileus from intrinsic reflexes as described above is readily understood. Less clear are those cases which seem to arise from irritants acting at a distance, the effect of which must be by way of an extrinsic reflex. While it is true that most of the control of the motility of the bowel is effected by the myenteric plexus of Auerbach and Meissner, the celiac and inferior mesenteric plexus, made up of sympathetic and vagus elements, do exert some control. Talma demonstrated experimentally that vigorous stimulation of the celiac ganglion resulted in active motility of the intestine, chiefly in the form of spasmodic contractions. There are on record several clinical cases of spastic ileus which were due to inflammatory or cicatricial processes involving the celiac plexus. Maer and Mosse have demonstrated changes in the celiac ganglion in experimental lead poisoning, to which they attribute the colics and spasms accompanying this condition. Recent observations with regional and spinal anesthesia have given further support to the assumption that irritants at a distance, acting by way of the extrinsic reflexes, may cause spastic ileus. Denk states that, with satisfactory injection of the splanchnic plexus (by the Kappis method), he often notices moderate cyanosis and definite spasms of the bowel. Wagner found that spinal anesthesia was frequently sufficient to initiate peristalsis in paralytic ileus, and his observations have been confirmed experimentally and clinically by Markowitz and Campbell, and Ochsner, Gage, and Cutting. Mayer made similar observations and noted further that spastic ileus could also be relieved by intraspinal anesthesia. French surgeons in particular, have adopted spinal anesthesia as a treatment for ileus and Duval has collected 400 cases in which it has been used. Of this number 8 were said to have been cases of spastic ileus, and in every instance the condition was defi-

nately relieved by the spinal injection. The relief of obstructions due to atony and spasm by the same measure would appear scarcely credible, but Colmers explains the apparent contradiction as follows. Normal tonus of the intestine depends upon a balance between the pressor effect of the vagus and the depressor influences of the splanchnics. Should the balance be disturbed by excessive stimuli from either of these systems, interruption of the abnormal impulses by spinal anaesthesia would promptly restore the normal status. Granting that the action of stimuli by way of the vegetative nervous system may lead to the picture of spastic ileus, it will be seen that these stimuli may be direct, acting on the nerves or ganglion cells themselves, or indirect, acting by way of reflex irritation.

Lesions involving the celiac plexus. Exner and Jaeger report a case of spastic ileus due to an inflammatory lesion of the posterior wall of the pylorus, with involvement of the retroperitoneal nerve plexus. Klett's case was due to carcinoma of the pancreas with retroperitoneal extension, and Prader's to acute pancreatitis. Koennecke saw two such patients, one with an inflammatory tumor of the pancreas and one with an ulcer which penetrated into the pancreas. Although changes in the celiac ganglion have been described in experimental lead poisoning, the evidence has been held inadequate to warrant placing the cases of spastic ileus due to plumbism in this group.

Spastic ileus following contusions to the abdomen. While spastic ileus occurring after blunt contusions to the abdomen may be the result of injury to the bowel itself, it more often appears to be reflex from trauma to peritoneal surfaces. Several cases of this type are on record. Rehn operated upon a patient 9 hours after a severe contusion, with diagnosis of ruptured bowel. A portion of the sigmoid, corresponding in position to the site of the traumatism, was found contracted down to the diameter of a finger. Beyond this there was nothing, and recovery followed the simple laparotomy. Trendelenburg has opened the abdomen twice, following contusions, to find localized spasm of the bowel. Often the injury which gives rise to the spasm

is not severe. Fromme reports a case in a child, aged 11½ years, who was running on a springy wooden floor, and another in which the patient fell and fractured several ribs. I have seen a case very similar in its etiology to this last one.

CASE 1. The patient, J. H., a male aged 27 years, fell from a scaffold about 25 feet high, while at work on the morning of December 10, 1927. He was admitted to Wesley Hospital about an hour later, in a state of moderate shock (blood pressure 90-60) and complaining of pain in the back. The X-ray picture revealed an oblique fracture of the right transverse process of the first lumbar vertebra, all other bony structures being normal. The temperature was subnormal, and the pulse rate was 80. The abdomen was diffusely and uniformly rigid but was neither tender nor painful, and there were no external evidences of injury to the abdomen. No neurological findings were elicited. During the ensuing 24 hours the patient recovered from his shock and the abdominal rigidity relaxed somewhat. About 28 hours after admittance he began to complain of severe intermittent, cramp-like pain referred to the region of the umbilicus which soon became so acute as to cause him to cry out with each paroxysm. Vomiting occurred twice. The pulse rate rose rapidly to 122, and the abdomen became slightly distended but the temperature remained normal. Some of the rigidity was still present, and there was very slight tenderness in the right lower quadrant. Peristaltic sounds were increased, and vigorous peristaltic waves were heard to accompany the paroxysms of pain. Because of the picture of mechanical ileus the abdomen was opened under nitrous oxide anaesthesia. Exploration of the entire abdominal cavity revealed no evidence whatsoever of trauma. A segment of ileum about 3 feet long was found to be collapsed, empty, and ribbon-like. At either end the collapsed portion merged with normally distended bowel. There was no obstruction or other abnormality at these points. During the manipulation incident to the examination the contracted segment was seen to relax and resume the appearance and caliber of the rest of the bowel. The abdomen was closed without drainage. On the following day the patient had several paroxysms of abdominal pain which responded readily to opiates, atropin and external heat. Convalescence was rapid and there were no other symptoms attributable to his injury or operation.

Reimer lays great stress upon the irritating action of extravasated blood in the peritoneal cavity on the production of spastic ileus. He cites 3 cases following abdominal contusions, 2 of which were operated upon, in which the spasms persisted until the hæmoperitoneum was evacuated. A series of patients with

ruptured extra uterine pregnancies were closely questioned, and it was thought that a history could be elicited in every instance of pain suggestive of intestinal spasm, following the severe, tearing pain of the rupturing tube. In support of this may be mentioned the experience of Jordan, who operated for ruptured spleen following trauma and found in addition spastic contraction of the sigmoid and half of the small intestine.

Postoperative spastic ileus While most functional disturbances of the bowel following operations are paralytic in nature, occasionally true spastic obstructions are encountered. It is difficult to state whether these are due to trauma of the bowel during the laparotomy or to thrombosis of the mesenteric vessels, or whether in certain cases, they may not be due to beginning peritonitis or even to the primary condition for which the operation was performed. It is hard to understand why trauma, which usually gives rise to intestinal paresis or paralysis in these cases produces the opposite reaction. Furthermore, it has often been noted that the manipulation during reoperation has brought about relaxation of the spasm induced by the original operation. Braun and Wortmann state that intestinal spasm and intestinal paralysis may be caused by the same factors, that both may be present simultaneously, and that intestinal paresis may be preceded by a state of spasm. Spastic ileus following operation has been seen with particular frequency after gastric and gynecological procedures. Koerte has observed 6 such cases, 5 of which ensued after gastroenterostomy. I have also seen a case following operation for peptic ulcer.

CASE 2 The patient A. S., a male aged 46 years, was operated upon for perforating post pyloric ulcer. Resection and retrocolic side to end gastrojejunostomy (Polya) was done. Mobilization of the duodenum was very difficult because of the extensive inflammatory adhesions and considerable soiling occurred requiring the placing of a drain down to the duodenal stump. On the second day symptoms of obstruction appeared which were thought to be due to mechanical block at the site of anastomosis. Reoperation revealed local peritonitis about the stump of the duodenum. The gastrojejunostoma was free and intact. The stomach and proximal half of the small bowel were dilated, the distal half was empty, collapsed, and contracted. The point

of transition between the distended and collapsed portions was abrupt and free from any abnormality whatsoever. Jejunostomy was done and the abdomen closed. Death occurred 3 days later and autopsy revealed localized peritonitis as its cause. No statement was made as to the condition of the small bowel at that time.

It is significant that in the cases observed by Koerte, in which spastic ileus followed gastroenterostomy, several times the spasm was located in the jejunum. We know from the experimental ulcer studies of Mann and his co-workers that the acid contents of the stomach are irritating to the jejunal mucosa. This suggests the possibility that these cases arise frequently after gastric operations because of the local irritating action of the stomach contents on the jejunum, which produces local spasm. This also may explain certain cases of "vicious circle" following gastrojejunal anastomoses, particularly those in which re-operation fails to reveal a mechanical explanation for the accident. The following case may have been illustrative of this occurrence.

CASE 3 The patient M. F., a male 56 years old, was operated upon for very early carcinoma of the stomach. Partial resection was done with retrocolic end to side gastrojejunal anastomosis (Polva), and an uneventful recovery ensued. The patient, however, complained of fullness as though of gas, in the epigastrium and chest with relief on eructation. X-ray examination 12 days after the operation showed a large fundal portion remaining with a 5 hour residue. Patient left the hospital on the following day, but was compelled to return a week later because of persistent vomiting. Aspiration revealed high grade retention and re-operation was done. No obstruction could be found. The line of anastomosis was completely freed and found entirely satisfactory. Incision was made into the stomach above the anastomosis and a good free opening into both jejunal loops could be demonstrated. The opening was enlarged somewhat and the gastrotomy incision closed. An enteroanastomosis was done just below the gastrojejunal stoma and the jejunum was sutured to the colon to insure against invagination. The patient made a slow recovery since convalescence was delayed by the development of a fecal fistula.

In a rather extensive series of currently appearing articles, Reischauer has voiced a similar opinion regarding the relation of vicious circle to enterospasm and he has attempted to show, moreover, that most of the

other obstructions following stomach operations have their origin in spasm

Spastic ileus accompanying lesions of other organs Those cases of spastic ileus associated with lesions of other intraperitoneal, or even with extra abdominal, structures would seem of necessity to be reflex in origin. One interesting group of this type is that due to mechanical obstruction involving some other bowel segment. Thus Hardenhain, Jenckel, Schlesinger, and Brunn have seen spasms of the small bowel associated with carcinoma of the rectum, Miller's case was associated with mechanical obstruction of another loop of bowel by a band, Barsony's patient had tuberculosis of the cæcum producing spasm in the ileum, and Hardenhain's patient had volvulus. Whether the spasm in these cases is reflex or whether it is due to stagnation of contents above the mechanical obstruction cannot be determined. Franke saw enterospasm during operation for peptic ulcer, Braun and Wortmann saw enterospasm from hydrocele, Mueller from early appendicitis, Brodnitz from adrenal hæmorrhage, Engstad from cystic ovary, and Huguer and Parvu from renal colic.

A word should be said regarding the relationship between intestinal spasm and intussusception. Nothnagel demonstrated experimentally that invagination could be produced by causing local spasm of the bowel by means of faradic stimulation. He believed that clinical intussusception began as enterospasm. This theory has been substantiated by the experiments of Propping and others and by numerous clinical observations. Fromme describes a case in which symptoms persisted after release of an invagination and resulted in the death of the child patient. At autopsy spastic narrowing of the small bowel was seen. In 2 other cases observed by the same author intussusceptions and enterospasms were seen simultaneously, apparently having had a common origin. It would seem therefore, that enterospasm and invagination may arise from the same source and may be present simultaneously. Localized spasm may lead to intussusception, and injury to the bowel during intussusception may determine an enterospasm which may persist after release of the

invagination and may even result in the death of the patient.

CAUSES ACTING BY WAY OF THE CENTRAL NERVOUS SYSTEM

Although there is no known "center" for intestinal control in the brain, nevertheless some degree of influence is exerted on the bowel by the central nervous system. This finds expression in the frequently observed emotional diarrhoeas, which, like the vomiting that often accompanies intense psychic stimulation, denote a connection between the cortical centers and the gastrointestinal tract. Spastic ileus has been described accompanying both organic lesions and psychic disturbances. Steindl, as mentioned, found degenerative changes in the medulla of 2 patients who died of postoperative spastic ileus. He believes that there must be a "tendency to spasm" as a prerequisite to the development of enterospasm and attributes the increased irritability to organic changes in the brain stem. So bold an assertion requires wide confirmation beyond the few instances he has described. Schuele has seen enterospasm for which no local cause could be found, and only autopsy several months later revealed a small inflammatory tumor in the floor of the fourth ventricle as a source of the mischief. Spastic ileus has been seen, too, in tabes dorsalis, and Deutschlander states that enterospasm frequently occurs in Little's disease. The cases due to lead poisoning might be placed in this group, as might also those observed in influenzal infections.

Much has been written regarding the role of hysteria in the etiology of spastic ileus. Some of the earlier writers have even gone so far as to state that a hysterical background is necessary to the development of such a condition. It would seem that the term hysteria has been rather loosely used in this connection. There are cases, described as hysterical ileus, in which the picture of intestinal obstruction was fictitiously assumed by the patient, even to the swallowing of fecal matter in order that it might later be vomited. These, obviously, have nothing in common with spastic intestinal occlusion. There are other instances in which a history

and stigmata of hysteria are present, but in which there is also some local cause for the enterospasm. Finally, there is the group in which no regional explanation is found, and in which "hysteria" has often been invoked to account for the occurrence. In some of these last mentioned cases, local causes may well have been present though undiscovered. In others, simply increased local or general irritability of the nervous system may have determined the spasm. In none does the term "hysterical" seem justified. We recognize different degrees of irritability in the nervous systems of different persons, and it is to be expected that the most sensitive nervous apparatus is most likely to give exaggerated responses to ordinary stimuli. In its final analysis the matter reduces itself to the relative intensity of the stimulus for the irritability of the affected nervous mechanism.

To sum up, enterospasm is a state of exaggerated contraction of a portion of the intestinal musculature, which leads to obliteration of its lumen and owes its origin to a stimulus that is excessive for the degree of irritability of that particular nervous apparatus. The stimulus giving rise to the spasm may act anywhere in the complicated nervous system supplying the bowel. In some cases the irritability of the local or general nervous mechanism may be so greatly increased that spasms will occur without known extrinsic cause.

ANALYSIS OF THE COLLECTED CASES

I have collected from the literature 157 cases of spastic ileus (Table I), in which the findings at operation or autopsy were sufficiently definite to warrant their acceptance, and to this number have added the 2 cases here reported. Of the total 159 cases, 56 occurred in males and 73 in females. In the remaining 30, the sex was not stated. The ages varied from 5 months to 82 years. Three of the patients were infants less than 1 year old and 17 were children under the age of 15 years. The largest number, however, were adults in the middle span of life, 78 of the 129 stated ages falling between 20 and 60. The cause of the enterospasm was either not determined or not stated in 39 cases. In an

other 39 cases the contraction occurred seemingly in response to local or intrinsic causes, in 57 cases the contractions appeared to be reflex, and in the remaining 24 cases they were due to disturbances of the central nervous system.

CLINICAL PICTURE

The clinical picture of spastic ileus is the clinical picture of mechanical ileus. Like mechanical obstructions, the spastic occlusion may be acute or chronic, may be high in the small bowel or in the colon, and may be incomplete with mild manifestations or complete with the full stormy picture of bowel obstruction. The phenomena dependent upon strangulation, however, are absent. Only one difference in the manifestations of spastic and organic occlusions has been encountered with any degree of consistency, the general condition of patients having functional obstructions is good as compared with that of patients having mechanical ileus. Furthermore spastic obstructions are much more apt to be intermittent and to subside spontaneously. It must not be inferred from this, however, that a differentiation on this basis is clinically possible. Cases of enterospasm are reported in which the patients presented the picture of serious collapse, and death has not infrequently resulted from purely spastic occlusions.

The onset of symptoms may be gradual or abrupt. The patients usually complain of severe, cramp-like pain, vomiting and obstipation. Tympanites may or may not be present. If the case is seen early, no dilatation of the proximal bowel is found, if seen late, the abdomen may be ballooned as in neglected mechanical obstructions. Similarly, if the spasm is high in the alimentary tract, there will be no distention, if it is low, abdominal distention may occur. Furthermore if the major portion of the bowel is involved and is spastic and contracted the abdomen may be scaphoid rather than distended.

Haidenhain called attention to a bradycardia in his cases and several subsequent authors have observed a similar symptom. This has been attributed to vagal irritation and has been considered by some to be of diag-

nostic value. It is very inconstant, however, for many cases with a marked tachycardia, rather than with a slowing of the pulse rate, have been described. In the cases which I have reported there was no noticeable slowing of the heart rate. In the first the pulse rate rose rapidly as the symptoms of ileus developed. In the second case definite tachycardia prevailed.

The diagnosis of spastic ileus cannot be made before the abdomen is opened. There are no criteria by which a given case of ileus may be definitely adjudged spasmodic, and attempts to do so which lead to delay in operation should be avoided. At laparotomy the diagnosis of spastic ileus is permissible when spasm of the bowel is demonstrated and when there is no mechanical cause for the obstruction.

The findings at operation vary considerably, but, in general, three types of contractions have been found. The most frequent condition is a spasm of one or more segments of considerable length, varying from a few inches to a number of feet. In some instances the entire small bowel has been compromised. The affected portion is usually described as being empty, pale or mottled in color, of increased consistency, and resembling tape or ribbon or having the caliber of a pencil, of rope, or of a finger. The second type of contraction is a ring like furrow, "as if a string had been tied around the gut." In a few instances multiple, transient spasms, moving from place to place along the course of the bowel, have been encountered.

The prognosis of spastic ileus, in the uncomplicated case, is said to be good. Nevertheless, death has not infrequently resulted. In the 159 collected cases, 102 patients recovered, 47 died, and the outcome in the remaining 10 was not stated. This constitutes a mortality rate of 31.6 per cent in those cases in which the outcome is given. Of this number, however, 9 (6.2 per cent) presented spastic ileus as a more or less incidental finding and not directly as a factor in the cause of death. Thus, in 2 cases death resulted from uræmia and in 1 case each from meningitis, encephalitis, brain tumor, retroperitoneal phlegmon due to carcinoma of the rectum,

TABLE I—ETIOLOGY AND MORTALITY IN ONE HUNDRED AND FIFTY-NINE CASES CONFIRMED BY OPERATION OR AUTOPSY

Cause of enterospasm	Recovered	Deaths	Not stated	Total
Local causes				
Foreign bodies	3	3		6
Intestinal worms	13	2	1	15
Irritating foods	3	2		5
Bleeding into bowel		1		1
Strangulated hernias	7	3		10

Lead poisoning	3	2		5
Brain tumor	1	1		2
Cause not determined or not stated.	16	7	6	29
Totals	102	47	10	159

pulmonary embolism following rib fracture, pneumonia after operation for intussusception, and ileocolostomy for intestinal tuberculosis. In 19 additional patients (12.8 per cent) it was a contributory factor but not the sole cause of death. Many of the post-operative cases fall into this group. In the remaining 20 lethal cases no other cause of death was found, and in these the fatality must be attributed directly to the enterospasm. Of the patients who did not succumb to the disease, there were some who were not cured. Although the subsequent history of most of these persons is not stated, in 14 (14 per cent) symptoms recurred after operation. Some of this group responded to medical treatment, others submitted to repeated operations, and in several the condition apparently persisted indefinitely, in spite of all treatment. From this review, it is seen that spastic ileus, while apparently offering a good prognosis in uncomplicated cases, has been associated with a very considerable mortality and persistent morbidity in the entire series.

The treatment of spastic ileus is essentially surgical. If it were possible to make a positive pre-operative diagnosis of enterospasm, temporizing with conservative measures, such as the use of morphine, atropine, and external heat, would be justified. Inasmuch as the diagnosis cannot be made with certainty, however, every bowel obstruction must be considered

organic in nature until proven otherwise Surgery must, therefore, remain the treatment of choice What is done when the abdomen has been opened will depend somewhat on the cause of the spasm and the condition of the patient As has been stated, usually the manipulation incident to the laparotomy has sufficed to bring about relaxation of the contraction If the cause of the ileus can be corrected at the same time, this should, of course, be done In the occasional case, in which the condition of the patient is seriously impaired by long standing obstruction, enterostomy may be advisable Amberger strongly urges enterostomy in every case of spastic ileus, feeling that one of his patients might have been saved had this been done In those instances in which the spasm is not due to purely local factors, there is no assurance that it will not recur in other places after enterostomy at the site of the original contraction has been done Resection or entero anastomosis hardly seem indicated for obstructions of spastic origin After the diagnosis has been definitely established at operation, further postoperative treatment with sedatives, antispasmodics, and external heat should be carried out It must be remembered that operation for the relief of a spastic bowel occlusion may in turn give rise to a mechanical obstruction which can be alleviated only by a second operation

SUMMARY

Spastic ileus is a form of intestinal obstruction the origin of which depends upon a persisting contracture of the musculature of the bowel, leading to obliteration of its lumen The spasm producing the occlusion is usually of nervous origin and is due to a stimulus which is excessive for the degree of irritability of the local or general nervous apparatus involved The impulse may arise in any portion of the complex nervous mechanism controlling the motor function of the bowel The cases therefore, fall into three groups corresponding to the three major divisions of the nerve supply to the intestinal tract Thus we see spasms from irritants acting locally at the site of spasm, by way of the intrinsic nervous plexus, reflex spasms, through the coeliac and

inferior mesenteric plexus, from lesions distant from the spastic bowel segment, and those enterospasms arising from organic or functional disturbances of the central nervous system If the local or general nervous irritability is sufficiently increased, excessive contraction may result from physiological stimuli, and no extrinsic cause for the spasm may be found The clinical picture in spastic ileus is the same as that in mechanical obstructions, except that intermittency and spontaneous recovery are more apt to occur, and the general condition of the patient is usually less seriously impaired The diagnosis cannot be definitely made except at operation, and is then acceptable only when the spasm is demonstrated and no organic obstruction is found Treatment is essentially surgical most cases responding to simple laparotomy The prognosis is said to be good in uncomplicated cases, although, in the series of 159 cases analyzed, there has been a considerable mortality and a number of the patients have continued to have symptoms in spite of all types of treatment

organic in nature until proven otherwise. Surgery must, therefore, remain the treatment of choice. What is done when the abdomen has been opened will depend somewhat on the cause of the spasm and the condition of the patient. As has been stated, usually the manipulation incident to the laparotomy has sufficed to bring about relaxation of the contraction. If the cause of the ileus can be corrected at the same time, this should, of course, be done. In the occasional case, in which the condition of the patient is seriously impaired by long standing obstruction, enterostomy may be advisable. Amberger strongly urges enterostomy in every case of spastic ileus, feeling that one of his patients might have been saved had this been done. In those instances in which the spasm is not due to purely local factors, there is no assurance that it will not recur in other places after enterostomy at the site of the original contraction has been done. Resection or entero anastomosis hardly seem indicated for obstructions of spastic origin. After the diagnosis has been definitely established at operation, further postoperative treatment with sedatives, antispasmodics, and external heat should be carried out. It must be remembered that operation for the relief of a spastic bowel occlusion may in turn give rise to a mechanical obstruction which can be alleviated only by a second operation.

SUMMARY

Spastic ileus is a form of intestinal obstruction the origin of which depends upon a persisting contracture of the musculature of the bowel leading to obliteration of its lumen. The spasm producing the occlusion is usually of nervous origin and is due to a stimulus which is excessive for the degree of irritability of the local or general nervous apparatus involved. The impulse may arise in any portion of the complex nervous mechanism controlling the motor function of the bowel. The cases therefore, fall into three groups corresponding to the three major divisions of the nerve supply to the intestinal tract. Thus, we see spasms from irritants acting locally, at the site of spasm, by way of the intrinsic nervous plexus, reflex spasms through the coeliac and

inferior mesenteric plexus, from lesions distant from the spastic bowel segment, and those enterospasms arising from organic or functional disturbances of the central nervous system. If the local or general nervous irritability is sufficiently increased, excessive contraction may result from physiological stimuli, and no extrinsic cause for the spasm may be found. The clinical picture in spastic ileus is the same as that in mechanical obstructions, except that intermittency and spontaneous recovery are more apt to occur, and the general condition of the patient is usually less seriously impaired. The diagnosis cannot be definitely made except at operation, and is then acceptable only when the spasm is demonstrated and no organic obstruction is found. Treatment is essentially surgical, most cases responding to simple laparotomy. The prognosis is said to be good in uncomplicated cases, although, in the series of 159 cases analyzed, there has been a considerable mortality and a number of the patients have continued to have symptoms in spite of all types of treatment.

CLINICAL SURGERY

FROM ST. STEPHEN'S HOSPITAL, BUDAPEST

OPERATION FOR CARCINOMA OF THE SIGMOID¹

DR. EUGEN PÖLY, BUDAPEST HUNGARY
Surgeon to St. Stephen's Hospital

DANGERS AND COMPLICATIONS

INSECURITY of the suture line is the principal danger in operations upon the sigmoid and other portions of the large bowel. Suture of the large intestine is much more difficult than that of the small intestine because of its wide mesenteric attachment and its fatty appendages. In addition, the large intestine is thinner and has a poorer blood supply. The presence of dry, hard fecal masses in the large intestine is another unfavorable factor because on the one hand their presence hinders the rapid passage of the contents and on the other, it adds to the mechanical injury of the suture line. All these difficulties are magnified many times in the presence of obstruction, the usual complication of sigmoid cancer. In these cases the bowel cannot be properly evacuated before the operation, and the retention of fecal matter further adds to the infectiveness of the bowel contents. This together with the great difference in the lumen of the bowel above and below the site of obstruction constitute additional difficulties and hazards in operative work. When total obstruction is present the bowel becomes enormously distended with gas and fluid contents the bowel wall though apparently intact is permeable to bacteria, it is friable and tears easily. The resistance of the patient is lowered by the stercoræmia.

In operative work upon sigmoid cancer, attention should be paid to the question of fecal load in the bowel. In the presence of a complete obstruction the radical removal of the tumor is postponed until a more favorable moment. One must in the meanwhile be content with creation of a temporary fistula. This is best made in the cæcum so as not to interfere with subsequent procedures. There is no objection to a primary end-to-end anastomosis after resection, provided the bowel has been thoroughly cleansed before the operation. For the cases which lie between these two extremes, in other words for cases in

which a complete evacuation cannot be obtained, the two-stage Mikulicz procedure is preferable. The resection here is completed by formation of a fistula which is closed at a later date.

The location and the extent of the cancerous growth is another consideration to keep in mind. We shall consider as typical sigmoid cancers those growths which are located at the summit of the sigmoid coil or close to it, or at any rate, tumors so located that after their removal an end to end anastomosis without undue tension is possible. In view of the difficulties inherent to colon suture, even the slightest tension must be avoided. It can compromise the end-to-end suture as well as the double barrel flint formation of the Mikulicz operation. For these reasons growths involving either the descending colon or the abdominal portion of the rectum present especial difficulties and do not lend themselves to the same operative procedures as do cancers of the sigmoid proper. In cases of carcinoma involving the transition to the descending colon the best procedure is to resect the entire descending colon, the splenic flexure, and the aboral half of the transverse colon, and to restore the continuity by an anastomosis of the mobile portion of the transverse colon to the sigmoid. Cancers which extend downward to involve the rectum are best attacked by the abdominosacral route. However, we shall here consider those cases only which are limited to the mobile portion of the sigmoid bowel, and which are amenable to resection and to end-to-end anastomosis without undue tension.

The previously mentioned danger of suture line insecurity together with the handling of the distended bowel in obstructive cases resulted in peritonitis which was responsible for the terrific mortality record of the older literature. This complication can be to a great extent eliminated by the proper choice of the time of resection, by the proper choice of the site and extent of resection, by the proper method of closure of bowel

¹Translated by George Halperin, M.D., Chicago

stumps, and above all, by the introduction of the method of extraperitoneal fixation of the suture line after resection. This method however, is not applicable in most localizations of the cancer of the large intestine. Tumors of the cæcum, of the ascending colon, of the hepatic flexure, and of the proximal portion of the transverse colon preclude the use of this method. They are best treated by a blind closure of the colonic stump and the implantation of the small intestine into the transverse colon end to side. Neither is the method of extraperitoneal transposition of the stump to be recommended in operations on tumors involving the transverse colon. It may lead to angulation or, as I saw it in one case, to strangulation of a loop of the small intestine over the transverse colon which was fixed to the abdominal wall. On the other hand, the method is applicable both in cases of carcinoma of the splenic flexure and of the descending colon in which a circular anastomosis between the sigmoid and the transverse colon can be made after resection and in carcinomata of the sigmoid itself. In the last mentioned group one need not fear angulation or undue tension. The use of the method insures against the grave consequences of a leaky suture line. It is readily conceded that drainage in the vicinity of the suture line endangers its security perhaps to a great extent it may be responsible for its insufficiency. On the other hand however it mitigates against its very danger and renders the operative procedure safe.

The second grave danger is that of recurrence. In the absence of mesenteric involvement and in the absence of invasion of neighboring tissue this danger is relatively not great. Generally speaking lymph node liver peritoneal and bone metastases are much more rarely seen than, for example, in gastric cancer. In every case resection of the bowel should be carried out as far away from the seat of growth as possible, and in the event of mesenteric and lymph node involvement, the latter should be widely excised. Demonstrable involvement of mesenteric lymph nodes seriously compromises the prognosis.

PREPARATION OF THE PATIENT

Thorough cleansing of the bowel is the principal point in the preparation of the patient. This of course, is possible only in cases not complicated by high grade obstruction. Cases with complete or almost complete obstruction are treated by a preliminary cæcal fistula formation. The use of cathartics in high grade obstruction is contraindicated. It causes exacerbation of the colic like pains and may lead to much graver consequences,

such as complete obstruction or rupture of a decubitus ulcer in the bowel wall above the obstruction. When passage of flatus and feces is not interfered with, medicinal treatment is indicated. Castor oil in a single massive dose of 30 grams can be given 2 or 3 days before the operation and if necessary may be repeated on successive days. One should however, guard against exhausting the patient by heroic purgation. The patient should receive a fluid diet spare in residue and rich in nourishment. It is wise to postpone the operation for a few days if the patient appears to be exhausted by the purgation. Proper results can be accomplished by rest, by proper diet enemas and laxatives. Catharsis should be finished not less than 24 hours before the operation. A tepid water enema is given on the eve before. I consider the use of opiates both before and after operation superfluous in some respects even in jejunos. On the eve of operation the patient receives a mild hypnotic. All nourishment and fluids are withdrawn 6 hours before the operation and morphine in a dose of 1 to 3 centigrams, according to the size and condition of the patient, is given one half hour before the operation. If a fecal fistula is present it is utilized for washing out the bowel.

ANÆSTHESIA

I prefer ether anesthesia induced by ethyl chloride. The operation however, can be done under local anesthesia especially in cases with a freely movable tumor perhaps with a very short general anesthesia during the search for the sigmoid. In difficult cases requiring freeing of adhesions removal of organs such as the small intestine the ovary, the uterus requiring dissection from the posterior abdominal wall or resection beyond the limits of the sigmoid a general anesthesia is necessary. When an objection to general anesthesia exists, these difficult cases may be operated upon under an extensive left sided paravertebral anesthesia.

TECHNIQUE

Position. A dorsal recumbent position with a high pad under the buttocks is used. The tail end of the operating table is markedly elevated. The operator stands on the left, while the two assistants stand on the right side of the patient.

Isolation of the operative field. Two large towels are placed transversely, one over the symphysis so as to cover the thighs, the other across the abdomen its lower edge reaching the level of the umbilicus. Two smaller towels are placed obliquely so as to create a rhomboid the long axis of which corresponds to Poupart's ligament and the crest of the ilium.

Incision of the abdominal wall The incision begins four finger breadths lateral to the anterior superior spine of the ilium and parallel to Poupart's ligament and is continued in a medial direction as far as the edge of the rectus muscle. The incision is carried down to the aponeurosis of the external oblique, and subcutaneous veins and small spurting arteries are ligated. The external oblique is split in the direction of the incision while the internal oblique and the transversalis muscles are split in the direction of their fibers and are forcibly retracted with blunt retractors. The peritoneum is split parallel to Poupart's ligament. The muscular incision can be made more ample by prolonging it backward into the fleshy portion of the internal oblique and by carrying the incision of the aponeurosis of the external oblique into the sheath of the rectus muscle. The approach is thus made much easier. Should there arise a need for a still greater exposure, the flat abdominal muscles may be cut transversely. When the transverse colon or the splenic flexure require exposure, one had better resort to a second incision. This is made parallel to the left costal border, the underlying muscles being split in the same direction.

Localization The sigmoid is usually found close to the incision. It frequently prolapses into it. When it is not visible the small intestine is packed off to one side with the aid of a large laparotomy sponge. Elevation of the end of the tube at this stage aids in exposing the operative field. The sigmoid is seized and is brought out of the peritoneal cavity. The tumor is readily delivered when it is located in the mobile portion of the sigmoid and when it is not bound down by adhesions or by a shrunken mesosigmoid. In favorable cases of this type, the peritoneal cavity is packed off and all further manipulations are carried out outside of the abdomen. When adhesions are present one must first expose them properly in order that one may decide by direct inspection as well as by palpation the feasibility of attacking them. The possible extension of the growth into the depth, the presence of metastases in the peritoneum of nodes in the mesentery, in the pouch of Douglas in the vicinity of the growth etc. Further consideration is to be given to the kind of adhesions. They may be of the type that are easily separated or on the other hand firmly bound to the abdominal wall or to an abdominal viscus or embedded in an indurated mass. The presence of just such indurated tumor foci should suggest the possibility of an abscess in the vicinity of the new growth, or an abscess the result of sigmoiditis. The unexpected

unguarded breaking into one of these may result disastrously for the patient.

Freeing of the growth When we rule out the slender adhesions, such as result from a previous laparotomy made for an acute obstruction due to the tumor or from an inflammatory disease of the female adnexa, we must regard as serious complications all other adhesions of the new growth to the tissue about it and to the neighboring organs and every fixation caused by mesenteric involvement. This must be clearly kept in mind before the radical procedure is decided upon, for once begun there is no backing out. The bowel may be injured, and then the radical removal of the growth and of the tissue about it must be completed in the face of every difficulty and hazard without this an acute peritonitis is unavoidable. One must be prepared in these cases to remove a neighboring viscus such as the uterus the ovary or an adherent coil of the small intestine. Tumors involving the mesosigmoid as well as those fixed to the iliac region are dissected out by incising the posterolateral peritoneal wall and working from their lateral aspect in the median direction. In the course of this dissection, one should particularly remember the ureter. The iliac vessels may come into the operative field. They should be freely exposed so as to avoid injury to them.

Choice of the method of resection Upon the delivery of the tumor from the peritoneal cavity one is confronted with the question of a one stage or two stage method of procedure. A condition *sine qua non* for a one stage procedure is a thoroughly emptied bowel. When this condition does not obtain one had better resort to the two stage method. We shall next describe the one stage method.

Ligation of mesosigmoid vessels If the mesosigmoid is easily accessible then with the aid of an artery forceps a slit is made in it and sections 1.5 to 2 centimeters wide are grasped between two artery forceps to the right and to the left of the slit. These are cut between the clamps and the centrally directed portion is ligated. This is continued until the bowel to be resected is freed. When there is not sufficient room to work in, the cutting of the mesosigmoid may be made between a ligature on the one hand and the clamp on the other. Mesosigmoid ligature of course must be made central to the diseased part of the bowel as well as to the diseased lymph nodes. In difficult cases it is best to begin with the ligation of the biggest vessel. If there are enlarged lymph glands or much fat, the vessels must be carefully dissected and doubly ligated, and only if the vessels are plainly visible and easily approached, transfixed

Fig. 1

Fig. 2

Fig. 3

Fig. 4

Fig. 5

Fig. 6

Fig. 7

Fig. 8

Fig. 9

Fig. 10

sutures may be applied. No preliminary ligations should be made in the immediate vicinity of the line of resection. Here close to the bowel the mesentery is freely incised and the bleeding vessels are separately clamped and ligated.

Resection of the intoloid bowel. This is done with the knife between two hard clamps. The line of incision is made oblique so that more is removed from the anti-mesenteric than from the mesenteric border. If the bowel is long enough additional soft clamps may be placed three to four finger breadths above and below the line of resection. The resection is of course preceded by a careful isolation of the segment to be resected and by a careful packing off of the abdominal cavity. Two extra towels are now laid on the dressings and are secured with skin clips or artery forceps. These protect the underlying isolating dressing

against soiling and are to be immediately replaced when soiled. Dissection is made with a knife between two closely applied clamps.

Apposition of bowel stumps. After inspection and change of outer dressings, surrounding the bowel stumps the clamps are removed first from the aboral then from the oral side. The assistant quickly grasps the mesenteric and the anti-mesenteric ends of the bowel stump with artery forceps and holds them up high. The compressed edges are now carefully separated, the adherent mucus is wiped away with small sponges. In the absence of an upper clamp a piece of gauze is placed in the lumen and the edges of the stump are fixed by two or three artery forceps. The two stumps are now laid side by side at the point of mesenteric attachment and two or three interrupted catgut sutures are passed through the

Fig. 11

Fig. 12

Fig. 13

whole thickness of the intestinal wall at this point and tied within the lumen (Fig. 1). Next, a catgut suture passing through the whole thickness of the intestinal wall is placed at the antimesenteric border and is tied on the inside and left long as a stay suture.

Through-and-through suture. While the assistant holds up the antimesenteric stay suture a through and through catgut suture beginning at the mesenteric border is passed through the edges, the needle passing 2 or 3 millimeters away from the border thus bringing the stumps in apposition. When the suture has progressed to within 2 centimeters of the antimesenteric border another single catgut suture is passed through the whole thickness of the bowel on both sides and is tied from the inside. This now serves as a new stay suture. The continuous suture is taken up once more (Fig. 4). Two centimeters further another interrupted suture is placed and then still another at the same interval and so on until two thirds of the bowel circumference has been sutured. At this stage the running suture is tied to the last interrupted and cut. An interrupted suture is now placed on the outside so as to bring the bowel edges to within 2 to 3 millimeters so that serous flaps will approximate each other to that extent. This suture is left long and is tied to the end of the circular through and through suture which has now begun on the other side at the mesenteric end (Fig. 6). At this stage of the suture the bowel is sewed from the outside; the needle is made to pass through the serosa to reappear at mucous edge to pierce the mucosa of the opposite side and come out once more 2 to 3 millimeters on serous surface of opposite side. The soft clamps and gauze sponge within the lumen are removed when suture line is within 2 to 3 centimeters of completion.

Serous suture. The two large upper sponges are now removed even if not soiled. The suture line is wiped dry and the gloves and instruments are changed. The serous layers of the large intestines should always be sutured with interrupted sutures to make sure that each suture grasps a definite amount of tissue. The bowel serosa should prefer

ably be sutured to bowel serosa and epiploic appendages utilized only when bowel serosa is not to be had. These appendages must be grasped by the needle close to their base. The sutures are placed 3 to 4 millimeters apart. One begins 1.5 to 2 centimeters beyond the bowel border on one side of the mesentery and ends 1.5 to 2 centimeters above the mesenteric border of the other side. Contrary to the suggestion of some surgeons the epiploic appendages should not be removed. There is in the first place the danger of unwittingly opening into a Graser diverticulum, and on the other, these appendages may be utilized for the reinforcement of the suture line. They are secured to it by one or two serous stitches. For a serous suture I always use the finest silk and the small curved needle.

Suture of the mesentery. The breach next the bowel is closed as already mentioned with the serous suture 1.5 to 2 centimeters wide. The rest is sutured with catgut in such a way that the ligatures are covered with serosa.

Making the suture line safe. The sponges are now removed from the field of operation and from the peritoneal cavity. The peritoneal edges are grasped with forceps and the peritoneal cavity is examined for bleeding, sponges, etc. The parietal peritoneum is stitched to the sigmoid anastomosis in such a way as to leave at least four finger breadths of the oral portion of the bowel outside of the peritoneal cavity (Fig. 9). If possible the suture line of the mesentery is included as well, though this is not so important. Aboral from the anastomosis only about one finger breadth of the bowel is thus extraperitonealized. If a cecal fistula is present this width would do for the oral segment as well. The peritoneum is stitched with fine interrupted silk sutures, 3 to 4 millimeters apart in the immediate vicinity of the anastomosis elsewhere 1 to 1.5 centimeters apart. In the lower medial angle of the wound where the peritoneum was sutured to the bowel one finger breadth below the anastomosis the parietal peritoneum is grasped not at its edge but 2 to 2.5 finger breadths back of it, and is thus sutured to

Fig. 14

Fig. 15

Fig. 16

the serosa of the sigmoid. This results in a free peritoneal flap some two finger breadths in width which is to be utilized later to protect the anastomotic line against the dressings (Fig 16). One might utilize an epiploic appendage or a piece of omentum for the same purpose, although this is best accomplished by means of the peritoneal flap just described.

The segment which lies over (orally from) the anastomosis is now designated by passing two very fine silk sutures through its serosa and muscularis. These sutures are tied loosely and left long. They indicate the location where the bowel is to be opened when the case requires it. When a cecal fistula is present this precaution is not necessary nor is it necessary to extraperitonealize much of the oral segment.

Dressing. Three gauze drains are used ordinarily. One is placed over the anastomotic line protected by the peritoneal flap, by an epiploic appendage or by omentum. One is placed over the bowel over the anastomosis and one to the lateral side of the bowel. In cases in which much retroperitoneal dissection is done more packing is necessary.

Suture of the abdominal wall. The abdominal wall is sutured in layers: muscles and aponeurosis with catgut; skin with silk and metal clips sufficient room being left for the gauze drains.

Bandage. Gauze dressings are held in place by adhesive strips laid transversely across the abdomen. Cotton and a calico binder are placed over these, the latter being secured with safety pins.

MULTIPLE STAGE RESECTION

First procedure—resection. The preliminary steps—incision, ligation of mesosigmoid vessels—are the same as for the one stage operation. When however because of the presence of feces in the bowel the one stage method appears inadvisable one proceeds as follows:

The two limbs of the delivered sigmoid are placed parallel to one another in a flint barrel

fashion and are joined with a fine serous suture for such an extent as the case permits at least three finger breadths. Undue tension must be avoided in order not to run the risk of angulation perforation etc.

The parietal peritoneum is now sutured with fine serous sutures 1 centimeters apart to both limbs in a circular fashion so that the peritoneal cavity is completely shut off at the base of the delivered bowel.

Gauze dressings are placed above and below both limbs and the wider dressing to the side of the bowel.

The abdominal wall is sutured in layers, room being left for the gauze drains and the bowel.

On completion of the skin suture the wound is covered with large dressings and the bowel is tied off with heavy silk on either side at the level at which it is to be amputated. Next, the bowel is compressed with a powerful clamp 2 to 3 centimeters above the silk ligature and is severed between the ligature and the clamp. This is best accomplished with a thermocautery.

Bandage. Same as in the one stage operation.

Second act—crushing of the spur. This is done 2 to 3 weeks later. By this time the bowel empties itself normally through the proximal stump and the incision is to a great extent healed. Small defects in the wound corresponding to gauze drains are of no consequence. The patient is thoroughly purged a day or two before the operation and the aboral stump is thoroughly washed out by an enema or by a catheter introduced through the proximal opening of the aboral stump. The extent and the width of the partition between the two limbs is ascertained by passing the index finger into each lumen. The straight forceps is now introduced under the guidance of the finger one blade into each lumen so that when the two are closed the partition is grasped between them. Instead of one wide forceps one can use two small ones placed close to each other. This forceps is closed with considerable force. In a day or

two the partition dividing the two limbs necrotizes and the forceps are removed (Figs 11 to 13). About a week later the communication between the lumina of the two limbs is explored with the finger. If it is deemed insufficient, a forceps is placed on the remaining spur in the same manner as before.

Third stage—closure of the fistula. One must wait for the complete healing of the incision and for the complete union between the bowel mucosa and the skin. When the mucosa prolapses the operation is much easier. The patient is once more purged a day before the operation and the segment of the bowel between the fistula and the anus is irrigated. This operation can easily be performed under local anesthesia (infiltration with a one per cent novocain solution).

An incision is made in the scar between the skin and the mucosa. The edges of the latter are seized with fine artery forceps, are pulled away from the skin and are dissected from it by scalpel. The bowel is freed all around and is then closed by a number of interrupted sutures of fine catgut if possible, in a direction transverse to the long axis of the bowel (Fig. 14). On completion of suturing the wound is wiped with a well diluted solution of tincture of iodine and a change of gloves, instruments and dressings is made. The cutaneous scar is now excised. When the latter is thin it is sufficient to remove a width of 0.5 to 1 centimeter. The sutured bowel is dissected free from the subcutaneous fat and aponeurosis and the first suture line is buried by means of a few serous sutures of fine silk (Fig. 15).

The skin and the aponeurosis may be mobilized if necessary and closure is accomplished by means of two U shaped mattress sutures of stout silk worm gut. This is the most important step in this stage of the operation. A suture on a large curved needle is made to pass say from the right side of the wound 1.5 to 2 centimeters from its edge through the skin. It is made to appear above the aponeurosis to cross over to the opposite side then goes below that (left) side of the aponeurosis and around the (left) side of the bowel comes out under the (left) edge of the aponeurosis wound and returns to the opposite side passing above the aponeurosis through the subcutaneous fat and skin and emerges again 0.5 to 2 centimeters from the skin wound (right) edge. The same procedure is repeated from the opposite side the needle being passed through the skin and subcutaneous fat of one side, then below the aponeurosis and around the side of the bowel of the opposite side to be returned through the subcutaneous fat and skin of the original side. Each suture is tied over a roll

Fig. 17

of gauze (Fig. 17). This procedure results in bringing wide segments of soft tissue over the repaired bowel. No further suture of the skin is necessary as a rule. Eventually one or two superficial silk sutures may be added. A small gauze drain is inserted into each angle.

POSTOPERATIVE TREATMENT

After the one stage operation. The patient is put to bed in a half sitting posture. No food is given the first day. On the second and third days tea, water lemonade, and fruit juices are given. On the fourth and fifth days bouillon and thin soups are added. When flatus has been passed milk, sour milk, coffee, and thicker soups may be given. From the sixth day apple sauce, paps of potatoes, of green vegetables and gruel are added, meat being given only after the first copious bowel movement. No opiates or enemata are administered. After the second day a thick rectal tube is frequently passed. If the flatus is not passed before the third or fourth day, small enemata of oil and glycerin diluted in water not to exceed 50 cubic centimeters are administered. After the fifth or sixth day, when flatus has been passed spontaneously, cathartics, preferably castor oil, may be given by mouth.

Change of dressings. On the day following the operation the outer dressings are changed, after that every day or every other day. The gauze drains are moistened lightly with hydrogen peroxide and are not changed until the eighth day. In the presence of a profuse secretion, however, this may be done a day or two earlier. If fecal matter appears in the wound the dressings must be changed daily and oftener. The wound is liberally irrigated with hydrogen peroxide and the skin is protected with a thick layer of zinc paste or veroform salve. In most cases there is very little fecal discharge in the dressings and that soon disappears. Extensive separation of the suture line followed by profuse discharge of feces is not frequent and even these heal in the course of a few weeks.

The after treatment after the first act of the two stage operation is the same as that described for the one stage operation.

Faeces appear in the incision on the third or fourth day. The ligature on the bowel will cut through spontaneously. However if the patient complains of distention, the ligature may be removed from the proximal stump as early as the day after the operation. The dressings may have to be changed several times in the course of the day. The skin is protected with a heavy layer of xeroform or zinc oxide. The gauze drains are changed on the eighth day. Baths are given after the second week.

The treatment after the *second act* does not differ from the preceding one. After the *third act* the dressings are changed on the day following the operation thence once every 2 days. The drains are removed on the eighth day, the superficial skin stitches at the same time. The deep mattress sutures are left in for 10 to 12 days as long as they are not cutting through. A slight faecal discharge may appear in the incision. If the wound is not infected and the patient is afebrile nothing is done. Should an abscess eventually form it is treated by timely spreading of the wound. As a rule the healing progresses

smoothly. An occasional faecal fistula closes spontaneously.

Stress must be laid upon the diet during the first week after the repair of the fistula. This should consist so far as possible of tea, lemonade, orangeade, and thin soups. The bowel is relieved by rectal tube and small enemas. Copious enemata are to be avoided. Laxatives by mouth are given on the sixth or seventh day. A more solid diet is given only after a bowel movement has been obtained.

COMPLICATIONS

Among these are collection of secretions under the drains and abscess formation in the incision. These are treated by removal of superficial and deep stitches and by separation of the wound edges. Phlegmons are treated by incision. The danger of peritonitis may be said to be almost positively excluded by the use of the method of extraperitonealization of the suture line in both operations. This is true however only if meticulous care is exercised at the time the tumor is delivered that proper protection be given to the peritoneum in the course of suturing that gloves and instruments are changed often and all tension is avoided. The danger of pneumonia is less than after gastric operations.

FROM THE CLINIC OF THE WOMAN'S HOSPITAL, NEW YORK

THE "WARRFN APRON" IN REPAIR OF HIGH LACERATION OF THE RECTUM ASSOCIATED WITH THIRD DEGREE LACERATION OF THE PELVIC FLOOR

LILIAN K. P. FARRAR, A.B., M.D., F.A.C.S., NEW YORK

In 1882 Dr. J. Collins Warren presented before the American Gynecological Society a contribution entitled "A New Method of Operation for the Relief of Rupture of the Perineum through the Sphincter and Rectum." The operation has been used extensively and endorsed by surgeons for the third degree lacerations of the pelvic floor but is considered not to be applicable when the laceration extends high in the rectum. If however the dissection of the flap is begun high on the posterior wall of the vagina just below the cervix and is extended out side and below the sphincter and pits on either side the apron or flap will be sufficiently long to extend below the tear in the rectum and thus protect the wound which now lies anterior to the flap.

The technique of the operation to be described differs from the Warren operation chiefly in the outline of the flap to be used and the modern method of repairing injuries to the pelvic floor by suturing the torn urogenital diaphragm and reuniting the separated levator muscles. This method of repair has been used by the writer in 12 patients, 10 of whom have had an absolutely perfect result. Two cases required additional suturing owing to excessive catharsis in one case

and a too wide separation of the legs when placed in the holding stirrups in another. In neither patient was there any injury to the flap and both had a satisfactory result. The operation is best done after a full 6 months' interval has elapsed from the last confinement, as this allows ample time for the tissues in the pelvic floor to undergo involution. The most favorable time in the month is 2 or 3 days after the cessation of the menstrual flow so that there will be time for healing before the next period begins. The bowels should be moved thoroughly the week of the operation preferably with castor oil (1 ounce) given 4 and 6 days before the operation, and a high enema the day of the operation—6 to 8 hours before the time set for the repair. A limited diet with little residue should be given on the 3 days previous to the day of the operation.

FIG. 1. Outline of apron (After J. Collins Warren)

FIG. 2. Outline of operation field (After Howard A. Kelly)

The after treatment after the first act of the two stage operation is the same as that described for the one stage operation.

Fæces appear in the incision on the third or fourth day. The ligature on the bowel will cut through spontaneously. However, if the patient complains of distention the ligature may be removed from the proximal stump as early as the day after the operation. The dressings may have to be changed several times in the course of the day. The skin is protected with a heavy layer of iodoform or zinc salve. The gauze drains are changed on the eighth day. Baths are given after the second week.

The treatment after the *second act* does not differ from the preceding one. After the *third act* the dressings are changed on the day following the operation thence once every 2 days. The drains are removed on the eighth day the superficial skin stitches at the same time. The deep mattress sutures are left in for 10 to 12 days as long as they are not cutting through. A slight fæcal discharge may appear in the incision. If the wound is not infected and the patient is afebrile nothing is done. Should an abscess eventually form it is treated by timely spreading of the wound. As a rule the healing progresses

smoothly. An occasional fæcal fistula closes spontaneously.

Stress must be laid upon the diet during the first week after the repair of the fistula. This should consist so far as possible of tea, lemonade, orangeade, and thin soups. The bowel is relieved by rectal tube and small enemas. Copious enemata are to be avoided. Laxatives by mouth are given on the sixth or seventh day. A more solid diet is given only after a bowel movement has been obtained.

COMPLICATIONS

Among these are collection of secretions under the drains and abscess formation in the incision. These are treated by removal of superficial and deep stitches and by separation of the wound edges. Phlegmons are treated by incision. The danger of peritonitis may be said to be almost positively excluded by the use of the method of extraperitonealization of the suture line in both operations. This is true however only if meticulous care is exercised at the time the tumor is delivered that proper protection be given to the peritoneum in the course of suturing that gloves and instruments are changed often and all tension is avoided. The danger of pneumonia is less than after gastric operations.

THE "WARREN APRON" IN REPAIR OF HIGH LACERATION OF THE RECTUM ASSOCIATED WITH THIRD DEGREE LACERATION OF THE PELVIC FLOOR

LILIAN K. P. FARRAR, A.B., M.D., F.A.C.S., NEW YORK.

IN 1882 Dr. J. Collins Warren presented before the American Gynecological Society a contribution entitled "A New Method of Operation for the Relief of Rupture of the Perineum through the Sphincter and Rectum." The operation has been used extensively and endorsed by surgeons for the third degree lacerations of the pelvic floor but is considered not to be applicable when the laceration extends high in the rectum. If however the dissection of the flap is begun high on the posterior wall of the vagina just below the cervix and is extended out side and below the sphincter and pits on either side the apron or flap will be sufficiently long to extend below the tear in the rectum and thus protect the wound which now lies anterior to the flap.

The technique of the operation to be described differs from the Warren operation chiefly in the outline of the flap to be used and the modern method of repairing injuries to the pelvic floor by suturing the torn urogenital diaphragm and reuniting the separated levator muscles. This method of repair has been used by the writer in 12 patients, 10 of whom have had an absolutely perfect result. Two cases required additional suturing owing to excessive catharsis in one case

and a too wide separation of the legs when placed in the holding stirrups in another. In neither patient was there any injury to the flap and both had a satisfactory result. The operation is best done after a full 6 months' interval has elapsed from the last confinement, as this allows ample time for the tissues in the pelvic floor to undergo involution. The most favorable time in the month is 2 or 3 days after the cessation of the menstrual flow so that there will be time for healing before the next period begins. The bowels should be moved thoroughly the week of the operation preferably with castor oil (1 ounce) given 4 and 2 days before the operation, and a high enema the day of the operation—6 to 8 hours before the time set for the repair. A limited diet with little residue should be given on the 3 days previous to the day of the operation.

Fig. 1 Outline of apron (After J. Collins Warren)

Fig. 2 Outline of operation field (After Howard A. Knapp)

FIG. 3

Fig 3. Outline of apron. 1. Dissection begun just below cervix *B* upper end of tear in rectum. *C* point on imaginary line between ends of sphincter ani muscles.

FIG. 4

Fig 4. The flap has been turned down over the tear in the rectum.

FIG. 5

Fig 5. Silver wire sutures placed anterior to flap.

Before outlining the flap, the sphincter ani muscles are thoroughly stretched and a 12 inch strip of 1 inch wide iodoform gauze is packed lightly into the rectum. The technique of the operation is well shown in illustrations. Figures 1 and 2 show the Warren and Kelly flaps. Figure 3 is an outline of the apron which we use. The dissection is begun just below the cervix *A* to *B* must equal or be a little longer than *B* to *C*. The incision must extend outside of the sphincter ani pits and a little below them. Dissect free a thick flap in the area outlined up to the lines extending from just below the sphincter ani pit on one

side to the point *B* and down to a point just below the sphincter ani pit on the other side, keeping a finger back of the flap as a guide when approaching the edge of the rectum. The flap will now hang down over the tear in the rectum and *A* will cover point *C* (Fig 4). Carry 3 to 5 silver wire sutures anterior to the flap in the vaginal portion of the operating field (Fig 5). The first suture should be above the apex *A*, to take the strain off the rectum when it is united. The second wire suture should be introduced into the mucous membrane on the left side about $\frac{1}{8}$ inch from the margin of the denuded area and deeply enough to pick up the edge of the torn urogenital diaphragm. It should come out at the margin of the flap and catch up lightly tissue in the flap to prevent a dead space as first advised by Tait and should be re introduced at the right margin of the flap taking the torn edge of the diaphragm on the right and out on the mucous membrane. Successive sutures should be passed in exactly the same way until the mucocutaneous junction is reached. The anterior fibers of the levator ani muscles are then found.

The levator muscles are sutured with No. 2 catgut and 2 to 3 silver wire sutures are passed from the skin surface of the perineum under the levator muscles (Fig 6).

When the levator muscles are united they act as a guide to the torn sphincter muscle which should be sutured with No. 1 tanned gut after they have been dissected out. Two wire sutures

FIG. 6. Levator muscles sutured with No. 2 catgut.

Fig 7

Fig 8

Fig 9

Fig. 7 Torn sphincter is sutured with No. 1 tanned gut
Fig. 8 Purse string suture closes edges of flap which may be attached to or spread out to fit the edge of the anus

Fig. 9 All wire sutures are twisted and those in the vagina have their ends covered with a washer and shot turnly crushed

are then passed deeply under the torn edges of the sphincter muscle. The upper edge of the sutured sphincter muscle may be sutured to the levator muscle where Luschka's fibers normally are. A continuous No. 2 tanned gut suture closes Colles' fascia and is tied later to the end of a No. 1 tanned gut suture passed subcutaneously in the skin margins beginning at the mucocutaneous junction and ending at the anal margin (Fig. 7).

The flap now hangs in the restored anus and a purse string suture will close the edges which may be attached to or spread out to fit the edge of the anus. This flap will contract and be withdrawn into the rectum where it can be felt weeks later only as a slight thickening on the anterior wall of the rectum (Fig. 8).

All wire sutures are now twisted and each one in the vagina has its ends covered with a washer and a shot firmly crushed. The twisted wire sutures on the skin surface are passed through a piece of perforated rubber tubing covered with thin rubber. The ends of the wires are covered with shot and the outer rubber covering is tied over the tube to keep it water tight as in the technique which is employed by Dr. Herman Grad of the Woman's Hospital. The gauze is removed from the rectum and the knees are kept tied until the patient becomes conscious (Fig. 9).

AFTER CARE

The perineum must be kept clean by pitcher douches of potassium permanganate solution

after each urination or bowel movement. The diet should be liquids chiefly—no milk should be given, however.

The bowels are moved on the fifth day by Epsom salts repeated if necessary. Enemas are never given.

The silver wire sutures are removed on the fourteenth day under gas oxygen anaesthesia, care being taken not to stretch the pelvic floor by placing the legs in stirrups.

The principles of the repair of the pelvic floor have been taught by Emmet Tait, Marcy, Watkins and Ward, the anatomy demonstrated by Edouard Martin Testut and Jacob, Halban and Tandler and others the method of repair of third degree laceration of the pelvic floor by Kelly, Watkins, Ristine and Noble. So completely has this been done that one can only assemble the technique to fit each individual case keeping always in mind the importance of uniting the edges of the torn urogenital diaphragm and suturing together the levator muscles after reaching the mucocutaneous line where they normally decussate with one another before the injury. The support of the pelvic floor depends not on muscle or fascia alone but upon the integrity of both muscle and fascia working together.

My appreciation and grateful acknowledgment are due to Dr. Howard A. Kelly for his invaluable guidance of many years and in this instance for his teaching the repair of the complete laceration of the sphincter and muscle.

CHRONIC DUODENAL ULCER¹

JOHN B. DEAVER, M.D., F.A.C.S., PHILADELPHIA

DUODENAL ulcer is an ever absorbing subject of contention among the profession. Some maintain that especially in its early stages it is a medical condition and should be so treated, others urge more radical i.e. surgical treatment. Some claim that even a positive X-ray report does not always establish the diagnosis; others base their diagnosis on the roentgenogram and on the results of laboratory tests. Some contend the symptoms are simulated by duodenitis and inflammation of a duodenal diverticulum; others stress the differentiation between ulcer and disease of the gall bladder and the appendix. Even among those who advocate early surgery there are differences of opinion as to the proper surgical procedure. As a matter of fact each and every one of these opinions is justified and it is practically impossible to describe a definite picture or prescribe a definite course of treatment that will apply to every case. Duodenal ulcer in short refuses to conform to the modern trend of standardization because the human subject itself cannot be completely standardized.

This tendency to resist standardization depends on various factors. One of these is the site of the ulcer. The typical duodenal ulcer is found in the upper 3 centimeters of the anterior wall of the duodenum and in many cases the per ulcerous exudate extends up to or within a short distance of the pylorus. The deepest part of the ulcer will usually be found just below the pylorus where the acid secretion which is ejected with considerable force from the stomach produces an impact upon the duodenal mucosa at this point. Ulcer is rarely met with below the papilla of Vater where the acid chyme is neutralized. Physiologically the consensus of opinion seems to be that the acid in the pyloric end of the stomach stimulates the gastric and secretory functions. In the upper duodenum it controls pyloric function and the rate of the gastric excretion is regulated by the rapidity with which this acid is neutralized by the alkaline biliary and pancreatic secretions. According to some authorities pathologically the acid gastric juices either because of perverted secretion, or through lack of local resistance, or both become the most important factor in the development of ulcer and largely confine their ravages to the duodenum.

The ulcer is usually round and varies in diameter from 1.5 to 3 centimeters or more. The base

is either the submucosa, the head of the pancreas, or the thickened connective tissue (Fig. 1).

Inspection shows stippling or a white central exudate with radiating white lines which can be likened to a wheel; the central white point representing the hub and the radiating white lines the spokes of the wheel. Not all ulcers however give so distinct a picture. Ulcer of the anterior wall of the duodenum, the most common site, cannot always be recognized even when the duodenum is exposed and drawn upward and partly out of the wound by traction upon the pyloric end of the stomach because it is often covered over by or grizzled exudate in the shape of a peritoneal sheet which may be styled pathological peritoneum, the surface of which frequently is greasy and dirty looking (Fig. 2). This may be one reason for overlooking an ulcer unless the surgeon adds careful dissection and palpation to inspection. When operating before an audience of students I cleanse the surface of the duodenum by carefully dissecting off the covering referred to so as definitely to demonstrate the ulcer (Fig. 3).

When the ulcer is on the posterior wall of the duodenum its recognition is even more difficult. Here likewise we must look well and palpate well otherwise the ulcer will be missed. The recognition of exudate in the lower portion of the free border of the gastro-hepatic (Fig. 4), lesser omentum in juxtaposition to the duodenum is a sign post that points to the site of the ulcer which with the detection of the crater (which can be done by contacting the anterior bowel wall with the ulcer) justifies opening the duodenum. Then as the margins of the incised walls of the duodenal wound are retracted, the ulcer will be exposed (Fig. 5). I place great value on the use of the Cameron light in these cases. In fact by this means I am able to demonstrate the ulcer to the visitors in my clinic. Furthermore by this technique if there is more than one ulcer present, it can be detected.

While writing this discussion I was much pleased to read of Balfour's ingenious method of determining the presence of ulcer of the posterior wall of the duodenum by incising the stomach close to the pylorus and introducing the finger into the duodenum to detect the ulcer and immediately closing the opening. This simplifies the detection of the ulcer. Incidentally I may say I have also done this to determine the patulousness of the

FIG 1 Ulcer of duodenum Stippling of surface

FIG 2 Pathological band of peritoneum covering ulcer

pylorus where I have been in doubt as to its size after making a plastic operation upon it

W J Mayo has called attention to the appearance of an anæmic spot on the duodenum which may be mistaken for ulcer. The arrangement of the blood vessels of the duodenum just below the pylorus is such that if the pyloric end of the stomach is pulled forward rather firmly as must often be done to obtain a view of the parts this anæmic spot will appear in the duodenum just below the pyloric ring. This is very striking and may closely resemble an ulcer. The tissues apparently involved are normal to the touch and do not have the milky appearance of the peritoneal covering of a true ulcer and stippling, an open area of organized exudate with white lines radiating therefrom adhesions and other abnormalities are absent. When the traction is relieved it will be seen at once that no ulcer exists. The underestimation of surgery of the stomach and duodenum and some of the unsatisfactory results reported are without doubt largely due to mistaken diagnoses and unnecessary operations for supposed but non existing ulcer.

Duodenal ulcer is usually single although occasionally there may be a second ulcer so that examination for more than one ulcer is important (Fig 6). When the ulcer is demonstrated the duodenal cap usually is easily shown since it is not apt to be surrounded by adhesions. Periduodenal adhesions due to ulcer are not nearly so frequent as are pericholecystic adhesions the result of a diseased gall bladder. On the other hand, the duodenal deformity as shown by the roentgenogram and caused by pericholecystic adhesions a duodenitis or an inflamed diverticulum may simulate ulcer findings, so that the X ray report

is not always conclusive except that it shows pathology, which after all is the most important finding.

There are no known constitutional peculiarities which predispose to duodenal ulcer. The etiology I believe is infection from a more or less distant focus although the many theories offered to explain its origin show that many other factors may play a part in its pathogenesis and that these factors probably differ in different cases.

Duodenal ulcer occurs most frequently in the male sex the reason for this preponderance is not clear. Mayo explains it on the basis of mechanics the first or ascending portion of the duodenum in the average male ascends somewhat higher than in the average female and as a result the alkaline secretions may rise higher and thus more readily neutralize the acid secretion in the first portion of the duodenum in women than in men.

The diagnosis of typical duodenal ulcer does not present great difficulty because the symptoms usually appear in a well defined sequence so well defined in fact that in most instances we need not hesitate to make the diagnosis from the clinical history and feel confident of having it confirmed at operation.

The typical case history of duodenal ulcer reveals years if not a lifetime of attacks of epigastric discomfort after meals that is a sense of fullness often described as a blown out feeling and a gnawing burning sensation rather than pain with acid eructations coming on from 2 to 4 hours after meals. This distress rarely appears after breakfast but with constant regularity after the heavier meals the so called hunger pain at night (about 2 a m) is one of the distinguishing features of the complaint. The reason for this

Fig. 3 Ulcer of duodenum

Fig. 4 Palpable exudate in extreme lower portion of right border of gastrohepatic omentum

hunger pain has not yet been satisfactorily explained. Moynihan attributes it to changes in the muscular activity of the stomach and the duodenum stimulated by changes in the chemical quality of the chyme, especially toward the end of digestion. Food relief or subsidence of pain after eating or taking an alkali (soda) is another characteristic feature. The rhythm of duodenal ulcer then, is food comfort, pain, and again food, comfort, pain. Mayo believes that in the greater number of cases the pain is caused by the irritant action of the acid acrid contents on the ulcer area of the duodenum itself, heightened by the accompanying pylorospasm and gas formation, while in the remaining cases it is due to a perforating peritonitis, a complication more frequent in duodenal than in gastric ulcer, because of the thinner walls of the duodenum. The field of radiation of the pain is usually limited to the gastric and the duodenal areas.

The periodicity of these attacks with intervals of complete well being is emphasized by all authorities. The attacks usually begin in early adult life. The patient complains of stomach trouble of which hyperacidity is a prominent feature. This appears in about 50 per cent of the cases. The symptoms recur with increasing frequency as the patient grows older. In the later stages mechanical obstruction of the pylorus occurs.

The physical signs in duodenal ulcer are practically nil, however, in long standing cases with much organized peri ulcerous exudate, tenderness to deep pressure high up over the rectus muscle may be elicited. Hemorrhage from the bowel or by mouth as evidenced by tarry stools or the pres-

ence of blood in the vomitus is noted in about one third of the cases. Some patients also show a low hæmoglobin percentage. Vomiting is not considered one of the commoner symptoms of ulcer of the duodenum, but it does occur in a few cases.

The motility of the stomach is an important finding. That the motility is abnormally rapid is shown by the fact that in a good percentage of cases nothing of the test meal or the full meal is recovered in the usual time when the stomach is siphoned after the administration of the meal. This hypermotility is also demonstrated by the X ray and the barium meal; they are thus of confirmatory rather than contributory value in the diagnosis.

Briefly stated, then we may say that epigastric distress 3 or 4 hours after meals, relieved by eating or by alkalis, high acidity, hyperactivity of the stomach and, in some cases, vomiting and hemorrhage, are indicative of duodenal ulcer, that is, of the typical case.

It is, of course, the atypical ulcer that presents diagnostic difficulties. It more often simulates appendicitis especially if the appendix is high than other conditions from which it can more or less easily be differentiated, such as gastric ulcer, cholelithiasis, cholecystitis and chronic pancreatitis.

Chronic appendicitis frequently presents the same hunger pain as duodenal ulcer, while hyperacidity is not unusual and many cases show the same chronicity as exists in duodenal ulcer. The chief difference between the two is the freedom from discomfort in the duodenal ulcer between the attacks, while in appendicitis flatulency, gen-

FIG. 5. Incision in anterior wall of duodenum to show ulcer on posterior wall

eral abdominal discomfort and lower abdominal discomfort and sometimes pain are apt to be constantly present. But the patients with appendiceal indigestion usually suffer more pain after certain kinds of food especially starchy food and red meats. The pain however is usually not so severe as in duodenal ulcer and the fact that it radiates downward is one of the principal points in the differential diagnosis. In appendicitis exercise frequently increases the local discomfort which is not true of duodenal ulcer. In fact the appendix is found diseased in so many cases of duodenal as well as of gastric ulcer that these peptic ulcers may be considered secondary conditions that is to say the result of infection from some other organ with the evidence strongly in favor of the appendix as the *corpus delicti*.

In distinguishing between gastric and duodenal ulcer we may to some extent be guided by the time relation of the ingestion of food and the onset of the symptoms. If pain appears soon after eating in one half to two hours and the food relief is not prompt, we may expect to find a gastric rather than a duodenal ulcer. Again the radiations of pain if any in duodenal ulcer are usually to the right while in gastric ulcer they are generally to the left. The pain is also apt to be more constant than in duodenal ulcer. The rhythm of gastric ulcer is food comfort pain comfort vomiting and hemorrhage usually in the form of

hematemesis are more frequent in gastric ulcer while in duodenal ulcer melena is more frequent. Seasonal variations are less common in gastric than in duodenal ulcer. The diagnosis of gastric ulcer is a most uncertain one in fact it can be definitely made only by X ray examination or exposure at the operating table. Frequently the diagnosis of gastric ulcer is a myth and is not verified at operation.

The differential diagnosis of duodenal ulcer and cholelithiasis presents more difficulty but care in taking the history will usually enable the experienced clinician to forecast the true state of affairs. The diagnosis is oftentimes uncertain when adhesions exist between the gall bladder and the stomach and duodenum or when gall stones have been pushed toward the duodenum and since hyperacidity is also a symptom of gall stone disease it adds to the confusion. On the whole however cholelithiasis is marked by such severe colic like pain with sudden and unaccountable onset and almost as sudden and mysterious cessation that recognition as a rule should be easy. Lavage will frequently cut short an attack of biliary colic but will have no influence on the pain of a duodenal ulcer.

Pain in cholecystitis is sudden and usually severe with a wide field of radiation and comes with no regularity as to time. It is rarely caused by food however food by increasing gastric

peristalsis when there are adhesions, particularly to the gall bladder, will cause pain

The chronic gall stone case with impacted stone, ulceration and adhesions, and the absence of jaundice, in which gastric symptoms such as gas, vomiting, burning, distress, sour eructation, and impaired appetite predominate and pain is moderate and follows the taking of food, is too often mistakenly diagnosed ulcer, while duodenal ulcer if there is an early history of irregular attacks of sudden, sharp, intense pain, peritonitis or acute spasm, the absence of obstruction or hyperacidity and the presence of gas, vomiting or sour eructation is usually mistaken for gall stone

Symptoms similar to those of chronic pancreatitis or some pancreatic involvement such as peripancreatic lymphangitis, are not rarely met with in duodenal ulcer. This is not surprising in view of the close relationship existing between the duodenum and the pancreas and the frequent infiltration of ulcer into the pancreas itself as well as the close intercommunication between the pancreatic and duodenal lymphatics. For example, loss of weight and strength, pain in the back, a fairly constant clinical feature of chronic pancreatitis is recorded in a number of cases of ulcer. The character of the pain in chronic pancreatitis is moderate as it is in the majority of duodenal ulcer cases and there is the same epigastric oppression. A valuable distinguishing feature of pancreatic disease, however is that the pain has no definite relation to eating or drinking or the kind of food taken.

Duodenitis is by many regarded as a very early stage of ulcer and is not easily differentiated from actual ulcer. According to Judd it is the only lesion found in a surprisingly large number of cases giving a long and typical history and positive roentgenogram. Inflammation of a duodenal diverticulum likewise presents a syndrome scarcely distinguishable from ulcer although X ray study should demonstrate the presence of a diverticulum.

Malignant neoplasms of the intestines in their early stages sometimes simulate the symptoms of duodenal ulcer but careful inquiry will usually elicit the fact that the attacks of pain though presenting the same periodicity as in duodenal ulcer bear no relation to food neither in their onset nor in the relief of symptoms. In the atypical ulcer however nothing short of X ray examination or incision and inspection will enable us definitely to determine the nature of the lesion.

Unlike gastric ulcer duodenal ulcer rarely undergoes carcinomatous degeneration. Perforation is comparatively common in duodenal ulcer but fortunately the contents of the duodenum are

Fig 6 Duodenal ulcer just beyond pylorus

relatively sterile and small in amount, thus favoring plastic protection. W J Mayo calls attention to the fact that acute perforation of the duodenum is sometimes diagnosed perforative appendicitis and that a careful examination of the appendix in some cases of septic peritonitis from supposed appendiceal perforation would show that its peritoneal surface only is involved and that the lesion is in the duodenum. I have seen cases having all the earmarks of a perforative peptic ulcer, the sudden onset of most atrocious abdominal pain appearing like lightning out of a clear sky and in a short time followed by general board like rigidity of the abdominal wall and upon opening the abdomen high up I have been surprised to find the appendix perforated at or near the base. Again in cases of perforated ulcer that were not seen until several hours after the occurrence of the perforation, so that the spilled visceral contents had gravitated to the right lower abdomen by way of the external paracolic groove I have operated, believing the condition to be due to appendicitis, to find a perforated ulcer.

Hæmorrhage in duodenal ulcer is usually recognized from the appearance of the patient and the history, however this does not always apply, especially when the history is not typical. Confusion may arise in the differential diagnosis between hæmorrhage in duodenal ulcer, early Banti's disease and an ulcerative œsophageal varix. It is difficult in fact impossible to estimate the frequency of hæmorrhage in duodenal ulcer because of the causes of bleeding to which I will refer. It is certainly true that only a small proportion of the bleeding cases come under the surgeon's notice. When in doubt the patient's condition being good it is my practice to open the abdomen to settle the question at the same time if the lesion can be corrected mechanically. I of course do so. There is a difference of opinion whether the

patient should be operated upon immediately or allowed to recover from the effects of the hæmorrhage. This will have to be decided in the individual case; however, it has been my recent practice to operate in cases in which the red blood count is not below 3 500 000, the hæmoglobin correspondingly good, and the diagnosis as nearly certain as can be. Following this course I have had good results and see no reason for not continuing this practice, but it goes without saying with a display of good judgment. In my experience the operative mortality of a bleeding duodenal ulcer is very low, and if surgical measures were always resorted to sufficiently early the general mortality would be still lower. In the case of hæmorrhage from a gastric ulcer, however, we are dealing with a different proposition as the condition is more serious and the surgery more extensive.

Obstruction of the pylorus is not an uncommon condition in the old ulcer patient. It was formerly believed to be due to a gastric ulcer but since operations for duodenal ulcer have become increasingly frequent, it has been shown to be due to the *peri ulcerous erudate* of the latter. Pyloric obstruction is readily diagnosed by means of the X ray but a very simple test is to give an evening meal of raisins and wash out the stomach in the early morning before breakfast, when if raisin skins are recovered obstruction is self evident. Giving a full meal and washing out the stomach several hours later will also show obstruction if the meal is recovered.

Although it is generally said that the question of treatment of chronic duodenal ulcer is not settled I feel that the results of surgical treatment are as a rule, most satisfactory. I believe that the gastroenterologist the roentgenologist the internist and certain surgeons who lack confidence in their work, are to a great extent responsible for the doubt as to the good accomplished by operative as against medical treatment. Personally I can say the longer I practice surgery the more confidence I have in its efficacy and the less in the medical treatment of chronic ulcer. The place which I give to the medical treatment of chronic ulcer is before the diagnosis is definitely established and after recovery from operation. This statement is based on a study of the non perforative as well as the perforative ulcers on which I have operated. Nearly all of these patients have had medical treatment for years before they came to operation. It is a reflection on the profession that so many people, who many times have been pronounced cured of ulcer die from perforation or hæmorrhage. It is claimed that hæmorrhage

from an acute ulcer can be cured under medical treatment. This may be true for a large number of cases but not for all. It is also stated that recovery from hæmorrhage due to chronic ulcer takes place in the majority of instances. We all know of deaths due to hæmorrhage from acute ulcer and I have seen a number of cases of chronic bleeding ulcers that were medically treated to death. What I have just said is neither to discountenance medical treatment nor unduly to praise surgical treatment, but to give to each its proper merit. Medical treatment may often prove merely temporizing, to say the least. A good working rule is that the ulcer patient who fails to show decided improvement after one or two series of medical treatments should be confronted with the advisability of surgery.

Surgery in duodenal ulcer is not so urgent outside of the accidents perforation hæmorrhage and so forth, as it is in gastric ulcer, chiefly because of the risk of cancer in the latter which is rare in duodenal ulcer.

The type of surgery will, of course depend on the personal preference of the surgeon and on the presenting conditions. While gastrojejunostomy plays a prominent role as a surgical procedure it is not the only one at the disposal of the surgeon. According to the exigencies of the case such as size and location of the ulcer and other concomitant conditions he may merely excise the ulcer, or do a pylorotomy or a pyloroplasty or even a subtotal gastrectomy. Indeed wide resection was at one time and to some extent is still strongly advocated especially among European surgeons. It may have something in its favor but until sufficient data are at hand to prove that the more radical operation reduces the incidence or obviates the development of marginal ulcer the most serious sequel of gastrojejunostomy there seems no very valid reason *per se* for extensive gastric resection for duodenal ulcer.

Excision of a small duodenal ulcer is the simplest and would be the ideal operation if it positively insured the patient against future ulcers and if it were not for extensive and troublesome adhesions which may form after the operation. For these reasons it is often advisable to supplement excision by a posterior gastrojejunostomy. The small duodenal ulcer on the anterior or anterolateral wall can be treated by excision or by perforation with the cautery (Balfour operation) followed by posterior gastrojejunostomy. For a large ulcer on the anterior anterolateral posterior, or posterolateral wall of the duodenum, gastrojejunostomy alone may suffice, but ulcer of the

bleeding type requires excision or cauterization if possible, or a pylorotomy and a gastrojejunostomy. The results of these methods, however are sometimes minimized by the fact that these operations do not always effectively reduce gastric acidity, or if it is reduced the reduction the great desideratum of the operation, is not maintained. Posterior gastrojejunostomy alone is indicated when the ulcer is located low down on the duodenum close to the head of the pancreas as well as for ulcer obstructing the pylorus or the terminal duodenum. The latter fortunately, is rare.

Having dwelt on some of the disadvantages of medical therapeutics, it is only fair to call attention to the complications that may follow surgery. The most unpleasant and disheartening of these is of course marginal ulcer, which as we all know has the same inherent possibilities of hæmorrhage and perforation as pertain to the primary condition. The incidence of marginal ulcer varies from 1 to 3 per cent or more. The cause may be faulty technique or ulcer diathesis that is the persistence of a hyperchlorhydria. But whatever its cause its incidence helps to keep the surgeon humble. The treatment of marginal ulcer is eminently surgical. The best procedure when the pylorus and duodenum are patulous is to cut out the anastomosis including the ulcer and peri-ulcerous exudate close the opening in the stomach and anastomose the cut proximal and distal ends of the jejunum. Otherwise the procedure would be to undo the anastomosis and to perform a gastric resection either a sleeve operation or a subtotal gastrectomy. In the hope of avoiding

this sequel I have for the past 2 years or more been making fewer gastro-enterostomies. Instead, I have been removing the anterior half of the pyloric sphincter when feasible. This can be ideally done only if the ulcer is distant enough from the pyloric ring to make possible a complete dissection, but if the peri-ulcerous exudate abuts the pylorus the muscle cannot then be completely removed.

The complete operation entails removal of the anterior muscular wall of the upper duodenum to a distance of a little less than one fourth of an inch from the pylorus as well as that of the muscular wall of the stomach to a distance of one half to three quarters of an inch proximal to the pylorus. In the small ulcer favorably located I have simply removed the anterior half of the pyloric sphincter. In the comparatively large ulcer in which the peri-ulcerous exudate is not too extensive I excise the ulcer including the peri-ulcerous exudate in addition to removing the muscle, terminating the operation by a gastroduodenostomy. I have done this in bleeding ulcer and in a few cases of acute perforated ulcer. The greater number of excisions of the anterior half of the muscle that I have made, however, have been for pylorospasm due either to gall stone disease or to hyperchlorhydria. The results have been satisfactory. The rationale of this operation is that it provides for better intermixture of the gastric and duodenal contents. This does away with a gastro-enterostomy, which is an advantage, especially as it does not interfere with making a subsequent gastro-enterostomy should the occasion arise.

PSEUDOMUCINOUS CYSTADENOMA

ANALYSIS OF THIRTY CASES IN WHICH THE CYSTS WERE NOT RUPTURED BEFORE OPERATION¹

JAMES C. MASSEY, M.D. ROCHESTER, MINNESOTA

Clinic of Surgery The Mayo Clinic

AND

ROBERT A. HAMRICK, M.D. ROCHESTER, MINNESOTA

Fellow in Surgery The Mayo Foundation

OVARIAN pseudomucinous cystadenomata comprise a large proportion of the ovarian cysts with which the surgeon has to deal. According to the classification as given by MacCarty and Sistrunk the cystadenomata include the ovarian cysts which are lined by columnar or cuboidal epithelium and which contain highly albuminous material. Those which contain serous material are unilocular whereas those which contain soft gelatinous material or highly mucinous fluid that is, the pseudomucinous cysts are multilocular and have thin walls. The gelatinous material may show a mixture of yellow red gray or green depending on the degree of hemorrhage and on the amount of fatty material of cellular detritus or of cholesterol which is contained within the cyst. The epithelial lining may be hyperplastic and may be thrown into folds or papillae which have connective tissue pedicles and which are covered with epithelium continuous with that lining the cyst. The papillary growths may be intracystic or extracystic. When seen under the microscope the cells of the epithelial lining of the cysts may exemplify all stages of the process of secretion. Hertzler differentiated two main structural types of pseudomucinous ovarian cysts the papillary and the glandular and stated that the papillary type is more frequently bilateral.

The course of pseudomucinous tumors is slow. They may produce pseudomyxoma peritonei following spontaneous rupture of the cyst or following accidental rupture at the time of operation. As a result of such rupture and of the consequent spilling of the cystic contents into the peritoneal cavity epithelial cells may become implanted on the peritoneum and may continue to secrete. These tumors frequently are unilateral and pedunculated and grow to large dimensions. Ewing gave the occurrence of pseudomucinous cystadenoma as bilateral in 17.7 per cent of cases whereas Lehmann estimated that 50 per cent of women with a pseudomucinous cystadenoma in one ovary will have a similar tumor in opposite ovary. The tumors consist mainly of pseudomucinous

Wilson found 144 ovarian pseudomucinous cystadenomata in a series of 331 cases of ovarian

tumor in which he operated. Taylor stated that the frequency of pseudomucinous tumors is variously reckoned as from 30.6 per cent (Stuckler and Bravdes) to 53.6 per cent (Lippeot) and even to two-thirds (Pfannenstiel) of all ovarian new growths of these only 6.7 per cent are said to be malignant. This same author carefully reviewed 139 cases of ovarian tumor in which he had operated. He found 6 cases of benign papillary pseudomucinous cystadenoma and 5 cases of mucous carcinoma graded 1. Probably 2 to 5 per cent of pseudomucinous cystadenomata as reckoned by different authors (14-15), give rise to the condition of pseudomyxoma peritonei.

Different ideas have been expressed as to the etiology of pseudomucinous ovarian cysts. MacCarty concluded from his histological studies of ovarian cysts that the pseudomucinous cysts develop by hyperplasia of the lining epithelium from simple cysts or from the stratum germinativum of the ovary. He found a small ovarian cyst with a lining which contained the many layered epithelium of the graafian follicle and simple cyst the columnar epithelium of the cystadenoma and the papilloma of the papillary cystadenoma. Goodall expressed the belief that pseudomucinous cysts not only are ovulogenic but that they also take origin from the germinal epithelium. Taylor in a recent article expressed the opinion that pseudomucinous cysts may perhaps be similar in ultimate origin to the serous tumors of the ovary but that there are elements in their etiology and pathology which justify their being considered as constituting an entity. He suggested that they may be of teratomatous origin. Mueller also expressed the belief that pseudomucinous cystadenomata are of teratomatous origin.

Usually when the ovarian cysts are removed at operation with an intact capsule the prognosis for cure is excellent. Occasionally there is recurrence even when the capsule is kept intact some times after many years. Olshausen reported a recurrence under such circumstances 17 years after the removal of the ovarian tumor and Lewis reported one 2 years after primary operation. Mayfield in a detailed analysis of 100 cases of

papillary cystadenoma, found 6 cases in which recurrence took place and in which the capsules of the cysts were said to have been intact at the time of operation. The presence of malignant tissue in the primary cystadenoma may be a significant factor in such recurrences.

ANALYSIS OF CASES

The histories of 30 unselected cases in which pseudomucinous cystadenomata of the ovary were surgically removed at The Mayo Clinic within the last 6 years were reviewed. The cysts were unruptured before operation. This number was chosen so that a comparison could be made with a study, given in another paper (11) of 30 cases of ruptured pseudomucinous cystadenoma which had produced pseudomyoma peritonæi. A questionnaire was sent to the 30 patients regarding their health at the time when they received the questionnaire. Replies were obtained from all but 4. The material was treated on a basis of percentage because it was thought that by this means the relative values could be more clearly brought out.

The average age of the patients was 48.4 years. The youngest patient was aged 24 years and the oldest, 71 years. The greatest number, or 11, were in the sixth decade of life; 7 were in the fourth, 6 in the fifth, and 4 in the seventh decades. In 8 of the cases the tumors were malignant as determined by microscopic examination. The average age of the patients with benign conditions was 46 years and the average of those with malignant conditions, 55 years. Seventy-three per cent of all the patients were aged more than 40 years. Sixty-three and six tenths per cent of the patients with benign conditions and 87.5 per cent of those with malignant conditions were beyond the age of 40 years. In 2 cases there was a family history of malignancy, but in neither of these cases was the cystadenoma malignant. Twenty-five of the patients had been married and 24 of them had had children. Twelve were past the menopause and 6 of these had had recent recurrences of uterine bleeding. In 72.3 per cent of 18 cases in which the menstrual history was given definitely, menstruation was normal and in 27.7 per cent there was a history of some irregularity previous to the menopause.

The symptoms in most cases were of gradual onset and included enlargement of the abdomen, increase in intra-abdominal pressure, a sensation of bearing down, urinary frequency, and dysuria. The complaint of increase in size of the abdomen was noted in 16 (53.3 per cent) of the cases. Abdominal pain, mostly in the lower quadrants, was

Fig 1 Pseudomucinous cystadenoma showing typical honeycomb appearance

complained of by 13 (43.3 per cent) of the patients, in 3 patients the pain was acute.

The duration of symptoms at the time the patients presented themselves at the clinic was given fairly definitely in 23 cases and averaged 20.2 months. Sixteen of these patients had benign cystadenomata and the average duration of symptoms was more than 2 years (25.8 months). In 7 patients who had ovarian tumors that on microscopic examination were found to be malignant the average duration of symptoms was only 7.7 months.

General examination revealed pelvic or pelvic and abdominal tumors which presented cystic characteristics in most instances. One of these tumors reached from the pubis to the xiphoid process of the sternum. Marked anemia was not present in any of the cases, the reading for hemoglobin usually was between 60 and 70 per cent (Dare).

At operation, either one or both ovaries were removed. In several cases the uterus, tubes, or appendix with associated fibromyomata or inflammatory disease and the affected organs were removed. In one case cholecystectomy for cholelithiasis was performed a few days after laparotomy. In 7 cases tenacious adhesions caused the cyst to be adherent to the surrounding structures. In 5 cases there was marked gross evidence of old pelvic inflammatory disease. In 3 other cases notable quantities of straw-colored, ascitic fluid were present; the quantity amounted to several liters in one case. The pseudomucinous cysts varied in size from that of a mass 6 millimeters in diameter to that of a mass larger than a normal pregnant uterus. Most of them were from 15 to 30 centimeters in diameter. In several of the cases in which the cysts were larger, marked thickening and injection of the parietal and

Fig 2 Lining of pseudomucinous cystadenoma showing columnar type of lining epithelium

visceral peritoneum were to be seen. The ovarian pedicle was long in several cases and it was definitely twisted in two. In 4 cases the pseudomucinous cystadenoma was unavoidably ruptured in the separation of adhesions and removal of the cyst (Figs 1 and 2). In 2 of these cases cysts were microscopically malignant. In the cases in which the cysts were ruptured the spilled cystic content was removed as cleanly as possible and the region was thoroughly washed with physiologic solution of sodium chloride. In 6 cases the uterus contained single or multiple fibromyomata. In one case of malignant cystadenoma, there was a metastatic carcinomatous nodule in the body of the uterus. The patient in this case was 57 years old; she had had a foul bloody, vaginal discharge for 7 months previous to operation (Fig 3).

The right and the left ovaries were affected in about equal proportion in cases in which involvement was unilateral. The condition of both ovaries was definitely known in 25 cases. Involvement with pseudomucinous cystadenoma was bilateral in 22, per cent of the cases in which the process was found to be benign on microscopic examination, and in 18 per cent of those in which it was found to be malignant. This gave bilateral involvement in 24 per cent of the cases.

In 26 (73.3 per cent) of the 30 cases the pseudomucinous cystadenoma was found to be benign on microscopic examination and in 8 (26.7 per cent), malignant. In the group of patients in whom the process was benign 6 had one normal or atrophic ovary. In these patients the other ovary contained a pseudomucinous cyst in 6 cases, a corpus luteum cyst in 2 cases and a simple cyst in 4 cases. Chocolate colored material

was in one of these cysts. In another case the simple cyst was associated with chronic oophoritis. In 1 case, there was papillary pseudomucinous cystadenoma in one ovary, and the other ovary was the site of chronic oophoritis associated with the presence of fibrous papillomata covered with epithelium.

In the group of patients who harbored a malignant process in one ovary, 2 had dermoid cysts in the other ovary, and in 2 the other ovary was senile or atrophic. In one woman who had a papillary carcinomatous pseudomucinous cystadenoma in one ovary there was chronic cystic oophoritis in the other. In 1 case one of the ovaries was the site of malignant papillomatous pseudomucinous cystadenoma and in the other ovary a pseudomucinous cyst but a malignant condition was not found.

Papillomata were seen on gross examination in 6 (27. per cent) of the benign pseudomucinous cystadenomata and in all of the malignant pseudomucinous cystadenomata. Broders is of the opinion that all growths which on microscopic examination are found to be papillary fibromyomata covered with layers of columnar epithelium are malignant. Unfortunately in only 2 of the cases in which a benign papillomatous condition involved one ovary was the condition of the other ovary definitely known. In both of these cases bilateral pseudomucinous tumors were present.

There were no postoperative deaths in hospital in the 30 cases. One of the patients with a benign condition had received roentgen ray treatment pre-operatively before coming to the clinic. Another woman, aged 71 years who had a bilateral papillary pseudomucinous cystadenoma was advised to have roentgen ray and radium treatment postoperatively. Five of the patients with malignant pseudomucinous cystadenomata had roentgen ray and radium treatment postoperatively.

Recent reports have been received concerning the health of 18 of the 27 patients who had benign conditions and concerning all 8 of those who had malignant conditions. The interval since operation in the group with benign conditions varied from 5 months to 6 years and 15 of the 18 patients were in excellent health and had no reason to believe that the pathological condition had recurred. In 3 cases however the state of health was questionable. One woman aged 56 years, who had undergone right oophorectomy for pseudomucinous cystadenoma 5 years and 4 months previous to the time when she answered our inquiry had gained 90 pounds in weight. She was not sure whether or not there was recurrence of

the growth. Another patient, aged 36 years, who 4 years and 7 months before she answered the questionnaire had submitted to bilateral partial oophorectomy for papillary pseudomucinous cystadenoma of one ovary and chronic oophoritis with papillomata of the other ovary, wrote that she had fluid in the abdomen. This probably denotes recurrence of the papillary tumor. A third patient, aged 40 years, who 3 years and 6 months before she wrote had undergone right oophorectomy for papillary pseudomucinous cystadenoma gave indefinite replies to the questionnaire. She affirmed that her old symptoms had returned and that she wished another operation.

The outcome in the 8 cases in which malignant conditions were present has not been so fortunate. The intervals since operation in this group have varied from 2 to 5 years. Two of the patients are dead. One, aged 59 years, died 2 years and 4 months after operation. The other, aged 61 years, died 3 years and 7 months after operation apparently from recurrence of the disease, she underwent left salpingo-oophorectomy for a papillary carcinomatous cystadenoma in the ovary and had not received roentgen ray and radium treatment after operation.

Five of the other women are in excellent health and have no reason to believe that the pathological condition has recurred. One patient aged 57 years, who was operated on 4 years before she answered our inquiry wrote that she is confined to bed part of the time but that there is no noticeable enlargement of the abdomen. She submitted to panhysterectomy for carcinomatous papillary pseudomucinous cystadenoma of the right ovary, 7 centimeters in diameter, within which was a solid area of carcinoma 2 centimeters in diameter. A small quantity of the content of the cyst was spilled when the cyst was removed from the abdomen. The left ovary was normal. Also this patient harbored within the body of the uterus near the internal os a unique annular papillary carcinoma which was thought to have been caused by extension of the ovarian malignant growth.

COMMENT

In comparing the results of this study with those of the 30 cases of pseudomyxoma peritonaei of ovarian origin it is seen that 50 per cent of the patients with pseudomyxoma peritonaei had bilateral pseudomucinous cystadenoma of the ovaries, whereas the involvement was bilateral in only 24 per cent of the pre-ent series, in which the cysts were not ruptured. Also malignant conditions were present in only 20.7 per cent of the cases in which the cysts were not ruptured as

Fig. 3. Malignant pseudomucinous cystadenoma.

against 43.3 per cent of the cases in which the cysts were ruptured and in which pseudomyxoma peritonaei developed. Odd as it may seem the average duration of symptoms before the patients came to the clinic was 20.2 months in the present series whereas in the series in which cysts had become ruptured the duration of symptoms usually was less than a year. This may be explained partly by the greater proportion of malignant cysts in the patients whose cysts ruptured and in whom pseudomyxoma peritonaei subsequently developed. However, when a malignant condition is present in these cases it is usually of a low grade of malignancy (grade 1 or 2 according to Broders' classification). The average ages of the patients in the two series were approximately the same, namely, 48.7 and 40.9 years respectively.

The prognosis is usually good when the pseudomucinous cyst is removed before rupture, but even under this favorable condition recurrence can take place. One of the patients who had a benign, papillomatous cystadenoma leads one to surmise, from her answer to the questionnaire, that she has a recurrence. In 2 other cases, recurrence seems possible. Two of the women who had malignant conditions apparently have had definite recurrence. One of these patients has died.

The treatment of patients with pseudomucinous cystadenoma is surgical. The use of roentgen ray and radium after operation is advisable in those cases in which evidence of a malignant condition is found by microscopic examination. After menopause the removal of both ovaries is worth while even though only one of them appears to be involved with pseudomucinous cystadenoma. Bilateral removal is more urgent when

papillomata are seen grossly or when a malignant condition is found microscopically. If there has been postmenopausal uterine bleeding the uterus also should be removed. In cases in which operations for bilateral pseudomucinous cystadenoma are performed before menopause the attempt to save a portion of one ovary that may appear not to be diseased is of questionable benefit. One of the patients in the group with benign conditions and who possibly had a recurrence was treated in this manner. When it is necessary to save one ovary the surgeon should give due consideration to the type of growth in the affected ovary, namely, as to whether a malignant condition or gross papillomata are present. When a pseudomucinous cystadenoma is unavoidably ruptured at the time of its removal, thereby soiling the pelvis with some of the cystic content, the spilled material should be cleanly removed as far as possible and the pelvis thoroughly washed with physiologic solution of sodium chloride. Covering of the raw surfaces with peritoneum is an important measure.

SUMMARY

Thirty cases of pseudomucinous cystadenoma of the ovary in which the cysts were not ruptured previous to operation are analyzed. The largest number of patients was in the sixth decade of life. The average age was 48.7 years. Seventy-three per cent were aged more than 40 years.

Twenty-two of the patients had tumors that were found to be benign on microscopic examination. Eight had evidence of a malignant condition in the pseudomucinous cystadenoma as revealed by microscopic examination. The average age of the patients who had benign conditions was 46 years and the average age of those who had malignant conditions was 55 years. Sixty-three and six tenths per cent of the patients with benign conditions and 87.5 per cent of those with malignant conditions were aged more than 40 years.

Swelling of the abdomen and pain were the most common symptoms. They were usually of gradual onset. The average duration of symptoms before the patients came to the clinic among those with benign conditions was 25.8 months, whereas among those with malignant conditions it was only 7.7 months.

The right or the left ovary was involved singly in about equal proportion. Bilateral involvement was present in 22.7 per cent of those cases in which microscopic examination revealed the condition to be benign and in 8 per cent of those in

which the condition was similarly disclosed as malignant.

Papillomata were visible to gross inspection in all of the malignant cysts. There is a greater tendency for bilateral involvement if papillomata are present. There was no operative mortality in the group.

The prognosis usually is good but recurrence may take place even though the cyst is not ruptured at the time of its removal. The removal of both ovaries is indicated if the women are past the menopause and especially if a malignant condition has been noted at microscopic examination or if gross papillomata are present. The uterus should be removed if there has been postmenopausal bleeding. The use of roentgen ray and radium after operation is advisable in patients in whom evidence of a malignant condition in the cystadenoma has been found on microscopic examination. If a malignant condition is found it usually is of grade 1 or 2 according to Broders' classification.

CONGENITAL DISLOCATION OF THE HIP

DIAGNOSIS AND A NEW METHOD OF TREATMENT IN INFANCY¹

CHARLES H. JAEGER, M.D., NEW YORK

Assistant Professor of Orthopedic Surgery, Columbia University; Consulting Orthopedic Surgeon, St. John's Guild, St. Luke's Hospital, Staten Island; Staten Island Hospital; St. Vincent's Hospital, Staten Island; Attending Orthopedic Surgeon, Lenox Hill Hospital.

THE subject of congenital dislocation of the hip is one of extreme importance, first on account of the great deformity and disability which are the fate in untreated cases, second, the low percentage of cures and the unsatisfactory results of the so called conservative treatment. By conservative treatment I mean the attempted reduction of the dislocated head under an anæsthetic and the application of a plaster of Paris cast. According to present practice, conservative treatment is started late, rarely before the third year of life. The poor results are due to the malformations of the head, the neck, and the acetabulum during the period of rapid growth in early childhood, to the constriction of the capsule which often makes it impossible to pass the head through, while making the manipulative reduction, and to the damage to the bony structures which may occur during the operative manipulation.

Galloway states that in the hip joints he has opened, it was clearly a physical impossibility to pass the head through in at least 95 per cent of the cases.

In opening a symposium on congenital hip dislocation at the annual meeting of the American Orthopedic Association held in Washington in May, 1928, Allison says: 'In the last 10 years a recognition of the possible damage done to the growing upper femoral epiphysis by manipulation has been slowly established. This fact is of great importance. It is realized also that the growing upper end of the femur may be seriously damaged by the force applied in attempts at the time of the manipulative reduction.'

Farrell says: 'I am going to agree with Dr. Allison that the results in congenital hips throughout the country are far from satisfactory and that the percentage of cures is very low, much too low for a condition that is as common as congenital hip.'

Gill says: 'The obvious reason for early reduction is that growth and development so change the upper end of the femur (I would also add the acetabulum) that reduction becomes increasingly difficult. The constant trauma of function in the unreduced hip also produces marked changes in the growing epiphysis.'

To all these early pathological changes must be added those that come on later in life. Osteochondritic and severe arthritic changes (Kreuz, Scholz, Calot). A case has been reported in which a perfect anatomical cure had been achieved, but 7 years later an X-ray examination revealed the total absorption of the femoral head. These poor results have started such a wave of operative procedures that some men will treat their cases only by open operation.

In this relation I will again quote Farrell: 'Personally I am rapidly coming to the conclusion that open operation is much preferable to manipulation unless the reduction can be done with very little trauma. Allison says: "One fact stands out clearly in a discussion of this question, namely, it will be by open operation, by early operation, and by gentle operation that the results in congenital dislocation will be improved."

Farrell, von Lackum, and Smith state: 'We believe that personally every congenital dislocation of the hip within a reasonable age limit can be reduced by open operation, and in this way improved. The results in this series of cases compel us to believe that a much larger percentage should be reduced by open operation than was so treated.'

Mr. Harry Platt, of Manchester, England, says: 'At the present time there is a growing dissatisfaction with the anatomical results of closed reduction, and we appear to be on the eve of a revival of the open operation in young children.'

Stephens reviewed the end result of the treatment of congenital hip dislocation. The cases embodied in the report were all treated as indoor patients at the Hospital for Ruptured and Crippled during a period of 20 years. He says:

'From this we might infer that the percentage of cures might be even less than fifteen. And further, if the percentage of good results is not markedly increased, then we might conclude that our methods of treatment have been unsatisfactory and should be changed.'

As a last authority I will quote Dr. David Silver discussing Dr. Allison's paper: 'Hope of future improvement. Dr. Allison said if I understand him correctly, it is to be looked for in open

Fig 1 Roentgenograms of Case 1 before treatment at the end of treatment and 4 years later. Note the late ossification of the dislocated head.

operation. This statement appears to me to be absolutely wrong. Hope for future improvement lies in early recognition. Since structural adaptation becomes increasingly greater as the child grows and hence the degree of function to be looked for, it becomes correspondingly less what ever the method of treatment used. Would it not be wiser for us to devote less time to the discussion of the relative methods of the closed and open methods, and concentrate our energies on efforts to secure diagnosis as early as possible?

I wish to tell how to make the diagnosis in infancy and having made it, how to apply a treatment that will avoid all deformities, complications, and the long and painful treatments of my own treatment, which can be applied without discomfort to infants as young as 3 or 4 months of age, will bring about a physiological restoration of the affected joint within as short a time as 3 months. By means of this treatment anesthesia, manipulation, open operation and plaster-of-Paris casts are all avoided.

I will not discuss the theories advanced as to the causes of congenital dislocation of the hip. My own conviction is that there is sufficient displacement in very early life to cause pressure of the femoral head against the upper rim of the acetabulum, which pressure prevents the growth of the upper rim. Removal of this pressure is promptly followed by development of the upper rim of the acetabulum.

In the first months of life growth and development are very active. A familiar phenomenon of birth fractures is that callus is thrown out quickly and in amazing quantity. I will demonstrate in the X-ray pictures of my cured cases how bone formation begins soon after removal of the resistance which retards it.

DIAGNOSIS

Several points may be mentioned in the diagnosis of unilateral cases.

1. Habitual outward rotation of the affected leg.
2. Shortening of the affected leg. This is often seen by inspection and may be ascertained by comparative measurement of both legs from the anterior superior spine to the inner malleolus. Another test for shortening is this: Lay the child on a hard smooth table and (a) flex both hip joints to 90 degrees and with the knees flexed the knee of the affected leg will then be at a lower level.
- (b) With hips flexed as above fully extend the knees. In this position the shortening which was apparent with the legs extended becomes more marked. There is in addition tension of the tubero-crural muscles and an absence of resistance backward.
3. Fullness over the trochanter causing an apparent widening of the pelvis on that side.
4. Abnormal mobility of the hip especially in rotation (a very important sign).
5. Very noticeable difference in the inguinal folds. On the affected side the fold is shorter, the angle is changed (being more vertical) and the inferior inner end is higher than on the normal side.
6. Exactly the same change in the gluteal folds as in the inguinal folds.
7. The diagnosis is verified by the roentgenogram.

In the bilateral cases we find

1. The same signs as in unilateral cases except that the inguinal and gluteal folds offer no help.
- Habitual outward rotation of both legs.
3. The pelvis is comparatively wide.

Fig 2 Roentgenograms of Case 2 taken before treatment 5 weeks after brace was applied and after 4 months of treatment. Note the late ossification of the dislocated head.

4. No lengthening of the measurements from the anterior superior spine to the external malleolus as in normal hips when both legs are forcefully abducted but instead an equal distance or even a shorter distance than if the legs were lying parallel.

5. A sort of crackling or click, which occurs spontaneously when the legs are moved especially when they are abducted and then extended. This sign, which has been described by Hoffa, is believed to be due to the rubbing of the femur against the posterior margin of the acetabulum within a loose capsule.

6. The diagnosis is confirmed by the X-ray plate.

TREATMENT

For years I have had in mind a new form of treatment based on an entirely new principle. This treatment should be begun in earliest infancy. Without force or violence without an anesthetic, it is my aim gradually to replace the dislocated head in the socket by means of a pressure pad over the trochanter while the leg is held in marked abduction by means of a long hip splint. I hope thus (1) to prevent the deformities that inevitably develop (2) to make use of the very rapid growth in infancy to aid in the formation of a socket and (3) to reduce the dislocation without traumatism, thus avoiding the consequences of rough manipulation.

I am indebted to Dr. F. Elmer Johnson of New York City for the opportunity of treating my first case, and I wish to compliment him for having made the diagnosis of a hip dislocation in a child $3\frac{1}{2}$ months of age. A brief history of the cases follows:

¹ This case was reported at the treatment described in a paper read at the meeting of the orthopedic section of the New York Academy of Medicine, May 15, 1915.

CASE 1. J. R., a female child, aged $3\frac{1}{4}$ months, was the first child of a first pregnancy which terminated in a full term normal labor. There is no history of congenital dislocation of the hip in the family. The patient weighed $5\frac{1}{4}$ pounds at birth. Dr. Johnson noticed preternatural rotation of the right leg and a centimeter shortening. He made the diagnosis of congenital dislocation. The child was in such delicate health and its condition so poor that no X-ray picture was made until 2 months later. This picture made at the Babies Hospital confirmed the diagnosis. On May 7, 1924, the patient was seen by the late Dr. Frauenthal, who advised reduction and plaster-of-Paris cast for the hip. The baby, still very delicate in health, was not referred to me until the age of 7 months, when it was considered treatment might be begun. I suggested my plan to the parents. Further advice was sought and Dr. Royal Whitman examined the child. He suggested waiting 2 or more years until the child was of an age suitable for reduction and plaster cast. When the parents told him of my plan for immediate brace treatment, he advised the parents to let me try it.

I began the treatment in this manner. A long hip splint of rustless steel was designed. This splint consisted of two circular bands to fix the pelvis and chest, two lateral bars to support the leg to the lower end of the bars was attached a footplate with a leather anklet. This maintained the midposition of the leg, i.e., it was in neither outward nor inward rotation. The long outer bar was bent to fit the leg at 45 degrees abduction. There was no provision for traction or extension because I deem it entirely unnecessary to subject a child to the inconvenience and irritation of the traction straps, and besides nothing is gained by their use.

In order to accomplish the gradual reduction of the dislocated head, I depend upon an adjustable pad controlled by a wing screw about 1.5 inches long placed directly over the trochanter. The pad pressing downward and inward gradually and easily directs the head into the acetabulum.

Fig. 3 The asymmetry of the inguinal and gluteal fold of right side is shown

The infant wore the brace continuously and this necessitated the substitution of sponge baths for tub baths. Notwithstanding this handicap, and that this period included the warmest months of the year the child developed rapidly and was in excellent physical condition. This shows beyond doubt that my treatment does not in any way retard the normal development of the child.

In this case I applied pressure very gradually over a period of months. I considered the comfort of the patient of greater importance than speedy reduction. The brace was applied on May 4, 1924. It was worn until February, 1925, a period of 8 months. On account of the rapid growth of the child, it was necessary on two occasions to remove the brace and substitute a plaster spica for a few days while the brace was being lengthened. The X-ray pictures taken at intervals of 2 weeks showed a progressive approach of the upper end of the femur to the acetabulum and a gradual development of the upper rim of the socket which was definitely apparent 4 weeks after the brace was applied. Toward the end of February the long brace was removed and a short abduction splint without the trochanter pad was applied.

In this my first case I was unnecessarily cautious in applying the pressure to the trochanter. It would have been perfectly feasible to bring the head into the socket within 4 weeks. Further more I left the brace on for several months longer than actually necessary. This child is now walking about without any limp or shortening or any sign that there has ever been anything the matter with her. The X-rays taken 4 years after the conclusion of the treatment show two normal acetabula so completely alike that it is impossible to tell which hip had been dislocated.

CASE 2. L. A. female first and only child. Nothing abnormal was noted until she was 13 months old. After the child had been walking 1 month the mother noticed a limp and she took her to the Hospital for the Ruptured and Crippled. There the diagnosis of congenital hip dislocation was made. Reduction under an anesthetic and a plaster-of-Paris cast were advised. The parents did not agree to this. Within 2 weeks they took the child to a private physician who also advised admission to the hospital, reduction of the dislocation and the application of a plaster-of-Paris cast. After seeing the X-ray plates however he said he would treat the child in his office without an anesthetic and without manipulation. A plaster-of-Paris spica was applied with the leg in slight abduction and kept on for 8 weeks. Three more spicas were applied with the leg in various positions for a period of 6 months. Then a brace was applied. This was a Thomas knee splint with leg attachment. The brace was used for 6 months. During this whole year the child was allowed to walk. At the end of the year's treatment the X-ray plate showed that the head was not in the socket although with traction applied to the leg the head could be brought down to the level of the acetabulum but it was separated a goodly distance from it. The mother was then notified that an operation including bone transplantation should be performed. This procedure was declined.

The child then came under my care when she was 2 years and 7 months old. I found the left hip still dislocated as shown in the X-ray picture (Fig. 2). A brace was ordered and at Christmas in 1925 was satisfactorily fitted and applied. This brace was similar to the one used on my first case. The screw pressure was applied to the trochanter more rapidly than in the first case and within 5 weeks the dislocated head was in the socket and has been there ever since. The patient was not allowed to walk during the entire time of the treatment. The brace was worn a little over 4 months.

I did not permit the child to walk for the following reasons. The frequent X-ray pictures showed that the socket was developing so well without weight bearing that I wished to challenge the theory advanced by Lorenz and others, that functional weight bearing is necessary for deepening the acetabulum. To my mind the main requisite for deepening the acetabulum is the removal of the pressure of the head from the upper rim. The X-ray pictures all show how rapidly this rim develops as soon as the trochanter pad has pushed the head down into what is to become the socket. I also feel that when the head is surrounded by a well developed acetabulum the traumatism of weight bearing will be less and that no damage will come to the head in later years. This damage has been seen with persistent regularity in cases treated by the method now in general use in which a soft cartilaginous head is supposed to pound out a hollow in the harder bony socket.

Case 2 has been very instructive. It shows that the trochanter pressure can be applied without inconvenience strongly enough to bring the head into the socket within 5 weeks. And this was

accomplished in a child 2 years and 7 months old. The development of the upper rim of the acetabulum in Case 2 progressed satisfactorily. You will see in Figure 2 how a curve is beginning to appear in what will be the roof of the socket. All of this shows that while the ideal time for treating these patients is the earliest months of life the method has been found equally effective in an older child.

These two cases had single dislocations. I am anxiously awaiting the opportunity to test the method in cases with both hips dislocated because we know that the prognosis in bilateral dislocations is not as good as in single dislocations. With my method I am confident that the treatment will be equally as successful in bilateral as in unilateral dislocations.

SUMMARY

It should be our duty to emphasize the fact that congenital hip dislocation can be diagnosed in the first 3 months after birth. This is important alike to the family doctor and the pediatrician.

The present method of handling these patients is unsatisfactory. Now, treatment is begun too late, for when treatment is delayed serious bony changes take place thus making reduction and retention difficult.

As to the closed method of treatment, this means of reduction must necessarily damage all the structures making up the hip joint. This damage is progressive and leads to further deformities and to disability in later life.

Regarding the surgical treatment some authorities advocate and use the open operation in every case. Such treatment requires much time—sometimes 9 months to several years—and the

result is uncertain. It requires repeated narcotics, the patient suffers much pain and inconvenience, and the method is not entirely free from danger to life.

The physiological treatment which I have just described is simple, is applied with little inconvenience to the patient, assures normal development of the femur in the acetabulum, furthermore it requires much less time than the other methods—no more than 3 months—and if the treatment is properly carried out, should result in a high percentage of cures.

FOUR RARE RECTAL TUMORS

INTRARECTAL SOLID TERATOMA, FIBROLEIOMYOMA, PARAFFINOMA, AND CHORIOBLASTOMA¹

HIRSH IRVING MD FACS AND HARVEY B STONE BA MD FACS BALTIMORE

From the Department of Surgery, Johns Hopkins Medical School

THE purpose of this paper is to report four cases unrelated except in that they are rectal lesions of rare occurrence and are interesting pathological types.

INTRARECTAL SOLID TERATOMA

Dermoid cysts and tumors are not uncommon and the supposedly related teratomata are scarcely rare, but the particular tumor about to be described must be considered a most exceptional lesion. In an extended search, only three descriptions of similar tumors were found, and references not accessible to a few others were encountered. Whether these latter are actually identical cannot be stated without study of the original articles, not so far available to us.

CASE 1. Mrs M L C white aged 35 years complained of hair growing from anus. She has been forced to cut this off at intervals and this has been going on for the past 8 years. She was very constipated had some discomfort in rectum if she sat for a long time and had pain in lower spine. No mass protruded from the anus and there was very little bleeding. On examination a strand of long fine straight dark brown hair was seen protruding from the anal orifice. The hair on the patient's scalp pubis and perineum was blond. On rectal palpation an ovoid mass firm movable about the size of a large plum could be felt. This mass was fixed by a broad pedicle to the posterior rectal wall about 10 centimeters above the anal margin. With the proctoscope an ovoid white tumor could be seen just above the lowermost rectal valve from which hair was growing. Operation was advised and on April 3 1928 was performed at the Union Memorial Hospital under ether anesthesia. The phincter was widely dilated and the tumor mass exposed. The mass was about 3 centimeters in diameter. It was connected by a pedicle 4 centimeters long to the back of the rectum about the level of the third sacral vertebra. This pedicle passed directly through the rectal wall and was covered with white skin. The red mucous membrane of the rectum formed a sharp contrast to the white skin of the tumor pedicle. The rectal mucosa was divided from the pedicle on all sides and the pedicle was dissected backward behind the rectal wall as far as its attachment to the fibrous tissue in front of the sacrum. A clamp was put across the base at this point the pedicle was divided and the tumor was removed. The base of the pedicle was then transected with a suture above the clamp and tied off. The open cavity thus made in the posterior wall of the rectum was packed with dry gauze which was brought out through the anal orifice. The patient left the table in good condition and made an uneventful recovery. At the end of 3 weeks the wound made in the posterior rectal wall had completely healed and the patient was discharged as cured. She was seen 8 months later and was entirely well.

Gross pathology. U M 2232 C H I 966. The tumor is comma shaped and smooth with small patches of delicate long brown hair growing on the under surface and sides. The head of the comma measures 5 by 3.5 by 4 centimeters while the tail measures 4 by 1.2 centimeters. On section the entire tumor is found to be surrounded by a well defined layer 2 millimeters thick which is radially striated. Beneath this the tissue consists of mottled white bands interspersed with irregular lemon colored areas. Projecting above the surface at about its center is a pearly white hard object 3 by 2 millimeters which looks very much like a tooth or piece of bone.

Microscopic examination. The tumor is surrounded with cornified squamous epithelium. The germinal layer dips deep down into the corium. The main body of the tumor is made up of bundles of smooth muscle and connective tissue but there are also alveoli of fat racemose sweat glands bone nerve fibers and hair follicles.

The tumor removed is well presented in its anatomical relations, its size gross appearance and cut surface by the accompanying sketches which also illustrate the steps of the operative removal (Figures 1 2 3 4 5, and 6). In short this tumor is a teratoid mass of mixed tissues, but unlike an ordinary dermoid is not cystic, and instead of being a cavity lined with skin is a solid mass covered with it. Further, it did not lie before or behind the rectum but swung free in the lumen of the bowel attached by its pedicle to the posterior rectal wall. As has been said dermoids and teratomatous tumors are not especially rare, and one of the regions where they are apt to occur is in the rectal environment behind the bowel near the coccyx or in the rectovaginal septum. Such cysts in rare instances may rupture into the bowel.

Maingot and Saphir report such cases in each the trauma of labor being the cause of the rupture. In Maingot's article the tumor passed per rectum was described as consisting of a mass with four distinct cysts, not communicating and containing caseous material hair unstriped muscle epithelium cartilage and fibrous tissue. A lacinated surface on the anterior rectal wall was thought to be the point of attachment of the tumor. Saphir's patient discharged a mass of hair and sebaceous material per rectum during labor and later a rent was seen in the anterior rectal wall which opened into a cyst cavity lined with a hair growing wall. Saphir refers to several other similar reports in the literature.

Fig 2 Teratoma cut surface

Danzel, Port, and Bensaude and Rachet each report one case very similar to the one herewith recorded. All of the patients were women. Their ages were 16, 25, and 39 years respectively. In each instance hair growing from the anus was the symptom that attracted attention. Danzel operated on his case and removed a tumor 4.5 by 4 by 3.5 centimeters which contained a tooth, much hair, bone, fat, and rudimentary brain tissue. The patient died over 3 months later from a slow perforation through the anterior rectal wall where the tumor had been attached.

Port's patient finally extruded the tumor per anum, and its pedicle was then ligated and the mass removed. It was a mass 2.5 by 2 by 1.5 inches covered with ordinary skin growing hair and containing fat, bone, a tooth, and muscle fibers.

Bensaude and Rachet did not remove the mass but saw it through a proctoscope and described it as a mass the size of a cherry, of a pinkish white color growing hair from its surface and attached to the anterior rectal wall 13 centimeters above anus. These writers refer to a

thesis by Salmonoff (Berlin 1902) who reports eight dermoid cysts above the anus, two of which had produced hair protruding through the anus. Neither of these was operated on as the symptoms did not seem to warrant it. They also quote Longuet who in 1893 reported 3 cases, but no details are given.

There are a few comments to be made on this assembly of cases. All are in women and all in the earlier half of life. In all the symptom complained of was hair protruding from the anus. In several there was some difficulty in defecation. No bleeding is reported in any case. Siphur's case of ruptured cyst suggests a possible explanation of the evolution of the form of tumor here considered: a tumor or cyst lying close under the rectal mucosa which ruptured into the lumen would if it continued to grow perhaps protrude into the bowel as a skin covered, hair growing mass. In other words a dermoid or teratomatous cyst which ruptured into the bowel might, by continued growth, turn inside out and its hairy skin lining would then become its covering. As to treatment, although surgical removal may at times seem a formidable problem, no other method offers a satisfactory solution. If the patient suffers little except the annoyance of the protruding hair and the tumor is so situated as to render operation exceptionally difficult or dangerous, good judgment would naturally lead one

Figs 3 4 5 and 6 Teratoma of rectum

to defer interference until it should become more clearly indicated

FIBROLEIOMYOMA OF RECTUM

Fibrous tags about the anus resulting from organized thrombosed hæmorrhoids or enlarged and fibrous skin folds are of course exceedingly common. Polypi in the anal canal and rectal lumen of small or moderate size with a fibrous stroma and epithelial covering are often seen. On the other hand true rectal tumors of distinctly neoplastic character as distinguished from chronic inflammatory or hyperplastic masses of tissue, that consist of smooth muscle or fibrous tissue or a mixture of both are very rare indeed.

Thus Ashton in 1863 quotes only one case a fibrous tumor weighing one half a pound growing from the anal margin. Tuttle says that true fibromata of the rectum are exceedingly rare and refers to two cases in the literature neither of them his own. Ball mentions fibromyoma as being a very rare rectal growth and reports one case. Gant does not remember encountering a typical myoma of the anal region but states that fibromyoma are occasionally met with in the rectum or recto-vaginal septum. Hill reports seeing only one case of myoma. Lynch reports records in the literature of 80 cases of myoma of the entire intestinal tract of which number 10 per cent or 16 cases occurred in the rectum or

Fig. 7 High power photomicrograph of rectal teratoma showing sweat glands and cross section of hair

Fig. 8 High power photomicrograph of rectal teratoma showing root of hair follicle and surface epithelium

anal region. These are all references from text books written by specialists in the field of rectal surgery men of wide personal experience and familiarity with the literature. Hunt in a special study of such cases published in 1921, reports 4 cases of his own, 2 of pure myoma and 2 of fibromyoma. In an extensive review of the literature he could find only 20 cases reported since 1872 that he accepts as myoma or fibromyoma. From his own cases and those collected he summarizes the few following data: 13 patients were women, 10 were men, and in 1 instance the sex was not recorded. The age incidence ran from 21 to 85 years. Malignancy developed in one case. He gives brief abstracts of all the cases from the literature and adds the record of his own 4 cases. Wolfer in an article on leiomyomata of the intestinal tract points out that rectal myomata may protrude into the bowel like polyp or grow outward from it usually behind toward the hollow of the sacrum. He refers to such a case reported by Senn, which weighed 1 pound.

It will be seen from the survey of the subject that we are dealing with a very unusual tumor of the anorectal region. Such tumors need to be borne in mind because of the possibilities they present for mistakes in diagnosis. Our case had been misdiagnosed before coming into our hands and our own recognition of its exact nature awaited the operative and histological findings. As seen by reference to the reported cases the

most common error is to mistake these essentially benign tumors for malignant disease, with the danger of being led into an extensive destructive operation unnecessarily.

The report of our case follows:

CASE 2. Mrs. I. V. C. aged 74 years had complained at intervals for several years of rectal trouble. For the past 2 months this has been more acute. There has been a good deal of pain in the anal region and difficulty in securing bowel movement, feeling of pressure and occasionally

Fig. 9 High power photomicrograph of rectal fibroliomyoma showing bundles of smooth muscle and fibrous tissue

Fig 10 High power photomicrograph of rectal paraffinoma showing intact mucosa, pseudo tubercles with giant cells and rarefied tissue about them. At the bottom there is a small hyaline area interpreted as paraffin.

Fig 11 High power photomicrograph of chondroma showing large polygonal cells arranged in strands with occasional syncytial masses and foam cells.

Gross pathology. Section No 8109. The specimen consists of a hard, oval, encapsulated mass measuring 6 by 4 centimeters. The mucous membrane is ulcerated down to the muscularis. Its base is smooth and clean. Section through the mass shows a thick capsule surrounding it. The tissue is a uniform grayish pink with the fibers arranged in whorls.

Microscopic examination. On examination under the low power, the section has the appearance of a fibromyoma of the uterus. There are strands of hyalinized connective tissue interspersed with whorls of smooth muscle fibers cut at various angles. Large venous sinuses are present and there are occasional smaller arteries with thick hyaline walls.

PARAFFINOMA OF RECTUM

No record of any case like this one has been found in a fairly extensive search of the literature. Paraffinoma, of course, is a lesion of definite etiology, and the history of this patient makes it quite evident that the treatment he must have received for hemorrhoids, consisted of the injection of paraffin into the rectal wall. The history of the patient follows:

CASE 3. Mr R Z D, aged 61 years. Patient used to be troubled with hemorrhoid which protruded but did not bleed much. In May 1926 he had these hemorrhoids treated by an injection method. The patient does not know what the material injected was. Following the injection there persisted some tenderness and swelling. The complaint at the present time is persistent and increasing constipation which has become very pronounced during the last 2 or 3 months. There has been no rectal bleeding, no pain and no definite tenesmus. No nausea, vomiting or abdominal cramps and no loss of weight. There have been no bladder disturbances of any kind. The principal and only complaint is extreme and increasing constipation. On examination nothing was made out in the abdomen. Rectal in section was also negative. Rectal palpation, however, showed an annular constriction just above the anal canal about at the level of the apex of the prostate gland. This constriction was quite hard, fixed with well defined edges and a smooth surface. With the proctoscope the lumen of the bowel was seen to

the passage of some blood or mucus. There has also been some aching in the back and down the legs. Six weeks ago she consulted another physician who found a swelling back of the anus which was taken to be an abscess and this was incised. The wound did not heal properly although no pus was found at the time of incision. The mass still persisted as before. On examination there was found an incision in the posterior midline just behind the anus with curious looking base and punched out edges. The base was firm, rather gelatinous looking with a tendency to bulge upward into the wound. Preliminary diagnosis was possible colloid carcinoma. A few small hemorrhoids were also present.

Operation was advised and on November 19, 1927 was performed at the Church Home and Infirmary, ethylene gas anesthesia being used. The wound already existing was enlarged and a large tumor was found underlying it. This tumor was completely and firmly encapsulated and it shelled out of its capsule very readily with very little bleeding. It formed an ovoid mass 6 centimeters long by 4 centimeters wide. There was a good sized cavity left by its removal which was partially closed by bringing the sphincter and levator muscles together from the two sides with interrupted catgut sutures. The remainder of the wound was packed with iodoform gauze. A naked-eye inspection of the cut surface of the tumor led to a diagnosis of fibroma as is shown in the pathological report which is given below. The wound healed very quickly and very cleanly.

The patient's constipation was greatly improved following operation and the pain in the back and down the legs disappeared. Patient was seen about a year after operation and there was no evidence of recurrence.

be reduced at the level of the stricture to about one half of its normal diameter. The mucous membrane at this point looked normal and no ulcerations were seen. Diagnosis was rectal stricture due to a tumor like mass of annular form not involving the mucous membrane. A preliminary diagnosis of sarcoma of the bowel wall was made but as this was by no means a strongly held opinion it was decided on March 15, 1928 to remove a specimen for microscopic study. The report from this small piece of tissue was tuberculosis of the rectal wall. As the lesion was strictly localized the patient was advised to have an operation done for the removal of the diseased area.

Operation was performed at the Church Home and Infirmary March 17, 1928 ethylene gas anesthesia being used. A circular incision was made at the anal margin and prolonged backward in a straight line toward the coccyx. The coccyx however was not removed. The sphincter muscle was carefully dissected away from lower portion of the bowel and preserved in place without being divided. The bowel including the mass in its wall was then dissected loose from the surrounding structures up as high as the peritoneal cavity which was not opened. The whole rectum was thus mobilized. The bowel was then drawn through the sphincter and the distal portion amputated a margin of about 1 inch being allowed above the area involved in the disease. The proximal stump of the rectum was then sutured into the anal skin as in a Whitehead operation. The patient left the table in good condition. His wound healed quite well although it was several weeks before he regained control of his sphincter muscle. At the present time his control is practically perfect. The microscopic examination of this tissue showed very interesting further development.

Gross pathology. The specimen is that of the lower portion of the rectum extending 7.5 centimeters from the anal margin. When the lumen was opened the mucous membrane appeared intact. Beneath the mucosa extending into the submucosa and muscularis is a hard circular cuff which on section consisted of gray fibrous tissue in which were hard clear transparent gelatinous and yellow fatty areas. Two glands about 2 millimeters in diameter removed from the external surface of the rectum were also present. These showed no abnormality in the gross.

Microscopic pathology. The mucosa over the entire section was intact. Just beneath this the tissue was heavily infiltrated with small round cells and from here down through the muscular coats were structures which at first glance gave the impression of tubercles. The tissue in these places seemed rarefied. The cells are stellate with fine fibrils connecting each with the other. Giant cells are present in large numbers some of them within the pseudo-tubercles and others loose in the muscle with practically no cellular reaction about them. They are characterized by having their nuclei grouped at their centers. Nowhere is there any evidence of caseation and there is usually no round cell reaction about the tubercle like structures. Dr. James Ewing saw the section and makes the following comment: "The section of rectal tissue which you sent me looks like a paraffin tubercle. I think the patient must have had an injection of paraffin which produced this chronic progressive productive inflammation. There are a few hyaline areas which were found after long search which we are willing to call droplets of paraffin."

The point of paramount interest here aside from the unusual employment of paraffin injections in the treatment of hemorrhoids was the

difficulty of diagnosis. It must be remembered that no statement was obtained as to the material that had been used for injections and that a considerable time had elapsed since the injections had been given. The case presented certain features suggesting that the easily felt stricture was a malignant growth. The annular mass was very hard and inelastic and fairly fixed to surrounding structures. On the other hand, it lacked the ulcerated nodular surface that a carcinoma of this size would be expected to present. The smooth intact mucosa over the mass did not suggest a tuberculous process either, and the preliminary diagnosis was sarcoma of the deeper structures of the rectal wall, without invasion of the mucosa. It was because of the unsatisfactory nature of this diagnosis that a biopsy was done before attacking the lesion surgically. The biopsy report of tubercle eliminated the question of malignancy and settled the type of operative procedure in favor of local resection rather than radical excision of the rectum. When the whole specimen was examined it was clear that the tubercle formation was of the foreign body variety and not due to infection with the Koch bacillus.

SACROCOCCYGEAL CHORDOBLASTOMA

Within the past few years the subject of tumors developing from the notochord has received a good deal of attention, as is evidenced by the carefully prepared case reports and reviews of the literature. In this paper we make no attempt to review the literature, as those who are interested may refer to the publications of Albert, Capell, Stewart, Hutton and Young, Ramsey, and others. We wish simply to report a case of this unusual condition.

As is well known these tumors occur at any point along the spine, but are most frequently found at the spheno-occipital synchondroses and more rarely at the sacrococcygeal junction. They develop from cell rests, remnants of the chordo dorsalis which are found in about 2 per cent of human embryos in the intervertebral discs.

The first case of chordoma was described by Lushka (1857). In this year Virchow also described these tumors under the name of "Echondrosis Physaliphora" believing them to be cartilage which had undergone hydropic change. Mueller, however, first described the true nature of these growths. He called attention to the notochordal remnants in the intervertebral discs and suggested that these tumors developed from them. It remained for Ribbert (1894) to give the name "chordoma" to these growths and offer experimental proof of their origin.

In the case about to be reported, the cause of the patient's illness was not diagnosed for nearly 9 years, during which time he was treated for fistula in ano, perirectal abscess and recurrence of these conditions. The true nature of the condition was discovered when the tract was laid wide open and pieces of the gelatinous tissue which lined it were subjected to microscopic examination.

CASE 4. Mr A. L. S. aged 27 years was first seen by one of us January 17, 1928. His complaint was rectal trouble which had begun about 9 years ago. He first noticed a swelling near the anus which later was operated on February 9, 1925 and was considered a perirectal abscess. Several months later he was operated on for condylomatous tags. He continued to have discharging sinuses and a few days before being seen by us another abscess opened externally on the right buttock. This was still draining at the time of the examination. He complained also of frequent inclination to defecate without being able to empty the bowel completely and had the sensation as if there were a lump near the anal margin. There had been no discharge of blood from the rectum but mucus and pus were frequently passed. He had lost about 18 pounds in weight during his entire illness.

The patient's general physical examination was quite normal except for a moderate anemia and a leucocytosis of 12,500. X-ray examination of the chest and long bones and pelvis showed no metastases. On rectal examination the sphincter control was found somewhat weak. A discharging sinus was found in the right buttock. A probe passed inward toward the anal canal but did not enter it. There were several granular looking skin tags about the anus. On digital examination there was felt a great deal of scarring about the lower rectal wall with bands and irregular nodules. Diagnosis of some unusual type of fistula was made possibly due to tumor.

Operation: Church Home and Infirmary, January 19, 1928. ethylene gas anaesthesia. The external opening on the right buttock was injected with a solution of methylene blue. This immediately came out of the anal canal in large quantities showing a complete fistula. The tract was divided on a grooved director and found to lead upward into the rectum to a point about 1.5 centimeters above the skin margin in the posterior midline. There were two or three lateral sinuses branching off from the main tract which burrowed upward a long distance into the pelvic fat. The entire fistula was lined with thick coarse granulation tissue and gelatinous material. It was laid wide open throughout its entire extent and thoroughly curetted. In order to do this it was necessary to divide part of the sphincter muscle in the posterior midline. Bleeding points were tied and the wound packed with five strips of iodoform gauze. The patient left the table in good condition. The fistula was an exceptionally deep and tortuous one and will probably take a long time to heal.

Postoperative history. For about 2 weeks following the operation the patient experienced considerable pain. The wound discharged copiously for about the same period. Gradually the pain and discharge diminished, the size of the wound reduced and the patient's general condition improved. He was given radium treatment to supplement

the obviously incomplete surgical removal of the disease. His sphincter control became better and he was discharged from the hospital in fairly satisfactory condition. When last heard from over a year after operation his wound had completely healed, he had gained weight, was working as usual and complained of nothing except some weakness of sphincter control.

Gross pathology. The tissue consists of small pieces of tissue varying in size from 3 centimeters to several scrapings. It showed small and large lobulated gelatinous translucent areas interspersed with bands of opaque connective tissue. Several hemorrhagic areas of various sizes are present in different regions.

Microscopic examination. The thick fibrous capsule so uniformly described about these tumors is absent because the tissue received was from curettings rather than an enucleation of the growth. There are however strands of fibrous tissue throughout the growth tending to divide it into pseudo alveoli. The cells are large oval to polygonal in shape with deep staining round and oval nuclei. Some of the syncytial masses contain several nuclei. The cytoplasm is pale staining and granular. Some of the cells are ballooned with masses of blue staining mucin, the so called physaliphore cells and others are vacuolated breaking up to form the characteristic foam cells. The cells are arranged in solid masses or in irregular strands, the appearance of liver tissue. The interstitial tissue being filled with vacuoles or mucin. Throughout the tumor and especially along the strands of connective tissue is a marked round cell infiltration.

Photomicrographs of tissue from each of these four rare tumors are presented.

THE USE OF INTRAVENOUS GLUCOSE IN DIABETIC PATIENTS

HENRY J. JOHN, M.D., CLEVELAND, OHIO
Cleveland Clinic

It is well known that in surgical cases the use of intravenous glucose following operation, and glucose or carbohydrate in some form the night preceding the operation, is a very valuable measure. This applies especially to cases in which the patient starts vomiting after the operation and can hold nothing on his stomach, not even water and through incessant vomiting, becomes partly dehydrated, developing a degree of alkalosis which in turn aggravates the vomiting, thus establishing a vicious circle. As the result of the administration of intravenous glucose solution, this vicious circle is broken, and the patient has an infinitely better chance of recovery.

While in the case of non-diabetic patients there is no doubt as to the value of the intravenous administration of glucose, in the case of diabetic patients, the following questions arise: "Can we safely give glucose to diabetic patients? Will we get the same result as in the non-diabetic cases?"

While a normal individual apparently has available an unlimited supply of endogenous

insulin, so that no matter how much carbohydrate he is given he can take care of it, the diabetic patient, on the other hand, has not enough endogenous insulin available. If the use of glucose in the case of a non-diabetic individual is a good physiological measure, it should be equally good in the case of a diabetic individual if in some way we can assist the patient to take care of the added glucose in the blood stream. In the pre-insulin era this was impossible, for any addition of glucose to the already increased sugar in the blood would have been an unsafe procedure. However, now that insulin is available and may be used as frequently as the need for it is indicated, the problem has taken on an entirely different aspect. We can supply the needed insulin to the body from without, and thus the diabetic individual may have the advantage of this, and the mortality of operations on diabetic patients may be lowered.

The method which I have used here in the Clinic has been the intravenous administration of 250 cubic centimeters of a 10 per cent solution of

Of a total of 54 cases, 44, or 81.5 per cent, showed a fall of blood sugar 3 or 3.7 per cent, showed no change, and 8, or 14.9 per cent, showed a rise of 11.5 per cent. The average fall of blood sugar for 44 cases, or 81.5 per cent, was 9.2 mgm. per hour; the average rise of blood sugar for 8 cases, 14.6 per cent, was 19.7 mgm. per hour.

Chart 7

Chart 8

Fig. 1 Withdrawal of specimen of blood before administration of glucose

glucose to which from 20 to 50 units of insulin has been added, the amount of insulin depending on the severity of the diabetes and the height of blood sugar at the time. This procedure can be repeated two or even three times a day, as the need for it is indicated.

When glucose is given intravenously in the case of a diabetic patient, the glucose apparatus should be filled to the tip with the warm solution. Cooling should be allowed for during the process, so that the solution in the bottle should be quite warm. A specimen of blood should then be secured through a venepuncture for blood sugar determination (Fig. 1). While the needle is still in the vein, the end of the needle next to the syringe should be grasped with a hemostat so as not to dislodge the needle from the vein. The syringe

Fig. 2 Apparatus for intravenous administration of glucose

Fig. 3 Method of sterilizing glucose solution and container

filled with blood is then disconnected from the needle, and the adapter of the glucose outfit inserted into the needle in the vein. In this manner blood is secured and glucose administered through one venepuncture. A practical outfit for the intravenous administration of glucose is illustrated in Figure 2. This consists of an ordinary bottle with a capacity of 250 cubic centimeters (8 ounces), rubber tubing, a three way stopcock, and a 10 cubic centimeter Luer glass syringe. By one turn of the stopcock the syringe is filled, by another turn of the stopcock its contents is emptied into the blood stream, and this procedure is repeated until all the solution is used up.

The preparation of the glucose solution is simple. Twenty five grams (1 ounce) of chemically pure glucose is dissolved in an Erlenmeyer flask in enough freshly distilled water to make 250 cubic centimeters. This solution is brought to the boiling point (Fig 3, A). The neck of another Erlenmeyer flask is sterilized in a beaker of water (Fig 3, B) and the dissolved glucose is filtered from flask A to flask B (Fig 3, C) the contents of which is simply brought to the boiling point, when the solution will be sterile and ready for use.

It may be difficult to make the venepuncture. Thus if the needle is quite sharp, as it should be, it may perforate both walls of the vein. Figure 4 illustrates such a mishap and offers a remedy. Simply pull slowly on the syringe and plunger at the same time, and as soon as the needle has entered the vein, blood will appear in the syringe.

When insulin is added to the glucose, the diabetic patient should theoretically be protected from a rise of blood sugar. That this is actually true in practically all instances can be gleaned from Charts 1 to 8, in which I have drawn the blood sugar curves following the intravenous administration of glucose plus insulin in a series of 54 cases of diabetes. These demonstrate clearly that there need be no fear of endangering the status of a diabetic patient by the administration of glucose if the blood sugar is checked by subsequent examinations. Even though the blood sugar should rise, this can be easily controlled by the administration of additional insulin either hypodermically or intravenously.

Fig 4 A remedy in case both walls of the vein have been penetrated through venepuncture

This series of charts has been drawn from data secured in cases of diabetes in which an operation has been performed, and in cases of diabetic coma in which also the use of intravenous glucose is a great aid in overcoming the acidosis and increasing the excretion of acetone bodies through the urine. Furthermore the practically glycogen free liver as well as the heart muscle is thus restocked with glycogen.

In Table I, the data illustrated by the charts are summarized. From these data, I believe that we can feel quite free, in cases of diabetes wherever this is indicated to use glucose intravenously to the great advantage of the patient.

THREE SCORE AND TEN

THE brain of man is a visual brain. The mind of man was built up coincidentally with the eye and it is this fact not the mechanics of the eye that has made intellectual progress possible. In the lower vertebrates an expanded olfactory ganglion was the forerunner of the cerebrum and the sense of smell not only controlled their behavior, but it remains in the lower animals the only special sense which is not relayed through intermediate ganglions. The great expansion of the cerebrum in man however completely overthrew the dominance of the olfactory sense giving control to vision, and establishing direct relationship with consciousness thereby governing behavior.

The microscope introduced by the Janssen brothers, in 1590, was the most significant scientific contribution of all time and was destined to change the history of mankind, because it extended vision into the more minute, and thus made possible comprehension of the vast realm of micro organisms.

My professional advent was early in the development of Pasteur's germ theory of

disease and Lister's application of it to surgery. As a result of that epochal work through which came the elimination of contagious and infectious diseases, the average lifetime of man has increased 20 years. But we have not been so successful as had been expected in carrying the individual from middle age to the Biblical age of three score and ten.

Why is it, that whereas the total number of persons who reach middle life has been enormously increased, the relative percentage of those who reach three score and ten has not been correspondingly increased? There is no known normal length of human life. In the problem of life expectancy there are many factors to be considered of which heredity is the most important. Exposure to disease producing influences, the character of employment of profession, and hazards of all sorts, all must be taken into account in attempting to establish an age probability.

We commonly think of hazards in nature as being physical but the emotional hazard must be taken into consideration as well. Generally speaking the medical profession is rated high for longevity but this is more true of the internist than of the surgeon. The statistics of the Royal Victoria Hospital of Manchester, England, showed that the death rate among surgeons after 50 years of age was more than three times that among physicians in the same age period.

However experience has shown that in the fifth decade especially if vitality is lowered for any reason life may terminate as a result of a relatively unimportant affection, such as a cardiorenal disturbance or a pulmonary disorder. We must now undertake to determine

the nature of those obscure metabolic changes which lie behind these too early fatalities

The investigations which are necessary to analyze the individual in his life processes lie in the colloidal field, beyond the microscope. With the microscope, particles $1/10$ micron, approximately $1/250,000$ inch, in diameter are visible, but the colloidal field includes particles between $1/10$ micron and $1/1,000$ micron, approximately $1/25,000,000$ inch, in diameter. In this field, not the object itself but its shadow is seen, because the colloidal particle is larger than a ray of light and it reflects the light as though it were a mirror.

Below the colloidal field, in the division of size, lies the molecular field, and beyond that the atomic field. Because the atom is larger than the electromagnetic manifestation of the X ray, it has been separated into the electron and the proton, which lie in the experimental field.

Although the single colloid particle or molecule cannot be seen with the eye, because it is so minute, colloidal particles or molecules may become visible in the mass aided by staining properties.

Geraghty and Rowntree took advantage of this fact in the development of the phenol sulphonephthalein test of the function of the kidney, which not only had the greatest scientific value in demonstrating the permeability of the kidney to certain substances with a urea like filterability, but by timing the process of elimination gave an extraordinarily correct estimation of the function of the kidney. Rowntree and his associates in later experimentation with phenoltetrachlorophthalein demonstrated that the drug was always eliminated in the bile and perfected the best test known for function of the liver when jaundice is not present. And again phenoltetrachlorophthalein was used as the starting point in cholecystography, in that it was

shown that bile containing this dye was more opaque than normal bile. This research led to the recognition of similar opaque substances of even more valuable aid in eliciting diagnostic evidence of disease of the biliary tract through the X ray.

We have become so "eye minded" that it is difficult for us to appreciate that invisible colloidal and molecular particles are just as physical as though we could see them. After all, it is merely a question of size.

As surgeons we are interested in the metabolic processes in the preparation of elderly patients for operation. The advances made by biochemistry in securing better results in surgery, through rehabilitation of the patient, have had an equally profound influence in medicine and point the way to prolongation of life.

W J MAYO

LUMINAL AND THE NEWER CONCEPT OF ANÆSTHESIA

THAT there is dissatisfaction with our present anæsthetics, as commonly employed, is shown by the number of new methods of inducing anæsthesia put forward in recent years both here and abroad. The most significant feature of the viewpoint prompting this movement is its indication of a changing conception of the function of an anæsthetic. One has now a right to expect that an anæsthetic shall do more than abolish pain during operation and give the necessary relaxation with the minimum risk. From an increasing regard for the needs of a surgical patient as an individual and not as a lesion or a disordered mechanism, there comes a sense of how greatly the patient's burden could be lifted if he could be promised that he would know nothing of what takes place from the time of going to sleep on the night before operation until the day following

THREE SCORE AND TEN

THE brain of man is a visual brain. The mind of man was built up coincidentally with the eye and it is this fact not the mechanics of the eye that has made intellectual progress possible. In the lower vertebrates an expanded olfactory ganglion was the forerunner of the cerebrum and the sense of smell not only controlled their behavior, but it remains in the lower animals, the only special sense which is not relayed through intermediate ganglions. The great expansion of the cerebrum in man, however, completely overthrew the dominance of the olfactory sense giving control to vision, and establishing direct relationship with consciousness, thereby governing behavior.

The microscope, introduced by the Janssen brothers, in 1590 was the most significant scientific contribution of all time and was destined to change the history of mankind, because it extended vision into the more minute, and thus made possible comprehension of the vast realm of micro organisms.

My professional advent was early in the development of Pasteur's germ theory of

disease and Lister's application of it to surgery. As a result of that epochal work through which came the elimination of contagious and infectious diseases, the average lifetime of man has increased 20 years. But we have not been so successful as had been expected in carrying the individual from middle age to the Biblical age of three score and ten.

Why is it, that whereas the total number of persons who reach middle life has been enormously increased, the relative percentage of those who reach three score and ten has not been correspondingly increased? There is no known normal length of human life. In the problem of life expectancy there are many factors to be considered of which heredity is the most important. Exposure to disease producing influences, the character of employment of profession and hazards of all sorts, all must be taken into account in attempting to establish an age probability.

We commonly think of hazards in nature as being physical, but the emotional hazard must be taken into consideration as well. Generally speaking, the medical profession is rated high for longevity, but this is more true of the internist than of the surgeon. The statistics of the Royal Victoria Hospital of Manchester, England showed that the death rate among surgeons after 50 years of age was more than three times that among physicians in the same age period.

However experience has shown that in the fifth decade especially, if vitality is lowered for any reason life may terminate as a result of a relatively unimportant affection such as a cardiorenal disturbance or a pulmonary disorder. We must now undertake to determine

The dose of luminal varied from 12 to 30 grains given in one dose, as is now our routine. This plan has no place, of course, in patients who have much gastric retention or in those who are vomiting for any reason and in whom fluid by mouth is contra indicated. One should be cautious in the use of luminal in conjunction with spinal anæsthesia, for the combined effect may cause sufficient drop in blood pressure to be temporarily embarrassing. We have experienced this only once, moreover, a patient, uncertain of his balance and not able to co-operate thoroughly, might conceivably make a sudden movement and cause breaking of a needle. Patients entering the hospital are tested for individual idiosyncrasy by small doses of luminal. In a few cases there was a very transient skin rash as the only toxic manifestation. The economic saving to a patient who is not vomiting excitable, suffering, or disturbing his neighbors is reflected by a lessened demand on nursing service.

We have found a wide field of usefulness

for this procedure. With a routine dose of 15 grains of luminal (for *non thyrotoxic* individuals) and nitrous oxide, occasionally supplemented by a few whiffs of ethylene during packing off, cholecystectomy and other procedures down to the hysterectomy level (where we ordinarily prefer "spinal") are readily accomplished. A moderate amount of abdominal exploration is entirely feasible. The radical breast amputation furnishes an excellent opportunity also. Certainly in the case of thyroid surgery the manifold advantages of the "luminal effect" are at their best. It is useful in the minor anal and rectal operations where one has been used to particularly deep anæsthesia.

But beyond all figures and an author's enthusiasm, the court of last resort is the feeling of a patient who has experienced this "semi anæsthesia" after previous operation under different methods. His enthusiasm for it makes even a casual visitor realize how nearly completely the dreads of a surgical patient can be removed. WILLARD BARTLETT

operation. An ideal anæsthetic would provide such an *oblivion* without complicating induction or adding to the risk and morbidity.

With this in mind, we have studied, during the last 9 years in over 1,100 selected cases, the two most widely known of the barbituric-acid compounds, *veronal* and *luminal*. In agreement with experimental and clinical work of other recent investigators, we believe that by a combination of anæsthetic agents one can stay within the limits of safety of each and exploit the good properties of several. We do not attempt to produce full surgical anæsthesia, therefore, with luminal (our preferred drug), but use it in doses sufficient to produce a narcosis, a "semi-anæsthesia." We prefer luminal because (1) there is a voluminous clinical and experimental literature, without a single authenticated death from the use of luminal alone (though single doses of 50 grains have been reported twice), (2) it causes less nausea and loss of equilibrium than does veronal, (3) veronal has a bad reputation, however undeservedly, as a suicidal agent, especially among the laity. The final surgical anæsthesia is induced by nitrous oxide or ethylene (in much lower concentrations than can be used otherwise), and is therefore *instantly controllable*, or by local or spinal anæsthetic.

We have learned to anticipate the desired "luminal effect."

Three hours before operation the patient is given the drug in one dose and it takes effect in about 1 hour. He comes to the operating room without interest in his surroundings, often asleep but can be roused to answer questions. The first needle prick of local infiltration or the first few whiffs of an inhalation anæsthetic are not noticed. Morphine is not used before operation and there is rarely vomiting or sweating during opera-

tion. By removing the mask during operation the patient can be roused to talk or swallow, if desired. After operation he lies quietly in any position in which he is placed, sleeps normally, or is quite apathetic but can be roused to drink. The reflexes, importantly the cough and gag reflexes, are not interfered with. This effect lasts ordinarily from 12 to 24 hours—in one case as long as 56 hours. Sharp pain will rouse the patient, as it will from normal sleep, and for such pain we give morphine, but the aches, the vague general discomfort, and the sense of frightened confusion that are the common sequelæ of all surgical procedures do not disturb these patients. On the day after operation, they rarely recall anything of the events of the previous day—going to the operating room, inhalation of anæsthesia, postoperative dressings, physician's examinations or even the faces of the special nurses who came on duty just before operation.

The last 164 cases in which this method was used have been analyzed and reported in detail. Of those who had luminal in one dose, it is interesting to note that 74 per cent of the thyroidectomies (the great majority being toxic) and 45 per cent of other major operations were accomplished with nitrous oxide alone with an ease hitherto undreamed of for this gas, 70 per cent of those having luminal in one dose did not vomit during or after operation, and 53 per cent did not require morphine in the first 24 hours after operation. There were no significant changes in blood pressure pulse or respiration. Except in those patients who were put on a *peritonitis* regimen as a precaution after operation hypodermoclysis was rarely used, the absence of nausea allowing the patients to drink freely. Sweating was rarely seen and we have never known such freedom from postoperative respiratory complications.

JOHN MORGAN
1735-1789

MASTER SURGEONS OF AMERICA

JOHN MORGAN

JOHN MORGAN, who was not a surgeon, was important in the history of American surgery because of his pioneer status as a medical educator and founder of our first medical school and because he was physician in chief and director general of the hospital in the Revolution, a position corresponding to that of the surgeon general of the Army at the present time

He was born in Philadelphia in 1735, the son of well to-do parents, Evan and Joanna (Biles) Morgan. He was first sent to school to Rev. Dr. Finley's Nottingham Academy where he received the classical training for which the place was famous, and then to the College of Philadelphia, where he graduated in the first class to be granted literary honors, that of 1757. During the last years of his college course, he took up the study of medicine under Dr. John Redman. With the medical education derived from this apprenticeship, he became a surgeon, as well as a lieutenant of the line, in the French and Indian War in 1758, being attached to Forbes' expedition against Fort Duquesne. In 1765 he spoke of having had four years of military experience but it is impossible to see how this could have been so. In 1760 he left the army and sailed to Europe to continue his studies in medicine. In London he worked under William Hunter for a year and then spent two years in Edinburgh, where he was given the M.D. in 1763. From Edinburgh he went to Paris and there spent a winter in the study of anatomy. Thereafter he made the grand tour, calling upon and being warmly received by Morgagni and Voltaire. His journal covering this tour has been published and it reveals the young man taking his sightseeing and art very seriously and systematically. He was made corresponding member of the Academy of Surgery of Paris, a Fellow of the Royal Society, licentiate of the College of Physicians of London and member of the College of Physicians of Edinburgh. During his residence abroad he planned with William Shippen the founding of a medical school in Philadelphia, and upon his return there in 1765 armed with a strong letter from the proprietor, Thomas Penn, he proposed the establishment of a medical school in connection with the College of Philadelphia (University of Pennsylvania). The idea was approved and he was elected professor of theory and practice of physics, and Shippen was given the professorship of anatomy and surgery. The new school prospered and it has always been one of the leading schools of America.

Before he left England and again in Philadelphia, Morgan wrote that he would attempt the practice of medicine without dispensing his own drugs or practicing surgery, and there is no evidence that he ever did either, except that he attended the wounded on the battle field. He brought from England an apothecary to whom he sent his prescriptions.

In October, 1775, Dr. Morgan was appointed director general and physician in chief to the hospital, in succession to Dr. Benjamin Church, who had been detected in correspondence with the enemy. Morgan at once repaired to Cambridge, where he assumed the duties which so nearly overwhelmed him for the next fifteen months. Morgan had trouble with Dr. Stringer, director of the Hospital of the Northern Department, with Dr. Shippen, director of the Hospital of the Flying Camp in New Jersey, and with the regimental surgeons and officers, who felt that he was negligent of their needs and opposed to their interests. Congress also, influenced by complaints, showed itself hostile to him and eventually, in January, 1777, it dismissed him and Dr. Stringer without trial, and a few months later it promoted Dr. Shippen to the position of director general. Dr. Morgan at once began to beseech Congress for vindication. This Congress granted in June, 1779, in a resolution which declared that he "did conduct himself ably and faithfully in the discharge of his office" but it did not reappoint him to the office. Meanwhile Morgan was joined by Benjamin Rush, James Tilton, and perhaps others, in making charges against Shippen. Shippen was brought to trial in 1780 and was honorably acquitted. Morgan's accusations against him were doubtless motivated in part by chagrin, while the writings of Rush and Tilton show them both to have been men of acrid humor and hearty dislikes. Such was the disorganization, poverty, lack of transportation, low state of discipline in the Army, such the jealousy between colonies and communities, such the lack of preparation for war and the ignorance and indiscipline of the people, such the meddlesomeness of Congress and its neglect of the Army, that it may be that nobody could have been more successful as director general of the hospital in 1776-7 than was Morgan. As a matter of fact, Washington's success with the Army of that time was little better. Nevertheless, Morgan's "Vindication of his Public Character," written by himself and published in Boston in 1777, does permit the inference that, despite the evils with which he had to bear or to contend, he might have accomplished more except for drawbacks due to his own personality. These faults were apparently two: first, an inability to delegate work, which was not wholly compensated for by the hardest of work on his own part, and second, a mistaken or too modest conception of his duties as director general. The individual regiments at first brought their own medical men, and Washington found the need at Cambridge to be for a general hospital service. Congress legislated for that, but not, as Morgan viewed the matter, for any regimental service, whereas the regiments and apparently the States, and possibly

Congress itself, expected him to make provision for all medical necessities. Had Morgan boldly taken this same view and regarded himself as the one responsible for all medical service, he might have had greater support from the regimental officers, line as well as medical, and so had greater success. As it was, he regarded himself as having to do only with "The Hospital" and not with the regiments, he was unable to furnish these with necessary supplies, the regimental surgeons thought him negligent of, and opposed to, their needs and they worked against him. From their enmity arose a large part of his troubles.

Another large part came from the promotions of Stringer and Shippen, due partly to politics, possibly in part to the machinations of the two, but possibly also in part to Morgan's too great concentration on the work in his immediate vicinity, with consequent inability to look after the service of distant forces in any effective manner.

As a young man, Morgan was admired and copied, he had his place among the intellectual elite of the city, he was sufficiently untrammelled by custom to be able to avoid surgery and the dispensing of drugs, things which all other American physicians did. He could even indulge in the then foppish peculiarity of carrying a silk umbrella.

After his military service he wrote nothing except his "Vindication" and he largely retired from the public gaze, although continuing to practice and to teach. He died at Philadelphia on October 15, 1789.

He was a learned man, a delightful personality, possibly an excellent administrator, certainly a hard worker, but his army service came at a time when success in it was all but impossible, when Washington himself was meeting with every kind of defeat and discouragement. But he is one of the great figures in American medical education. His published writings are (1) *De Puoplesi, sive Tentamen Medicum Inaugurale de Puris Confectione* Edinburgh 1763 55 pp. (2) *Discourse upon the Institution of Medical Schools in America* Philadelphia, 1765 91 pp 12 mo. OLD MASTERPIECES IN SURGERY

ALFRED BROWN M.D. F.A.C.S. OMAHA, NEBRASKA

THE WORKS OF DANIEL SENNERT

DANIEL SENNERT was a contemporary of Cæsar Magatus and one of his most severe critics and bitter opponents. He belonged to the school which admitted no change from the ideas of the ancients and bitterly opposed anything which had to do with progress beyond the established routine. A believer in the supernatural and in alchemy, recommending to his colleagues and students the study and employment of astrology, and imbued with a belief in the origination of disease in witchcraft and magic, he could hardly be expected to be an unbiased observer and practitioner who would accept new methods or even consent to try them out. His first impulse would be to condemn them heartily.

Sennert was a German who received the best in education that his country afforded but went no farther than Switzerland to obtain outside information. Consequently, he would naturally be more or less narrow in his beliefs and viewpoints. He was born in Breslau in 1572. His education he obtained in Wittenberg, Leipzig, Jena, Frankfurt on the Oder and finally in the University of Basle. Then he returned home and began to practice and teach. He was appointed professor of medicine and served six terms as Rector of the university. It followed from his preeminence in medical and university affairs that he was appointed physician in ordinary to the Elector Johann Georg of Saxony. He died of the pestilence in 1637.

Sennert never wrote a book devoted to surgery alone. It is doubtful whether he ever practiced it actively. He was nevertheless well grounded in surgical theory and knew not only the beliefs and practices of the ancient authors but also those of his contemporaries and those who had shortly gone before. He shows that he was acquainted with the works of Dalla Croce and Fabricius of Acquapendente in Italy, Pare in France, Fabricius Hildanus in Germany, and Pieter Perw in Holland. In other words the authors of the surgical classics of the time. These he knew as a bystander on the side lines as it were but with his aloofness he nevertheless could not resist the opportunity to mix into the most active surgical squabble of the period and in fact became one of the principals in it. In 1611 he published his *Principles of Medicine and concerning*

the origin of the Living Principles in Brutes. This went through several editions and the second section of its fifth book is devoted to the type of surgery noted above.

Later in 1616, Cæsar Magatus published his work on wounds which aroused Sennert's antagonism and in his *Opera Omnia* published in three great folio volumes at Leyden in 1650 one finds the fifth book beginning with the fourth part discussing the question of wounds. After describing the various types of wounds their complications and the primary treatment of uncomplicated as well as complicated wounds of various types to which he devotes eight chapters Sennert finally comes to grips with Magatus on his new method of treatment of wounds with infrequent dressings. He heads the chapter "A judicial inquiry concerning the method of curing wounds of Cæsar Magatus and Ludovic Septalius," and concludes the first paragraph after stating that Magatus had brought out a new treatment which differed from that of the ancients by saying "Ludovic Septalius in his eighth book of medical considerations praises commends and defends Cæsar Magatus and thinks he deserves praise both for advancing the study of the art of medicine and for freeing the sick from a disagreeable cure. And I do not think that I am injuring the public welfare if I being of a different opinion, propose to discuss that opinion in this place. The arguments that Sennert advanced to prove Magatus wrong are long and wordy but always can be boiled down to one—that the ancients never treated wounds the Magatus way and their patients did fairly well. Hence why change? Magatus could not resist an answer but could not make it over his own name for he was a cleric and mundane quarrels were not for him. So he published his answer as if written by his brother Jean Baptiste and reiterated all his arguments against frequent dressings and the use of tents and added a few new ones. He neglected to set down any definite rules when dressings should be changed.

The argument augmented interest in wound treatment if it did nothing else and whenever interest is aroused in a medical or surgical subject more efficient therapy follows. So Sennert, though primarily mostly interested in internal medicine through his contentiousness accomplished much for surgery by bringing the subject of wound treatment prominently before the profession.

BONE CHANGES IN HYPERPARATHYROIDISM¹

EDWARD L. COMPERT, M.D., CHICAGO

From the Department of Surgery, University of Chicago

ENLARGEMENT of the parathyroid glands in certain diseases of the skeleton such as rickets, osteomalacia and osteitis fibrosa, were noted at necropsy by careful observers more than 20 years ago. Erdheim (10), in 1907 expressed the belief and offered experimental evidence to support his theory, that these instances of hypertrophy were an attempt on the part of the organism to compensate for the loss of calcium and thus a result rather than a cause of the disease.

While studying a case of osteitis fibrosa cystica, Schlagenhaufen in 1915 recommended the removal of double palpable tumors of the parathyroid glands. Maresch, one of his associates concurred in this opinion but J. Bauer, the surgeon who was responsible for the case, rejected the suggestion as too radical and dangerous a procedure. Mandl, however was possessed of a more adventurous spirit. In 1925 he gave Erdheim's theory a clinical test. Four parathyroid glands taken from the moribund victim of an accident were successfully transplanted to the abdominal wall of a man aged 38 years with generalized osteitis fibrosa but the bone disease became definitely worse following the transplantation. Mandl then decided that the previously mentioned hypertrophy of the parathyroid glands in similar skeletal conditions might be a cause and not a result of the bone changes. In an exploratory operation he found a tumor mass behind the left lobe of the thyroid gland and

removed it and at the same time he removed the parathyroid glands which had been transplanted to the abdomen. The tumor proved to be an adenoma of a parathyroid gland and following its removal there was steady improvement in the condition of the patient.

Since the report of Mandl's case parathyroid tumors have been removed from several other patients suffering from similar skeletal diseases. The similarity between the symptoms and observations in some of these cases especially that reported by Barr, Bulger and Dixon at St. Louis, and that of Wilder at the Mayo Clinic and the case which we shall report here led us to make a diagnosis of hyperparathyroidism.

Miss I. J. aged 50 years came to the University of Chicago Clinics in May 1929 complaining of pains in the bones of the legs particularly in the feet, bowing of both legs and general weakness. Although she had noted the bowing for only 2½ years the pains and weakness had been present for 3 to 5 years. The most recent development had been pain in the left hip. The weakness was so marked that she had fallen many times and on such occasions she could not regain her feet without assistance.

In spite of the fact that she had been breast fed as an infant the patient had suffered from infancy and until she was 3 or 4 years of age with an almost constant diarrhoea. She was never given cod liver oil and after she was weaned she had refused to drink milk. She first walked when 3 years of age. Dental caries developed early and while still a young woman all of her teeth were extracted. While she was never strong and never seemed to feel well the only definite illnesses which she could recall were rheumatic fever

REVIEWS OF NEW BOOKS

In presenting the third edition of a two volume work on pediatric surgery, Kelly¹ aptly states that "there should be children's surgeons as well as children's physicians or if one objects to cutting up surgery into little pieces" as Timothy Holmes says, it should at least be required that the surgeon extend his knowledge to *pediatrics*. The author understands the psychology of the child and beautifully expresses the relationship between physician and little patient. On the whole the work is well arranged and presented but is a work for general rather than specific reference.

In the consideration of general subjects in the first chapter various laboratory examinations are discussed but nothing is said of blood chemistry and the importance of stereoroentgenography. The section on postoperative care and on blood grouping and the various methods of transfusion in relation to hemorrhage and its control is very good.

The author in discussing the surgical treatment of hyperthyroidism makes the statement that "thyroidectomy should generally be preceded three or four months by ligation of the superior thyroid arteries one at a time some days or a week apart. Severe reaction may be looked for after each of these procedures." This advice since the introduction of iodine premedication by Plummer may be strongly contested. Multiphase operations are being abandoned even by such vigorous exponents as Lahey and Crile.

In the discussion of rickets one can hardly accept the statement that there is a "predisposition to general convulsions upon the slightest provocation, and further that 'vitamin A' the curative factor. Unfortunately the rôle of antirachitic vitamin D and the use of the irradiated sterols is omitted. The section on infantile scorbatus makes no mention of ascorbutic vitamin C.

The treatment of burns is excellently written emphasis being placed on the tannic acid method and on the importance of the extension position in healing with early skin grafting.

Early surgical interference in acute osteomyelitis and later sequestrectomy are correctly urged. In the discussion of tuberculosis of bones and joints the author aptly states that in local treatment there is to be no resort to any operative measures unless all other means have been exhausted and then there is not to be in the case of any growing child an operation which mutilates or which destroys the epiphyseal lines of growth. Secondary infection must be avoided. Rest is the most im-

portant of all agencies for local treatment and all other means sink into such minor positions as to be almost negligible when compared with rest.

The sections dealing with hydrocephalus and intracranial birth hemorrhages are excellent. A very complete discussion of intubation in laryngeal diphtheria appears in volume II.

The omission of bronchiectasis from the section on surgery of the thorax is regrettable. Its importance in relation to swallowed foreign bodies per tussis and other respiratory infections should have been emphasized. Of 32 operative cases listed by Lühenthal in his text 17 patients were 16 years of age or younger.

In the treatment of peritonitis in general the author advises emptying the bowels by the use of calomel and salines. "Pain and tenderness can be greatly relieved by smearing the abdomen with extract belladonna one drachm to glycerin one ounce under oil silk." Such statements are remnants of the medicine of a long past day. The repeated reference throughout this text to the use of calomel and the salines in the acute infections can hardly be accepted by the reviewer who has never had occasion at any time in his practice to employ these drugs.

Anomalies of the bile passages which are not infrequently seen in the early jaundice and death of infants are not mentioned nor is there a section on the liver or pancreas.

As a text devoted to the general surgery of children the work is commended to the profession.

I MICHAEL J EVIN

THE entire subject of gynecology is presented by Kelly² in a relatively complete 1000 page volume. This book is well organized and beautifully illustrated. The newer diagnostic aids the tubal patency test lipiodol pneumoperitoneum etc and recent work on internal secretion are well presented.

The recent advances in gynecology, adenomyoma, radium therapy, diathermy, uterine structure and electric cautery are discussed.

Kelly's own work comprises the larger portion in this volume. He has selected as collaborators such men as Ward who beautifully describes plastic surgery.

Burnham's chapter on radium in carcinoma of the uterus merits special note. This volume deserves a place in the library of everyone who is interested in gynecology or pelvic surgery.

¹SURGICAL DISEASES OF CHILDREN. A MODERN TREATISE ON PEDIATRIC SURGERY. By Samuel Walter Kelly, M.D., LL.D., F.A.C.S. Vols. I and II. St. Louis: The C.V. Mosby Company, 1929.

²GYNECOLOGY. By Howard A. Kelly, A.B., M.D., LL.D., and Col. Labatoz, New York and London: Appleton and Company, 1935.

TABLE III—METABOLISM EXPERIMENT
JULY 1 TO JULY 6*

	Daily ave ages				
	Intake	Output		Total	Balance
		Urine	Feces		
	Gm	Gm	Gm	Gm	Gm
Calcium	0.303	0.058	0.389	0.447	-0.144
Phosphorus	0.754	0.450	0.375	0.825	-0.041
Nitrogen	8.51	5.760	1.66	7.42	+1.090

*The diet during this period was held constant and as nearly like that given in the previous experiment as possible. Aliquot portions (1/10) of all food were set aside dried, and thoroughly mixed for analyses. Indigo carmine was used to mark the feces of the period. We are indebted to Dr. Calie Mae Coons for these analyses.

hyperirritable and hypercritical anxious moving restlessly in bed and complaining of tingling fingers and numbness of the hands. No definite Chvostek sign could be elicited but the tendon reflexes were all exaggerated. On the following morning as the serum calcium was found to be at what is usually considered to be a tetany level 6.97 milligrams for each 100 cubic centimeters of serum the administration of calcium lactate (2 grams three times daily) was begun. The restlessness quickly became less marked and the serum calcium began to rise to higher values. The serum phosphorus rose to normal values immediately after operation (Table I).

A metabolic balance run for the 6 day period July 1 to July 6 revealed a decided change in the mode of excretion of calcium (Table III). Before operation nearly 65 per cent of the calcium had been eliminated by way of the kidneys while the renal fraction after operation was reduced to about 11 per cent of the total the fecal fraction being correspondingly greater. The negative calcium balance of this period may be accounted for in part by the fact that contrary to orders that all intake be limited to the diet and distilled water the patient was given mineral oil for the first 3 days of the experiment. Gross particles of food and much oil were noted in the feces and this fact suggests that absorption of food including calcium was somewhat interfered with. A further and probably more important source of error is the fact that until 24 hours before the beginning of the experiment the patient had been receiving 6 grams of calcium lactate daily. While an indigocarmine marker was used it is possible that the first sample of feces contained some of the calcium given as medicine and not previously expelled. The low calcium content of the urine is ample evidence that the calcium in the blood and tissues was being retained. The diet in this metabolic period was identical with that used in the pre operative metabolic period June 3 to June 9 both being weighed diets of pre determined composition.

The patient returned to the clinic on August 21 stating that she was much stronger and was having less pain although following a fall she had noticed some pain in the left thigh. The observations at the

TABLE IV

Date	Blood serum				Product of Ca & P
	Calcium	Phosphorus	CO ₂ Content	pH	
	Mg per cent	Mg per cent	Vol per cent		
1929					
Aug 19	11.11	3.64	61.3	7.63	40.4
Aug 20	Lost	3.904	66.4	7.57	
Aug 22	Lost	4.35		7.46	
Aug 26	10.57	4.212	65.4		44.5
Aug 28	11.05	3.8	68.3	7.53	42.0

general physical examination were essentially like those at the previous admission with the additional notation that the patient seemed to be more alert mentally reflexes were more brisk and she was generally more active than at the time of the first admission. The blood count was higher 5 100 000 erythrocytes and 80 per cent haemoglobin (Dare) and the basal metabolic rate was plus 1.

The appearance of the bones roentgenologically showed no change that could be detected at this admission which was less than 2 months after the operation. The serum calcium while not so high as when she first came to the clinic was at the upper limits of normal while the serum phosphorus during the admission was also a good normal ranging from 3.6 to 4.3 milligrams (Table IV).

On November 12 1929 the patient stated that she still had some pain in both thighs after standing for several hours but she declared that her strength was good and that in contrast to her previous lassitude it was difficult for her to reconcile herself to a daily rest period. She had gained 7 kilograms in weight since leaving the hospital following the operation. Reflexes at this visit were active. Serum calcium was 10.22 milligrams and serum phosphorus 4.21 milligrams. Calcium excretion in the urine for a 24 hour period with patient on her routine diet was 206.57 milligrams. This marked increase in urinary calcium output suggests a return toward a negative calcium balance but is not above the upper limit of normal. The general tone of the muscles was obviously much better than before operation but no change in the degree of skeletal deformity could be determined.

An X ray examination on December 12 1929 showed no change in the calcium content of the bones. The patient was given viosterol (irradiated ergosterol) with instructions to take 5 drops three times each day.

She was seen again in the clinic on January 3 1930 and was feeling exceedingly well at that time and stated that she was stronger than she had been in more than 10 years. Prior to the removal of the parathyroid tumor she had been unable to remain on her feet for more than a very short time because of weakness. For more than 3 years before coming into this clinic she had been so weak that she often fell down apparently from the fact that her knees

*The diet during this period was held constant. Aliquot portions of all food were set aside, dried, and thoroughly mixed. In the kitchen was used to make the feces of the period. Weighed by Dr. Call Mac Coons for these analyses.

pressure 134/90 and the basal metabolic rate was plus 4. The erythrocytes numbered 4,000,000.

Roentgenograms revealed osteoporosis of the calvaria, osteoporosis and bowing of the femora and the same rarefaction of the pelvic bones and the lumbar vertebrae with sinking in of and male like pelvis (Figs 3, 4, 5 and 6). Particularly noticeable was the thinness of the cortices of the shafts of the long bones. No sign of bone cyst or tumor was present.

Serum calcium was slightly elevated assuming 9 milligrams to 11 milligrams for each 100 cubic centimeters of serum to be the normal range while the serum phosphorus was lower than normal (Table I). Metabolic studies from June 3 to June 9 revealed a negative calcium balance and showed the excretion of an abnormally large proportion of the total calcium output by way of the kidneys (Table II).

A diagnosis of hyperparathyroidism was then made on the basis of the syndrome consisting of pain and bowing in the weight bearing extremities, osteoporosis of the bones of the skeleton, progressive muscular weakness, elevated serum calcium and lowered serum phosphorus, a palpable nodule in the lower pole of the right lobe of the thyroid gland and a negative calcium balance. Since it was thought that the nodule in the right lobe of the thyroid gland was a parathyroid tumor, exploration for the tumor was advised.

The operation was performed by Dr. D. B. McMaster on June 24, 1929. The right lobe of the thyroid gland was found to be about double the normal size and there was a nodular enlargement in the body of the lower pole. This nodule when excised proved to be a thyroid adenoma and not a parathyroid. The surfaces of the upper and lower poles were searched for enlarged parathyroids and none was found. The left thyroid lobe was about normal in size and a nodule projected from the posterior inferior portion. This had a pedicle containing blood vessels. It measured about 1 by 1½ centimeters and was removed. A small mass near the upper pole, considered to be a normal parathyroid, was also removed.

The postoperative course was normal until June 26, 2 days after the operation when the patient was

at the age of 9 and typhoid fever at the age of 18 years. Cardiac weakness with decompensation had caused dyspnea on exertion and some palpitation and this dated back to the attack of rheumatic fever.

The examination revealed a fairly well developed and fairly well nourished woman who did not look as old as her stated age (Figs 1 and 2). One was struck by the lack of tissue turgor for her skin, the subcutaneous tissues and the muscles themselves seemed to hang limply and in folds, giving the impression of extreme hypotonicity. All reflexes were present and equal but very sluggish.

The cardiac area was moderately increased in size and a loud systolic murmur was heard precordially and in the axillary line. A spherical nodule 2 centimeters in diameter could be palpated in the lower pole of the right lobe of the thyroid gland. Skeletal deformity was noted as follows: a marked kyphosis of the thoracic spine, slight thickening of both femora and some thickening and slight inward bowing of both tibiae and fibulae.

In walking there was just the slightest tendency to waddle and genu valgum was noted. This knock-knee deformity was not at all obvious when the patient was lying down but increased upon standing. In addition there was eversion of the feet and this became so marked after standing for a few minutes that the medial malleoli were less than an inch from the floor and the pes planus which was barely noticeable when she would first stand up became quite marked.

The body weight was 54.6 kilograms and height was 169 centimeters. The pulse rate was 75 per minute. The temperature was normal, the blood

logical diagnosis was benign adenoma of the parathyroid gland

Procedure in serving calcium balance diet The following diet was planned and the procedure in serving it was supervised by Miss Florence Smith in charge of the dietetic service of the hospital protein 49 grams per kilogram body weight fat 8. grams per kilogram body weight carbohydrate 156 grams per kilogram body weight calories 1556 (basal plus 15 per cent) Estimated calcium content 0.300 grams

These constant diets were served on 6 consecutive days breakfast on the first morning being served after indigocarmine was given and after venous puncture All dishes in which food was served and silver used on tray were washed dried and then rinsed in distilled water Dishes in which hot food was served were placed in food truck to warm All foods served on trays were weighed on balance scales and placed in dishes in which they were to be served, then one tenth that amount weighed for laboratory sample Chemically clean beakers with covers were secured from the laboratory each morning and labelled with the patient's name room number and date on both beaker and cover The total day's allowance of butter was weighed first One tenth of the total was placed in a beaker for analysis and allowed to stand in hot water until the butter melted then the beaker was tilted and turned until the butter was well distributed on the walls of the containers This procedure prevents food sticking and it is more easily removed from the container after drying The day's allowance of bread sugar fruits and cereal for breakfast was weighed and one tenth portion of each food was placed in the beaker All cooked foods were weighed hot and dishes in which they were to be served were placed in a food truck to maintain constant temperature All food was cooked with distilled water The eggs served were cooked in the shell removed from the shell with a spoon which had been rinsed in distilled water and then weighed in the cup in which they were served On the sixth day raw eggs were beaten in a bowl which had been rinsed in distilled water and an amount equal to one tenth the total weight of all eggs served was placed in the beaker containing the food aliquots for analysis

On the fourth day of the second balance study period the patient was given approximately 34 glass of orangeade by error of the nourishment nurse To minimize the error 15 grams of orangeade were added to the laboratory specimen on the sixth day On the next day the patient was given carmine in the morning before the regular diet was resumed

Methods of chemical analysis Food composites collected as described were left on a steam bath until practically dry then removed to an electric oven at 80 degrees C further dried to constant weight and then ground and mixed for analyses

The faces without transferring were covered with acidified alcohol and dried in the same manner as the food All collections for the period were composited and ground for analyses

Fig 3 The calvaria showing osteoporosis May 28 1929

Urine was collected into bottles containing toluol One fifth of the total excretions for each 24 hours were combined and preserved with toluol and strong hydrochloric acid until analyzed

Analyses for calcium were carried out according to the McCrudden method the hydrogen ion concentration being adjusted with sodium acetate as described by Shohl The precipitated calcium oxalate was collected on a Gooch crucible ignited and weighed as calcium monoxide The determinations were made on triplicate samples of food and faeces after they had been ashed in an electric muffle furnace and the ash dissolved in hydrochloric acid The acidified filtered urine was evaporated and ashed and dissolved in hydrochloric acid

The procedure used for phosphorus analyses involved moist oxidation with sulphuric and nitric acids according to Neumann and then double precipitation first as ammonium phosphomolybdate finally as magnesium ammonium phosphate following the McCandless Burton technique The last precipitate was collected on a Gooch crucible ignited and weighed as magnesium pyrophosphate

For total nitrogen determinations the Arnold Gunning (21) modification of the macro Kjeldahl procedure was used

The calcium in the blood serum was determined by the Clark and Collip modification of the Tisdall and Kramer method Phosphorus in the blood serum was determined by a slight modification of Fiske and Subbarow Carbon dioxide content was determined by the Van Slyke method and the hydrogen ion concentration was estimated by the colorimetric method as described by Hastings and Sendroy the Hastings bicolometer being used

Fig 1 (left) The patient. There is obvious loss of tissue turgor and muscle tone. (Before operation.)

Fig 2 The lower extremities. Note the lateral curvature of the femurs, the genu valgum, the medial curvature of the bones of the legs, the eversion of the feet, and the marked flattening of the plantar arches of the feet.

simply gave way under her and she would not be able to regain her feet unassisted. She estimates that these falls occurred on the average of about two times each week. Since the operation 5 months ago she has fallen only one time and that was soon after leaving the hospital and was occasioned by stumbling. The pain in her feet which had almost completely incapacitated her for any kind of work for 2 or 3 years prior to her admission to this hospital has not been present since leaving here nearly 5 months ago. She does have some pain in the distal third of the tibia which comes on when she has been on her feet for an hour or longer but this does not interfere with her daily routine. Serum calcium at this visit was 10.92 milligrams and phosphorus was 4.82 milligrams for each 100 cubic centimeters of serum. These figures are well within the range of normal.

The last visit to the clinic was on March 10, 1930. Some aching of the tibiae had persisted but her strength was good. Serum calcium was 12.5 milligrams and phosphorus was 7.12 milligrams for each 100 cubic centimeters of serum.

Throughout the course of these studies the hydrogen ion concentration and carbon dioxide content of the blood serum remained fairly constant although both were slightly higher than the accepted normal (Tables I and IV).

Pathological studies were made of the tissues removed at operation. The three specimens consisted of a wedge shaped mass of nodular thyroid tissue 2 centimeters in diameter from the lower pole of the right thyroid gland, a small nodule from the upper pole of the left gland and the tumor.

The wedge shaped mass of nodular thyroid tissue was not particularly interesting. Microscopic studies showed that except for the relatively large number of colloid containing vesicles in a few of which the lining epithelium was slightly flattened this section did not vary greatly from normal (Fig 7). The lining epithelium was smooth and regular and no portion of the section seemed to consist of an actively secreting gland. There were several areas of dense lymphocytic infiltration.

The second specimen which proved to be a normal parathyroid gland was a firm ovoid pinkish nodule measuring 2 by 4 millimeters with a delicate connective tissue capsule. The section stained with hematoxylin and eosin was seen to be composed almost entirely of cells resembling epithelial cells with a connective tissue network which divided the cells into irregular strands (Figs 8 and 9). These epithelial cells were of two types. By far the most abundant were relatively small cells with large nuclei containing many dark staining granules. There were also a few groups of large cells with relatively clear cytoplasm which stained pink with the eosin. In the central portion of the section there was an occasional vesicle or acinus. Numerous fat cells were noted and the entire section was quite vascular.

The tumor mass removed from the vicinity of the lower pole of the left thyroid gland was a smooth reddish brown semi elastic meaty nodule 1 by 1 1/2 centimeters with a fibrous capsule and a definite vascular pedicle (Fig 10). Microscopic sections stained with hematoxylin and eosin revealed a compact cell structure composed of cells resembling epithelium cells with numerous acini or alveoli which were lined with cuboid or low columnar epithelium in a number of which colloid material was noted (Figs 11 and 12). There were numerous blood vessels and while the bulk of the gland was composed of the alveoli in some portions of the section particularly near the periphery the epithelial cells were arranged in strands with blood spaces and some connective tissue between. Nodular figures were found but the nuclei of most of the cells were filled with large dark staining granules. A very few of the large clear cells noted in the normal gland were seen. As in the case reported by Wilder no foam cell or fat cells were present.

The structure of the tumor differed from that of the normal parathyroid gland in the presence of numerous acini, the compactness of the cellular elements, the absence of fat cells, the absence of any strand like or trabecular arrangement of the epithelial cells, the preponderance of deeply staining granular cells and the scarcity of the large cells with clear pink staining cytoplasm. The patho-

Erdheim and diagnosed hyperplasia. Strauch studied a tumor which was removed from the neck of a woman who died after a typical attack of puerperal osteomalacia. His diagnosis of hyperplasia was based upon the presence of all of the normal cell elements while, according to his belief, only one type of cell is found in the true adenoma.

The tumor which was removed from our patient was almost entirely composed of the one type of large epithelial cell with hyperchromatic nuclei and the predominating characteristic was one of acini formation. No portion of the gland resembled normal parathyroid tissue. We feel justified, then, from a pathological standpoint, in making a diagnosis of parathyroid adenoma. If this were a compensatory hyperplasia as Erdheim and others believe it is difficult to explain why another gland on the same side should be entirely normal. If we then assume that the changes in the calcium metabolism were due to increased parathyroid activity, we must conclude that either this adenoma was producing an abnormal amount of parathyroid secretion, grossly normal parathyroid glands were hyperfunctioning, or that there was some undiscovered and abnormally active accessory parathyroid tissue. The presence of a pathologically similar tumor in a rapidly growing series of reported cases lends weight to the first hypothesis.

The tumors of Wilder and Mandl were classified as malignant adenoma because of the presence of mitotic figures, the polymorphism of the cells, the hyperchromatic nuclei, and in Wilder's case because of the invasion of the neoplastic tissue into the capsule. The striking absence of foam cells and of fat which Wellbrock mentions may not be a criterion of malignancy for the same thing was true in our case and other cases in which the pathological study was reported in detail and in which there was no suggestion of malignancy.

The duration of the bone disease in both Wilder's and Mandl's cases of from 5 to 7 years speaks against a diagnosis of malignant tumor. However, a review of the literature of malignant tumors of the thyroid and of the parathyroid glands indicates that in almost every instance tumor of some kind preceded

Fig 6 The tibiae and fibulae showing osteoporosis, thinning of the cortices and inward bowing. May 28 1929

the malignant changes for several years. Balfour, in a series of sixty three cases of malignant struma, found that in not a single case had the condition appeared suddenly, but some form of diffuse or nodular goiter had preceded it. Wilson found that in 157 of 290 cases of malignant goiters, there had been an enlargement for 5 years or longer. In most of the 8 cases of malignant tumors of the parathyroid gland reviewed by T. Kocher, the tumor had been present for many years. Metastases to the neck, mediastinum, or pleura occurred in each of the cases described by Kocher.

In the case of Guy, the tumor of the neck had been noted for 5 years. When removed the section showed a few acini and a few mitotic figures with areas of degeneration and cyst formation resembling those found in Wilder's tumor. A diagnosis of adenoma of the parathyroid gland was made, but the patient returned after 11 months with 3 new nodules near the operative scar. The author noted here that her general health was good and there was no evidence of skeletal disease. These nodules and several glands in the posterior cervical triangle of the neck were removed and all were found to be carcinomatous and all recurred in spite of X-ray therapy. Guy concluded from his studies that apparently benign tumors of years' duration may suddenly take on malignant characteristics. While it is doubtful that the malignant changes in the tumor were responsible for bone changes which have been noted in so many other cases in which there was no suggestion

Fig 4 The proximal ends of the femurs and the pubic and ischial bones showing decalcification and thinning of the cortices May 28 1929

Fig 5 The pelvis and lower lumbar spine shown decalcification May 28 1929

Including the case of Mandl which was reported in 1926, there are descriptions of 8 cases, similar to that here reported from which tumors of one or more parathyroid glands have been removed. In seven of these cases, those of Mandl, Gold Barr, Wilder, Boyd, Snapper, and finally in our own case, a varying amount of improvement followed extirpation of the tumor. It is further learned at the time of going to press with this paper that another case of Barr has been operated on and an adenoma of one of the parathyroid glands removed with beneficial results. Wilder stated that following the removal of the parathyroid tumor in the case which he reported, the patient noted marked improvement in strength and in muscle tone and relief from pain in the bones, and roentgenologically there was some increased density of the bones and disappearance of a tumor of the maxilla. Mandl very recently reported that 3 years after the operation the condition of his patient is still favorable. Before removing the adenoma of the parathyroid gland the patient had been bedridden for months but she now has no pain and is able to take long walks with the aid of a cane.

In the case of Beck, reported in 1928 and diagnosed as generalized osteodystrophia. An olive sized tumor was removed from the lower pole of the right thyroid gland and a coffee bean sized tumor from the site of the upper parathyroid gland on the same side.

The patient developed tetany on the fifth day after and died 20 days after the operation. At autopsy no parathyroids could be found on the left side.

Diagnoses of adenoma of parathyroid glands as an explanation of a condition considered to be due to hyperfunction of the tumorous glands may not be accepted without some criticism. In discussing adenomatous changes in the thyroid gland, Rienhoff (26) declared that even though the cells lining the alveoli do function locally, there is no proof that these neoplasms produce a toxic secretion, and there is no evidence to suggest that these cells lining the alveoli function in such a manner as to affect the organism as a whole. Aschoff did not believe that adenomata of the parathyroid glands had anything to do with the bone changes occasionally found associated with them. Rienhoff (28) also states that adenoma and carcinoma of the parathyroid glands have in some instances been associated with low blood calcium and even with tetany.

Pathologically the tumors in all of the cases reported have been diagnosed adenoma. Functionally they resemble true hyperplasia. Both Ewing and Harbitz have recognized the difficulty of differentiating between a moderate diffuse hyperplasia and a true adenoma of the parathyroid gland. Tumors of the parathyroid gland grossly similar to those reported in this series and associated with similar skeletal conditions were studied by

Fig 10

Fig 12 The vesicles of the tumor are lined with cuboid epithelium and in some of them colloid like material is seen ($\times 150$)

of similar conditions. All of the patients in which a case history is given complained of progressive muscular weakness, pain and bowing of the weight bearing extremities and general lassitude. In all of the patients there was osteoporosis of the bones of the skeleton. In the cases in which blood chemistry studies were made there was an elevation of the serum calcium which varied from slightly above the upper limits of normal to the extremely high figure of 23.60 milligrams for each 100 cubic centimeters of serum which was reported by Snapper (Table V). In the 5 cases in which calcium metabolism studies were made, there was a negative balance in each case and in each of these cases the balance became positive following operation except in our own case, for which result an explanation has been offered.

Table V besides illustrating some of the points mentioned of similarity between the various cases reported shows that there were 7 females and 4 males while Bergman does not mention the sex of his patient. Fractures had occurred in 5 of the cases. In the cases of Gold Barr, and Beck the fractures which had occurred during the course of the disease healed very slowly but in Snapper's case the fractured femur united firmly soon after operation.

An ununited fracture of the femur brought Beck's case to him and symptoms and findings leading to his diagnosis of osteitis fibrosa were brought out during the subsequent examination. The death of this patient on the twenty first day after operation precluded any conclusions regarding the healing of the fracture after removal of the parathyroid adenoma. Tetany was noted after operation in 3 cases. In all cases in which the chemistry of the urine was studied there was found a calciuria and, following removal of the tumor the calcium of the urine fell to below normal values.

Complete descriptions of the roentgenological studies were not included in most of the case reports. In all of the 12 cases there was diminished bone density, spoken of by some as generalized osteoporosis and by others as decalcification. In 6 cases, in addition to the generalized loss of density of the bones, there were cysts of the femurs or of the pelvic bones. These were noted in the cases of Gold Richardson, Barr, Duken, Wilder, and Snapper. Following removal of the parathyroid tumor Mandl, Richardson Barr, Wilder, and Snapper reported X ray evidence of improvement, as shown by increased density in calcium content of the bones. No positive

of carcinoma, the cases in the literature of malignant tumors of parathyroid glands help to substantiate the pathological diagnoses of malignancy in the cases of Wilder and of Mandl.

Richardson, Aub, and Bauer explored the neck of a patient of DuBois with the clinical picture of hyperparathyroidism and after finding no tumor, removed two normal appearing parathyroid glands. The improvement in the condition of the patient which followed this operation was so marked that it indicated that hyperparathyroidism may result from hyperfunction of otherwise normal glands.

Bergman, of Berlin, reported a similar case in which, following studies leading to a diagnosis of generalized osteodystrophia fibrosa the surgeon was not able to find any tumor but did identify four normal parathyroid glands, which he was afraid to disturb.

Duken, of Berlin, basing his conclusion upon the clinical picture adds more cases to the list of those diagnosed as hyperparathyroidism. His patients were the youngest of the series, 1 being 7 years of age and the other 14. A diagnosis of late rickets had been made but from the X-ray and metabolic studies the author made the additional diagnosis of osteodystrophia fibrosa and expressed the belief that the condition was probably due to de-

range of function or to tumors of the parathyroid glands. Palpable tumors similar to those which in other cases had proved to be parathyroid adenomata were noted in the older of his two patients but neither case had been subjected to an operation at the time of his report and his diagnosis had thus not been confirmed. A definite diagnosis by palpation cannot be established between an adenoma projecting from the thyroid and a parathyroid tumor and the presence of a palpable tumor is not essential for the diagnosis as shown by our case.

Intensive metabolic studies in a case of osteomalacia with the effects of treatment over a period of 1 year have recently been reported by Blumgart and his associates. Marked improvement was noted when the patient was given a diet that was rich in vitamin D. When cod liver oil concentrate and ultra violet light were given with adequate amounts of calcium and phosphorus there was calcification of the softened bones and disappearance of all symptoms. On the basis of their results in this case the authors conclude that in their patient osteomalacia was definitely a vitamin deficiency disease.

A review of the symptoms of the patients reported by different writers together with the findings at examination reveals a number

TABLE VI—RÉSUMÉ OF CASES REPORTED

Case	X-ray		Blood studies Mgm Ca and P per 100 c cm serum		Mgm Ca excretion in urine for 24 hrs		Symptomatic improvement
	Before operation	After operation	Before operation	After operation	Before op	After op	
1	Generalized osteoporosis	Improvement	None made		54 m m	7.6 mgm 11 days after	Marked (lost 16 kgm in weight in 2 years)
2	Generalized osteoporosis	Patient died in 21 days					Patient died
3	Generalized osteoporosis	No operation					
4	Generalized osteoporosis and cysts	Not reported	13.1	Ca 9.9 after 27 days	4.2 mgm	26.4 mgm 5 days after	Marked (lost 11 kgm 6 m after operation)
5	Generalized osteoporosis and cysts	Marked increase in Ca deposits of bones 2 yrs later	13.1 to 15.3 mgm	4 to 3.2 mgm	No appreciable change	6 to 7 times greater than in normal controls	Marked
6	Generalized osteoporosis and cysts	Improvement	16.1	1.4	Tetany after operation		Marked
7	Generalized osteoporosis	No operation	14 mgm	5 mgm			No operation
8	Generalized osteoporosis and cysts	No operation	20.75 mgm	3 mgm			No operation
9	Generalized osteoporosis	No improvement noted in 2 m	17.6 mgm	2 to 3.3			Yes
10	Generalized osteoporosis and cysts	Improvement (increased density of skeleton)	11.6 to 1.79	1.71 to 2.11	Ca 9.06 (P 1.78 to 7.11) to 9.9	320 to 310	4 mgm (av) 1 week after
11	Generalized osteoporosis and cysts	Marked improvement	19.0 to 3.6		Ca 7.7 to 9.04	322 to 411 mgm	2.2 to 4.8 mgm
12	Generalized osteoporosis	No improvement in 5 mo	11.5 to 12.55	2.81 to 3.72	Ca 6.97 after 2 days to 1.1 after 4 mo	P 4.76 to 5.76	311 (v) 53 (v) during first two weeks after

Metabolic studies showed negative balance in cases of Wilder, DuBois, et al, Barr, Byrd, et al, and in our case. The studies were not carried out in our case. In all except our case the balance became positive immediately after removing the tumor.

the skeletal condition present in our case as osteomalacia.

The rather striking similarity between this entity which Barr and his associates have called hyperparathyroidism and rickets is pointed out by Wilder. Treatment with ultra violet light and a diet rich in vitamin D resulted in marked gain in strength and in weight in his case, improvement of anemia and retention of calcium and phosphorus. He suggested that a rôle of vitamin D is the inhibition of the activity of the parathyroid glands. This hypothesis is given additional support by the reports of Starlinger and Blumgart of great improvement in cases of osteomalacia through administration of irradiated ergosterol or of diets rich in vitamin D

and ultra violet light therapy. Likewise, Weil has noticed an improvement of patients suffering from osteodystrophia fibrosa after irradiation of the parathyroids.

SUMMARY

A case of osteomalacia is reported in which a diagnosis of hyperparathyroidism and tumor of the parathyroid gland was made and confirmed at operation. A second parathyroid was excised and found to be normal.

A resume of 11 other cases which have points of similarity and which have been recently described is briefly discussed.

Symptomatic improvement was noted in our case following removal of the parathyroid adenoma.

TABLE V — RÉSUMÉ OF CASES REPORTED

Case	Age	Diagnosis	Bone cysts reported	Giant cell tumors of bones	Fractures	Tetany after operation	Tumor of parathyroid
1. Mandl	35 Male	Osteitis fibrosa					Adenoma
2. Beck	47 Female	Osteitis fibrosa		Amputation of right leg 4 years before	Left femur	Died in tetany 31 days after operation	Adenoma
3. Bergman	Not given	Osteitis fibrosa					No tumor found
4. Gold	54 Female	Osteitis fibrosa	Yes		Left femur poor union		Adenoma
5. Richardson, Aub and Bauer	34 Male	Osteitis fibrosa	Yes		Several	None	No tumor. Two normal glands removed
6. B. Bulger and Dixon	56 Female	Hyperparathyroidism	Yes	Present healed after operation	Right clavicle Left humerus Healed slowly	Yes severe 3 or 4 days after operation	Adenoma
7. Duken Case 1	7 Female	Late rickets and osteodystrophia fibrosa					No operation
8. Duken Case 2	14 Female	Late rickets and osteodystrophia fibrosa	Yes				No operation Bilateral palpable tumors
9. Boyd Milgram and Stearns	1 Male	Osteomalacia or osteitis fibrosa				Chvostek positive No tetany	Cystic adenoma
10. Wilder	32 Female	Osteitis fibrosa	Yes	Healing followed removal of tumor			Malignant adenoma
11. Snapper	56 Male	Generalized osteitis fibrosa cystica	Yes		Right femur and several others Healed after op	Positive Chvostek and positive Trousseau's Cramp of hands and carpal spasm	Adenoma
12. Our case	59 Female	Osteomalacia				Slight twitching	Adenoma

evidence of healing of the bone cysts was included in these reports. In the case of Boyd and his associates, no roentgenological evidence of improvement was noted 2 months after removal of the parathyroid tumor. In our own case the X-ray appearance of the bones remained unchanged more than 7 months after removal of the tumor.

Giant cell tumors of the bones were noted in the cases of Wilder and of Barr and these were found to be healed within a few months after removal of the parathyroid tumor. In the case of Beck the right leg had been amputated following a diagnosis of sarcoma 3 years before the parathyroid tumor was found. When we consider the presence of giant cell tumors in the cases of Wilder and of Barr we are inclined to suggest the possibility that the lesion of the right leg of the case of Beck which did not recur following amputation

may have been a benign giant cell tumor also.

Based largely upon the X-ray appearance of the bones (Table VI) the diagnosis in 7 of the 12 cases those of Mandl, Beck, Bergman, Gold, Richardson, Wilder and Snapper was generalized osteitis fibrosa or osteitis fibrosa cystica in the cases in which bone cysts were noted. Barr and his associates avoided the issue and made a diagnosis of hyperparathyroidism. Duken classified his 2 cases as late rickets and osteodystrophia fibrosa. Boyd and his associates were undecided whether to call the condition osteomalacia or osteitis fibrosa. Because of the normal appearance of the bone trabeculae, the generalized loss of the calcium salts from the bones, the absence of cyst-like areas, the slight bending of the bones of the weight-bearing extremities and the sinking in of and male type of pelvis we have diagnosed

POSTOPERATIVE PULMONARY COMPLICATIONS AND BRONCHIAL OBSTRUCTION¹

POSTOPERATIVE BRONCHITIS, ATELECTASIS (APNEUMATOSIS) AND PNEUMONITIS CONSIDERED AS PHASES OF THE SAME SYNDROME

JOHN A. CORYLLOS, M.D., F.A.C.S., NEW YORK

Professor of Clinical Surgery, Cornell Medical College

IT is the aim of this paper to show the very close relation between the postoperative pulmonary complications usually described as postoperative bronchitis, atelectasis, and pneumonia, furthermore to show that these conditions generally follow one another in the order named without clear cut distinctive signs and that they represent evolutionary phases of one and the same postoperative pathological process—bronchial obstruction.

This theory if correct is of far more than theoretic interest. It is of practical importance because it is only with exact knowledge of the etiology and interrelation of these postoperative complications that we shall be able to establish a rational curative treatment based not on the symptoms but on the causes and furthermore that we shall be able to introduce efficient prophylactic measures.

The study of massive atelectasis so thoroughly carried out in recent years gives I believe the key to the solution of the important problem of postoperative pulmonary complications—factors of such prime importance to the surgeon.

In his commendable papers Elwyn (46) gives his opinion on the etiology of postoperative pneumonia which in essence is as follows: There is first a partial or total collapse of the lung; if the affected part does not expand within 24 to 48 hours pneumonia may develop depending merely upon the presence or absence of bronchial inflammation and upon the extent and severity of such inflammation. But he concludes: 'This explanation does not entirely solve the problem, it merely puts it back a step further. The question is how does the collapse of the lung arise?' At present we have no answer. It is exactly the purpose of this paper to endeavor to answer this question.

In previous studies on atelectasis and experimental and human lobar pneumonia Coryllos and Birnbaum (27, 28, 29) came to the conclusion that pneumococcus lobar pneumonia is a pneumococcus lobar atelectasis. In support of this view were presented experimental and clinical evidence to show that both conditions are accidents in the course of pneumococcus bronchitis and are due to the obstruction of bronchi by bronchial secretions or exudate. Differences in clinical evolution depend upon the presence, type and virulence of the microorganisms present in the occluding secretion or exudate.

Further study of postoperative complications offered new evidence in favor of this theory. Briefly stated, I believe that because of the stagnation in the bronchial tree of bronchial secretions or exudate after operation a bronchial occlusion may ensue and lead to atelectasis. The size of the obstructed bronchus determines the anatomical distribution of the disease—whether it will be multi-lobar, lobar or lobular. The outstanding factor in the production of these complications would therefore, be *bronchial occlusion and suppression of the free drainage of the pulmonary airways* by means of which normally the lung is maintained in an aseptic condition even though a great number of microorganisms are introduced with the inspired air. When bronchial obstruction is once established the type of complication will depend upon the microbes present in the bronchial exudate: aerobes and anaerobes as pneumococcus, streptococcus, staphylococcus, influenza bacillus, spirochæta, fusiform bacillus, perfringens, etc.—all normally or accidentally present in the upper respiratory tract may play a part. I certainly do not exclude the possibility of postoperative pulmonary complications secondary to large or

¹From the Laboratory of Surgical Research, Cornell Medical College, New York. Received for publication, September 10, 1934.

While removal of the tumors of the parathyroid glands has not resulted in complete recovery in reported cases, the symptomatic improvement, the chemical evidence of increased calcium retention, and the X-ray evidence of increased density of the bones in a few cases followed for a long enough period after operation are results which, as the operative risk is slight, do warrant surgical intervention in cases such as that reported here

Fig 3 Dog B 52 Obstructive atelectasis of middle and inferior right lobes. The obstructing balloon is filled with sodium bromide and it is visible in the right common bronchus. The pulmonary vessels are injected with lipiodol the injection being made into the jugular vein on the living animal. The branches of the pulmonary artery are perfectly injected. There is no difference whatever between the vessels of the healthy (left lung and upper right lobe) and the atelectatic portions of the lung. (Roentgenogram of the lungs extracted from the chest.)

Fig 4 Dog B 57 Experimental pneumonia of the right lower and subcardiac lobes. (Twenty four hours after insufflation through the bronchoscope into the right common bronchus of 10 cubic centimeters of pneumococcus type one culture.) Lipiodol injection on the living animal same technique as in Figure 3. There is no difference between the healthy and consolidated lobes. (Roentgenogram of the lungs extracted from the chest.)

atelectasis. In a recent paper, Lee, Clerf, and Tucker have given a practical demonstration in support of this theory. They cured postoperative atelectasis by bronchoscopic aspiration of the mucous exudate and produced a typical atelectasis in the anesthetized dog by introducing into its right bronchus the material which was aspirated from the patient.

Although it is almost universally conceded that a complete occlusion of a bronchus produces an atelectasis because of subsequent absorption of alveolar air, there is much discussion about the mechanism of the obstruction in postoperative atelectasis. A clear conception of this phase of the problem will go a long way toward solving its difficulties.

In the main, two theories are supported. One is the 'nervous reflex theory' and the other the 'mechanical occlusion of a bronchus by bronchial secretions.' I firmly believe that the key to the solution of the whole

question of postoperative pulmonary complications lies in a clear understanding of these theories, and it will be well worth our effort to discuss their merits fully.

Fig 5 Dog B 76. Roentgenogram of the heart of an atelectatic dog injected with lipiodol through the jugular vein. (Same technique as Figures 3 and 4.) The right heart is filled up with oil, but none passed into the left heart.

Fig. 1 Dog 195 Photomicrograph of experimental obstructive atelectasis. Simple uncomplicated apneumonia. Notice the dilated vessels. Compare with Figure 7.

Fig. 2 Dog 109 Experimental obstructive massive atelectasis. Complicated by pneumonia. Dilated vessels are easily distinguished. Compare with Figure 9.

small emboli. But I believe with Wharton and Pierson (130) that embolism can and should be differentiated from the "inflammatory lesions" with which I am dealing.

Under different headings are to be considered: First, the etiology of postoperative atelectasis and of postoperative pneumonitis; second, a comparative study of their similarities; third, a discussion of the theory proposed; and lastly, an outline of a new prophylactic and curative measures.

ETIOLOGY OF POSTOPERATIVE MASSIVE ATELECTASIS

Massive atelectasis can no longer be considered as a rare postoperative complication. I completely agree with the opinions of Mastics, Spittler and McNamee and Lee Clerf, and Tucker, that the incidence of this complication is not as low as has been stated: 0.6 per cent by Scott and Cutler (8) per cent by Pasteur (99), and 1.3 per cent by Scrimger,

but that it is in its different forms, lobular, lobar or massive, closer to 50 to 70 per cent. I only want to add that a great number of evanescent forms of atelectasis are often undiagnosed when they do not give rise to marked clinical symptoms or are diagnosed as "congestion" or "hypostasis" of the lung.

In a previous paper (29) the different theories for the etiology of this condition were extensively discussed and experimental and clinical evidence was given in favor of the theory of mechanical obstruction of a bronchus by mucous exudate.

This theory first confirmed experimentally by Lichtheim in 1879 and supported by Elliott and Dingley was given clinical proof by the work of Jackson and Lee Tucker Clerf Harrington Hearn and others who by repeated bronchoscopic examinations not only verified the occlusion, but by aspirating the occluding mucus, produced rapid inflation of the diseased lung and cured the

vagal section can lead to a collapse of the smaller bronchi from *paralysis* of their muscular layer

Moore objects to Scafer's opinion on the ground that if it were correct section of the vagus should result in a decrease of tidal air in the corresponding lung. Moore's experiments showed exactly the opposite. Immediately following a right vagotomy the tidal air of the right lung rose to 55 cubic centimeters (from 44) and of the left lung to 72 cubic centimeters (from 56 cubic centimeters), and later to 100 cubic centimeters on the right and 138 cubic centimeters on the left."

3 *Vasomotor reflex theory* Gwyn in 1923 suggested vasomotor disturbance of the pulmonary circulation as a possible cause of atelectasis. Scott and Cutler, after stating that many etiological factors have been proposed but that no primary cause has been found, express their belief that the "process is initiated by a nervous reflex probably largely vasomotor, which results in a narrowing of the lumina of the peripheral bronchioles by venous engorgement, swelling of the mucous membrane, and the elaboration of a tenacious secretion." Among the important factors contributing to the completion of the extent, and the localization of the complication they consider the quantitative changes in ventilation. They believed the diminished ventilation to be not a result but a cause of atelectasis. Lee in 1924, admitted as possible causes, besides obstruction of the corresponding bronchus, "possibly some paralysis or bronchial spasm due to a reflex irritation from other parts in the body." In his more recent paper (Lee with Tucker and Clerf, 1928), he modifies this opinion and considers that "at least the most important factors in the production of apneumatois are 'viscid bronchial secretion and some inhibition of coughing'."

Fontaine, Lenormant and Iselin more recently upheld the same opinion. "Up to this time," says Fontaine "atelectasis has been experimentally produced only by bronchial obstruction. It seems, however, that the pulmonary nerves have a preponderant part in the production of this symptom in the

human. If the direct irritation of the nervous fibres is responsible for massive atelectasis it must act through bronchospasm or reflex vasomotor influence." But he admits that "So far, no definite data have been produced in favor of this hypothesis." Rouillard (1929) does not express any definite opinion although he considers as possible reflex motor disturbances and congestion of the atelectatic lung which could explain the greater opacity of this lung as compared with the simple collapsed lung in pneumothorax. Bowen (1929) in a painstaking paper, containing the most complete historical review of the question, adheres unreservedly to the occlusion theory.

H. Santee and Bergamini and Shepard reported two rapidly fatal cases of bilateral atelectasis and suggested as the cause a vasomotor reflex or an angioneurotic edema, because of the rapid development of the disease, the engorgement of the capillaries, and the absence of bronchial occlusion at autopsy.

Fontaine and Hermann reported the results of experimental extirpation of all the extrinsic nerves to one lung in the dog. It is interesting that of the ten dogs used in their experimental work atelectasis occurred suddenly in only one of them on the third day after operation. No bronchial occlusion was found at autopsy, they conclude that "if there were any reflex responsible for this collapse the impulse must have come by way of the anastomotic branches from the opposite side or they must have originated in the peripheral ganglion of the affected lung." It will be interesting before closing this brief resume of the different reflex theories to report the experimental findings of Einthoven. After section of the vagi he did not notice the slightest modification in the intrapulmonary pressure or any noticeable changes in the cross section of the bronchioles. He concluded that when the bronchial muscles are at rest, the vagi exert little or no tonic effect upon them.

COMMENT ON THE NERVOUS REFLEX THEORIES

The theories attributing atelectasis to *paralysis of the diaphragm* (reflex or organic)

NERVOUS REFLEX THEORY

There is no single nervous reflex theory, different authors describe different reflexes originating at different points, transmitted by different pathways and producing the same result in different ways. They can be classified as (1) the diaphragmatic, (2) the bronchoconstrictor, (3) the vasomotor. I shall give a resume of each of them and then discuss them.

1 *Diaphragmatic and muscular theory.* W. Pasteur considered atelectasis secondary to paralysis of the diaphragm, whereas Briscoe considered it secondary "to a disturbance of the functions of the diaphragm and associated respiratory muscles due to inflammation affecting the retroperitoneal portion of the diaphragm." Soltau and Soltau and Alexander and Watson and Meighan believed that a reflex paralysis of the diaphragm was brought about by afferent impulses being conveyed to the respiratory center from the focus of irritation by way of the vagus, the efferent impulses being conveyed by way of the phrenic nerve. Ball considers diaphragmatic fixation as a possible cause of atelectasis in his case of suppurative pancreatitis with an occluded foramen of Winslow. Bradford suggested spastic contraction of the respiratory muscles as a factor. L. Sante believes that several factors existing simultaneously are necessary for the production of the condition such as inhibition of cough reflex by some toxic reflex stimulus in connection with an impairment of the respiratory function and immobilization of the respiratory muscles from a defense reaction or paralysis from toxic neuritis. This in time permits accumulation of secretion blocking the bronchi and results in atelectasis.

2 *Bronchoconstrictor theory.* The principal defender of this theory is Churchill who in his exhaustive paper concludes that atelectasis is due to a combination of weakened respiratory force and bronchoconstriction. Experimental support of this theory is presented in the work of Dixon and Brodie (16, 17, 36) who enclosed the lung in an oncometer and were able to produce bronchoconstriction or dilatation either by direct vagal stimulation or by means of injected drugs. Under

these conditions they produced either distention or collapse of the lung by varying the force of inflation and the time allowed for deflation. With rapid forceful artificial respiration which allowed only a short time for expiration, bronchoconstriction commonly produced distention. With forceful artificial respiration and intervals sufficiently long to allow full expirations constriction of the bronchioles resulted in collapse. They found that a lobe collapsed in such a manner, usually remained so, even after bronchial constriction had passed off. Churchill compares the condition of postoperative patients to that of experimental animals of Dixon and Brodie (36) because in the former shortened inspiration and prolonged expiration are present. It is to be noted however, that Churchill fully admits the possibility of bronchial obstruction by inflammatory exudate or even normal secretion.

Scott and Joelson consider that atelectasis is generally bilateral and is due to bilateral reflex. "In both lungs they say 'the lumina of the finer air passages are undergoing variation in size resulting from alterations of bronchomotor or vasomotor tone.' But they add, 'the initial reflex is possibly vasodilator in character, and the most striking feature is an extreme pulmonary congestion, almost an angiomatous condition.' In order to explain the transformation from the initial bilateral to a subsequent unilateral atelectasis they suggest that possibly the obstruction becomes complete on the dependent side because 'of greater congestion of the dilated pulmonary capillaries and of a compensatory hyperventilation of the other side which keeps those respiratory passages open. Should such hyperventilation fail to take place bilateral instead of unilateral atelectasis is produced. The above is a combined bronchomotor and vasomotor theory. L. Sante (110) expressed a similar opinion in 1927. 'the cause is not known but it seems most probable that some infection or insult to the region of the vagus supply produces a reflex on the bronchioles permitting their temporary collapse.

As against the reflex bronchoconstrictor theory Scafer calls attention to the fact that

contraction of the bronchial muscles there is no atelectasis but on the contrary an emphysema. In allergic asthma, in anaphylactic shock of the lung in the guinea pig, and in reflex asthma due to irritation of the nasal mucosa, there is always emphysema and not atelectasis. Dixon and Brodie believed that both constrictor and dilator fibers in the vagus supply the lung on the same side only, and only very few crossed fibers exist. Moore, however, proved that cutting one vagus produces a response from both lungs. How then, shall we explain by a bronchoconstrictor reflex the cases of bilateral or contralateral atelectasis, if we accept the first view? How will the cases of H. Santec, Bergamini and Shepard (bilateral atelectasis), and the case of the dog with denervated lung of Fontaine and Hermann be explained? Again if Moore's view is correct, why is the disease lobar and not diffuse and patchy in distribution as it obviously is in cases of emphysema due to bronchoconstriction? For these reasons I believe that bronchoconstriction cannot and should not be considered as a primary cause of massive atelectasis.

3. *The vasomotor reflex.* The last variety of nervous reflex to be discussed has neither clinical nor experimental facts in its support. There is a mere supposition based upon the pathological findings of distended vessels in microscopic sections, upon the two cases of Bergamini and Shepard in which complete bilateral collapse developed while the patient was still on the operating table and upon the cases in which no bronchial obstruction was found at postmortem examination. At first it would seem that the cases of Bergamini and Shepard could not be explained by bronchial obstruction with mucus even if such obstruction were found because complete absorption of the air by the alveolar blood cannot be completed in such a short time. In fact it is known that, although absorption of oxygen and carbon dioxide is completed in a very short time, nitrogen requires 10 to 20 hours. This difficulty however is only apparent. My explanation of the two cases of H. Santec and of Bergamini and Shepard is as follows:

These patients were under deep gas oxygen ether narcosis and breathed in air saturated with ether and nitrous oxide, consequently the rapidity of completion of atelectasis in these two cases would depend upon the absorption coefficient of the gases present in the alveolar air. Teschendorf (1924), studying the time of absorption of different gases in the pleural cavity (where the gases are absorbed by the alveolar capillaries less rapidly than when introduced into the lung), has found that carbon dioxide is so rapidly absorbed that it is impossible to produce a pneumothorax with even 600 or 700 cubic centimeters introduced into the pleural cavity of man. The absorption coefficient of carbon dioxide at 0 degrees C is 1.7967, of ethylene gas, 0.0946, and of nitrous oxide, 1.3052. The absorption of ethylene gas requires a few minutes, and the absorption of carbon dioxide and nitrous oxide is instantaneous. Van Mechelen in his paper "Ether Narcosis" writes: "The diffusion of ether in the blood of the lung capillaries is so rapid that within 2 seconds 95 per cent of even a massive dose of ether is absorbed." After one single inspiration of 500 to 800 cubic centimeters of air containing 39 per cent ether, only 0.2 gram are found in the expired air, the proportion of the absorbed ether is in direct proportion of its concentration in the inhaled air and in the anesthetic mixture the quantity of nitrogen is negligible. These facts give the explanation of the almost instantaneous absorption of the anesthetic mixture in case of bronchial obstruction and of the rapid development of atelectasis, as in the cases of Bergamini and Shepard (7) and the case of Lihenthal. The only remaining argument is that no obstructing plug was found at autopsy. However, it will be shown later that a real "plug" is not necessary to occlude a bronchus and produce atelectasis, but that even a thin secretion may cause this condition if the means of defense of the lung are sufficiently lowered.

So far as the atelectatic dog of Fontaine and Hermann is concerned, I can hardly believe that it presented true atelectasis. The interpretation of the findings in this animal is really puzzling. By a left thoracic incision

I had the opportunity of discussing the above cases personally with Dr. Bergamini who accepted the explanation given here.

or to its fixation, are no longer tenable. It is generally admitted that these conditions can not produce massive atelectasis. In cases of fixed deviation of the diaphragm (as in the case of Ball), we might perhaps have small atelectatic areas, as with pneumothorax or pleural exudate from compression of the lung. But this is totally different from massive atelectasis. It has been demonstrated that from phrenicotomy alone in humans or animals atelectasis does not occur and further more that the elevation of the diaphragm is not the cause of the atelectasis but the effect of it. Corvillo and Burnbaum (5) showed that if in dogs with phrenic nerve sectioned on one side atelectasis by bronchial obstruction is produced on the other side the diaphragm corresponding to the atelectatic lung will rise and even to a higher level than the paralyzed one.

I think for these reasons that the theory of diaphragmatic origin of the atelectasis should be definitely discarded at least as a primary and determining cause.

The reflex bronchoconstrictor theory. As a primary cause of massive atelectasis this theory has no clinical facts in its support. We know for example of no case in which reflex irritation of the nasal mucosa has produced atelectasis whereas this irritation often causes inflation of the lungs and asthmatic attacks. Dixon and Brodie on whose experimental work Churchill bases this hypothesis state that a reflex bronchial constriction is experimentally obtained by exciting the nasal mucous membrane and that little or no result from stimulating the central vagus superior laryngeal, or corneal nerves is obtained. These same authors state that atropine produces paralysis of the bronchial muscles and dilatation of the bronchi. This fact is of importance in connection with the case of postoperative atelectasis reported by Scott (Case 35 of this author) in which 75 milligrams (almost $1\frac{1}{2}$ grain) of atropine was administered within 30 minutes in 3 doses, while the patient was under fluoroscopic examination and atelectasis persisted. Not only was there no decrease in the density of the lung, or the displacement of the heart but on the contrary, rather a slight increase

was noticed. Adrenalin did not have any effect either, although Dixon and Ranson have proved that adrenalin produces an active bronchial dilatation especially marked when an increased tonus of the bronchi is present, the same striking effect should have been noticed in atelectasis if this condition were due to bronchoconstriction,—as occurs in cases of asthma, nor can the view be sustained that bronchoconstriction starts the atelectasis and the bronchioles are subsequently completely obstructed with mucous exudate, as was suggested by Scott and Jocson because in that case why should the bronchioles of one particular lobe only be affected and not of the other lobes? Why is there a characteristic lobar distribution of the disease if spastic contraction or occlusion of the small bronchioles is the cause?

Only a mechanical occlusion of a bigger bronchus supplying the whole lobe can explain the lobar distribution of the disease and a large bronchus cannot be constricted by a reflex or otherwise. Starling (131 p. 897) states that 'under the influence of vagal stimulation or inhalation of carbon dioxide expiration and not inspiration will be rendered more difficult because of the different mechanical conditions of the bronchi during the two phases of respiration. Normally the elastic structure of the lung is pulling upon the bronchial wall tending to maintain it patent and so opposes the action of the bronchial muscles. During inspiration this expanding force is so increased that in the presence of bronchial constriction the ingress of the air is rendered easier the more powerful is the contraction of the inspiratory muscles. On expiration on the contrary all parts of the lung collapse drawn in by the chest wall. The pull of the lung tissue on the bronchial wall is lessened but is still present. If however the respiratory muscles contract vigorously the intrapleural pressure becomes positive and the pull of the lung tissue on the bronchial walls is changed into a pressure tending to obliterate their lumen and so impeding the outflow of air.' This physiological mechanism is fully justified by clinical fact. In hyper-sensitization of the parasympathetic system (vagotonia) with spastic

capillaries would not favor atelectasis, because vasodilation, by increasing the blood supply through the lung, would on the contrary tend to increase the air content of this organ. In a study of "vital capacity in intrathoracic therapy," Yates states that deliveries of blood through bronchial arteries and through the pulmonary arteries are controlled by the functional activities of the lungs which are proportionate to vital capacities. When the air cells are inflated the capillaries are elongated and as they carry the air cells with them inflation is increased. These activities and reactions also take place in reverse order. In other words blood flow and vital capacity follow parallel courses. Whatever may be the objection to this theory of air cell capillary mechanism which is supported by E. K. Dunham, Yates says that the fact remains that, in the normal lung, expansion is accompanied by an increased blood flow through the lungs.

This being the case, how can we reconcile the above facts with the microscopic findings in sections of atelectatic lung where there is to be found dilation of the small vessels? This fact was reported by several authors and verified by ourselves in our cases of experimental atelectasis in dogs (Figs 1 and 2). We think that this contradiction is only apparent, *in fact the impairment of the circulation through the capillaries in atelectasis is progressive and proportional to the degree of absorption of air and of collapse of the alveoli.* The capillaries become more and more retracted as the atelectasis advances and as a result there is stasis in the pulmonary arterioles. What appear to be dilated capillaries in microscopic sections, are, in reality dilated terminal arterioles, the circulation in the capillaries is actually greatly impaired, and the apparent vasodilation is not the cause but the result of pulmonary atelectasis. This was proved by Coryllos and Birnbaum (26) by injecting lipiodol or India ink into the jugular vein of the living animals in which atelectasis was produced. Lipiodol injected into the jugular vein penetrates the small arterioles but not the capillaries of the lung. Ten to forty cubic centimeters of lipiodol (iodized oil) or even more have been

injected into the jugular vein, with survival of the animal from 3 to 10 minutes after the injection. Sufficient time was thus allowed the circulating blood to carry the lipiodol to the lung. Roentgenograms showed the finest details of the arterial tree (Figs 3 and 4), but whereas the right heart was filled with lipiodol no trace was seen in the left heart, although the aorta was clamped for avoiding dilution of the lipiodol (Fig 5), which shows that lipiodol does not pass through the capillaries. If now instead of using lipiodol the living animal is injected through the jugular vein with a 20 per cent solution of India ink in Ringer's solution according to the method of Krogh and Ehrlich, this passes through the capillaries which are readily injected. Microscopic sections show that capillary circulation in the atelectatic lung is markedly impaired and that differences between the healthy and atelectatic lung are conspicuous (Figs 6, 7, 8, 9, 10, and 11). As it is shown in these illustrations, the same procedure applied to the pneumonic lung yielded exactly the same pictures. This is a new and quite unexpected argument in favor of the conception developed by Coryllos and Birnbaum that lobar pneumonia should be considered as pneumococcal atelectasis (27). It throws a new light on the real mechanism of the impairment of the circulation in the consolidated pneumonic lung. From data to be published later with Dr. Birnbaum I can state here that this impairment would be due neither to thrombosis of the capillaries (Riebert, Kline and Wintermütz) nor to the pressure exerted upon the capillaries by the exudate filling the air cells (Binger and Christie), but to retraction of the capillaries due to the collapse of the alveoli. This would explain the rapid reestablishment of the circulation when the lung is aerated again, both in pneumonia and atelectasis, and would offer a new argument in favor of the theory of the close relation between these two diseases.

A last argument against the reflex nervous theory lies in the fact that by rolling a patient back and forth in the treatment of atelectasis, as shown by Sante, a coughing spell is induced and in many instances with the expectoration of thick sputum a clearing up

the entire vagosympathetic supply of the left lung was carefully excised and a piece of the left lung was removed for microscopic study and the pulmonary wound ligated, this fact is not mentioned in the text but it is reported in the legend of the figure. The chest was then closed in an air tight way after inflation of the lung. Three days later the animal was in good condition, it was placed on the table for taking a specimen of blood, suddenly it became cyanotic, very dyspnoic, and died in a very short time. In the roentgenogram (which is not given in his paper) "there were signs of atelectasis but without displacement of the heart or trachea." This absence of displacement was attributed by the authors to the "tearing of the flimsy and nonresistant mediastinum of the dog because of the rapid development of atelectasis." It is difficult to understand how the perfectly elastic mediastinum of a dog can be torn "by the rapid development of atelectasis," it never happened in my experimental thoracic work, but even if such were the case, the heart and trachea should have been displaced just the same, as the mediastinum of the dog normally does not impede the passage of air or fluid through it. The diminution in size of the atelectatic lung is the only factor responsible for the displacement of the mediastinal contents heart and trachea in atelectasis. The only thing the mediastinal membrane itself can do is to resist this displacement, so that with a torn mediastinal membrane the displacement should be even greater. I personally believe that the animal died because of the sudden production of a pneumothorax due to the sloughing off of the pulmonary ligatures in the area from which the lung specimen was taken and this would probably account for the non displacement of the heart to the affected side. Besides it would be very difficult to consider that in the denervated left lung the atelectasis was caused by a vagus reflex transmitted "through the plexus of the right lung" while this latter lung remained completely sound.

Having cleared the way I believe, of these 3 cases, I shall now briefly present what I consider physiological evidence against the so-called "vasomotor reflex."

Brodie and Dixon, in an exhaustive study of the innervation of the blood vessels of the lung came to the conclusion that "pulmonary arterioles possess no vasomotor nerve supply. They have never obtained the least effect upon the pulmonary blood by exciting the white rami communicantes from the upper thoracic spinal nerves, the sympathetic chain between the successive ganglia, stellate ganglion, the annular loop of Vieussens or the inferior cervical ganglion. Stimulation of the fibers at the root of the lung was ineffective. The results were the same in the dog, cat, or rabbit. Stimulation of the vagus was equally without effect, nor were they able to discover any vasodilator fibers to the lung in any of the nerves investigated. According to Starling even if they exist vasomotor nerves to the pulmonary vessels are of little importance.

It is not my intention here to discuss at length this phase of the subject. This question is taken up in detail in a forthcoming paper on the circulation in the atelectatic and pneumonic lung. Weber upholds the existence of vasomotor nerves to the lung, but Krogh has shown that all the "active vasomotor phenomena," supposed by Weber to occur in the pulmonary lobe enclosed in a plethysmograph with its bronchus tied are due to increased or decreased output of the right heart and not to vasomotor nerves. Krogh concluded that "the evidence obtained from Weber's experiments is not favorable to the theory of pulmonary vasomotors." I personally believe that if the atelectasis were due to the mechanical expression of air caused by vessels so greatly dilated as to give the lung "an angiomatous" appearance (Bergamini and Shepard) then that lung should be at least as large and not smaller than the healthy one as it really is in order to produce that mechanical expression of the alveolar air the dilated vessels would have to take the place of the actual alveolar space. Moreover even if reflex vasodilation were possible in a healthy lung inflation and not collapse of the lung would be produced. Vasodilation of the capillaries around the bronchi and narrowing of the bronchial diameter would produce emphysema for the reasons mentioned above, vasodilation of the alveolar

pneumonitis had greatly diminished or even disappeared, the papers of Finsterer Hackenbruch, Reinhard, Roth, and others showed that its frequency and resulting mortality were about the same as with general anaesthesia. Lichtenberg (83), Demmer Planner and Gottstein believed that the incidence was even greater after local anaesthesia.

In the more recent papers of Mindl Cutler and Morton, Cutler and Hunt Whipple, Elwyn (46), Cleveland, etc. the facts mentioned are corroborated. The question therefore, naturally arises as to the etiology and pathogenesis of postoperative pneumonitis.

The principal etiological factors brought forward are Aspiration of septic contents of the mouth, hypostatic congestion, chilling, embolism and retention of mucous secretion in the bronchi.

ASPIRATION PNEUMONITIS

Despite the opinion of Chlumsky Hoelscher and others, it is very improbable that a true aspiration pneumonia exists. I agree with L. Sinte (1928) who says that aspiration alone could hardly explain the condition since patients aspirating barium sulphate through broncho-oesophageal fistulae never develop atelectasis. Likewise postoperative pneumonia is a rarity after tonsillectomy and there is abundant proof of the extreme degree of aspiration which frequently occurs during this operation. It is known that during general anaesthesia or even local anaesthesia of the larynx, much infectious material passes from the mouth into the trachea. Myerson found blood in the bronchi of 75 of 100 cases bronchoscoped after tonsillectomy. Lipiodol passes into the trachea when instilled into the pharynx if the larynx is anaesthetized (Singer). Wessler has shown that aspiration produces suppuration and gangrene of the lung but, as Elwyn (47) points out, aspiration does not explain the occurrence of pneumonia within a day or two of operation and especially of that type of pneumonitis which disappears after 3 to 7 days with no evidence of pus formation. Furthermore, pneumonitis is more frequent after operations upon the abdomen than in operations on the

mouth, head, or neck performed either with general or local anaesthesia, although these procedures do remarkably favor aspiration. In discussing the embolic theory I shall quote respective figures of pneumonitis after operation upon the abdomen and other parts of the body including the head and mouth, which will show clearly that aspiration of septic material, which to my mind constitutes the principal cause of abscess and gangrene of the lung, cannot be considered as the determining cause of postoperative pneumonitis.

PULMONARY HYPOTENSIS

With regard to *hypostatic congestion* (as in bedridden, cachectic patients or patients with advanced diseases of the cardiopulmonary circulation) it might be considered a contributing cause for development of pneumonitis because of the increased bronchorrhoea posture and impairment of the physiological defense of the lung. But to consider it as a determining etiological factor, *per se*, serves rather to confuse than to clarify the situation. Diminished respiratory activity, the recumbent position or wasting illness alone cannot be the cause of postoperative pneumonitis which appears as well in strong young people with healthy cardiovascular systems. I shall only remark that under the same conditions atelectasis was said to develop and a similar discussion has been going on as we have already seen.

EMBOLIC THEORY

The embolic origin of postoperative pulmonary complications has had many staunch supporters. Lichtenberg (84), particularly, stressed its importance. Woller thought that the migration of thrombi from the pampiniform plexuses to the lung was the cause of postoperative pneumonias following the Bassini inguinal hernia procedure. Kelling considered that the great morbidity and mortality of postoperative pneumonia after abdominal operations for carcinoma of the stomach were due to the septic nature of the embolism in these cases. Rupp found at autopsy in 13,000 postoperative cases 5 per cent having demonstrable emboli and infarctions in the lungs. Cutler and Morton in 1917

of the lung rapidly ensues. Sante proposed this mode of treatment, which in several instances has proven successful. It is easy to understand how exudate flowing to dependent parts comes in contact with healthy bronchi and causes a spell of coughing which disrupts the obstructing column of mucus and transforms a complete obstruction into an incomplete one. This process in the mucous column is probably aided by a deep inspiration which follows a cough, because the forceful ingress of respiratory air into the bronchus could thus also create an airway by breaking up the column of mucus. Aeration of the affected lung would thus be initiated. But I do not see the mechanism by which the simple change of the position of the patient could abolish a bronchoconstrictor or a vasodilator reflex, nor can I understand how a reflex phenomenon would require so many hours to be established.

To the procedure advised by Sante can be compared the method used by Boulan and Cheret for prevention of atelectasis. They claim that by placing the patient in slight Trendelenburg position they avoided this complication. This was proved not only clinically but even by roentgenographic examination, the bases remaining clear and well aerated, whereas dark spots or massive opacity appeared in patients left in horizontal dorsal decubitus.

From the foregoing considerations it can be reasonably concluded that the so called vasomotor reflex has no physiological or clinical foundation and cannot be considered as a cause of atelectasis.

COMMENT ON THE THEORY OF BRONCHIAL OBSTRUCTION

The fact that complete bronchial obstruction is followed by atelectasis has already received definite clinical and experimental confirmation, and for the reasons developed above I consider *bronchial obstruction as the only determining cause of the disease*. The difficulties that have stood in the way of determining the etiology and mechanism of atelectasis have been due, I believe to the failure to distinguish between the determining cause and the contributing causes. The

theory of bronchial obstruction applied both to postoperative atelectasis and pneumonia throws a new light on the etiology of both diseases and dispels the cloud hanging over their manner of production. This theory will be thoroughly discussed in dealing with the etiology of postoperative pneumonitis.

ETIOLOGY OF POSTOPERATIVE PNEUMONITIS

The term "pneumonitis" is purposely used here instead of "pneumonia" because in this group, besides well defined lobar pneumonias, we find a great number of transitory forms bronchitides with areas of consolidation, bronchopneumonias with atypical evolution and symptoms and pneumonias with confused symptomatology which may be difficult if not impossible to differentiate. They form a group of postoperative pulmonary complications which still puzzle the internists and surgeons. Their etiology and pathogenesis have been, and still are, subjects of intense research and discussion.

Their importance has been recognized only since the advent of the aseptic era. With the popularization of aseptic methods and general narcosis it was recognized that in the absence of local infection the great majority of postoperative elevations of temperature were due to inflammatory conditions of the lung. At first it was believed that general narcosis particularly with ether was the cause of these pulmonary complications, Mikulicz, Poppert and Czerny in Germany favored this view which was supported by experimental work of Poppert who showed that ether could produce transudation and edema in the lung and by the work of Snell who asserted that ether vapor diminishes or abolishes the bactericidal properties of the lung. Lichtenberg created the special term 'Narcoepneumonie' for indicating this type of complication.

After the introduction of scopolamine morphine anaesthesia and more particularly of local regional and spinal analgesia surgeons were much alarmed on finding no reduction in the incidence or severity of postoperative pneumonitis. And although Neuber, Eiselsberg, Kummel and others had the impression that with these anaesthetics

temperature, without any physical signs until the second or third day after the onset. At this time there develops the characteristic friction rub and non productive cough or with sputum more or less tinged with bright or dark red blood. Following this after the second or third day the condition gradually improves. In the great majority of cases the physical signs are friction rub which is the most reliable symptom present in about 50 per cent of these cases and often impairment of the percussion note. In postoperative pneumonia on the other hand the onset is within 12 to 24 hours after operation is accompanied by cough, dyspnea, often cyanosis, as a rule a rise of temperature, and absence of friction rub, furthermore, the physical signs of consolidation are never absent. Very often the patient gives a history of "previous cold" before operation. The differences between this syndrome and infarction are so marked and so characteristic

that a careful examination of the patient must establish the diagnosis. Cutler and Hunt (31) make this distinction themselves by separating the cases of infarction from other postoperative complications, although I believe that their two cases of postoperative pleurisy seem to be clear cut cases of "minor embolism". The cases of these authors described as pneumonia bronchopneumonia, and bronchitis are I believe, all cases of postoperative bronchitis with atelectatic consolidation. Cutler and Hunt (31) themselves admit this point by stating that the "dividing line between pneumonia bronchopneumonia, and bronchitis is not always clear", out of 55 cases of postoperative pulmonary complications of these authors, 42 are called bronchitis, bronchopneumonia, and pneumonia. No one

and Cutler and Hunt in 1920, in two thorough papers, tried to prove that almost all postoperative complications of the lung were due to embolism. The emboli, according to these authors, are formed in the operative field and from there are carried to the lungs "both by blood vessels and lymphatics." They explain the great number of pulmonary complications after operations upon the upper abdomen by the ease of formation of thrombi in that region because "laparotomy exposes surfaces incised in the outer world and evaporation and chilling take place easily." Furthermore, they believe that thrombi thus formed are easily mobilized and "set free because of the mobility of the structures of the epigastrium and the easy path way to the lung and pleura from the upper abdomen both by the blood vessels and the lymphatics." They quote the experiments of Sabin demonstrating the facility with which lymphatic channels may carry sepsis or emboli from the epigastrium. According to these authors the small thrombi thus formed would be fixed in the lung, particularly in the congested or hypostatic areas of the organ.

Before any discussion of the embolic theory, it will be useful to review our knowledge on pulmonary embolism. Wharton and Pierson in their remarkable work on "Minor Forms of Pulmonary Embolism" state that the clinical aspect of embolism will depend upon four factors: the size of the embolus, the condition of the pulmonary circulation, the presence or absence of infection either in the lungs or the embolus and the position of the artery which was occluded.

We are not interested here with the large emboli which cause immediate death—*la mort sans phrases* of the French authors—or with the medium size emboli which produce a typical infarction. The emboli which are meant by the supporters of this theory as etiological factors in the production of pneumonia or atelectasis are the *minor emboli*.

Let us see now in review the pathological physiology and pathology of the lesions produced in the lung by these "minor emboli." As Karsner and Ash have proved experimentally, the lesions which are produced in the lung by very small emboli vary with the

condition of the circulation in the lung. They will produce significant lesions in the healthy lung "only when they lodge in vessels which are situated along the angular borders of the lobes." On the other hand in the lung with impaired circulation and vascular "stasis" emboli of the same size produce *infarcts* no matter where they lodge, and after 24 hours they produce the complete pathological picture of *infarction* showing hemorrhagic consolidation, pleurisy, and focal necrosis. In normal lungs, the lesions reach their maximum in 24 hours, never pass beyond the state of partial hemorrhagic consolidation, do not develop focal necrosis or pleurisy, and resolution is prompt. Very often minor emboli pass through the lung without giving rise to any lesions or symptoms exactly as happens in experimental embolism in dogs in which even large sized aseptic thrombi introduced into the jugular generally produce no lesion. It is known how difficult it is to produce embolic lesions of the lung in these animals with small or even good sized aseptic and often even with septic blood clots.

In the congested lung in the human, minor emboli according to their nature may produce aseptic or septic lesions. In the former, the pathology will be exactly the same as in infarctions, in the latter, suppuration with septic necrosis may follow. This pathology is very different from that of postoperative pneumonia. Whipple has given an excellent description of the latter and rightly compared it to the mild form of medical pneumonia, known as *maladie de H. oiller*, so well described by Carnere. Maurice Letulle gives a very good resume and photographs of it in his excellent book *Pathologie du Poumon*. Furthermore, the clinical symptomatology of embolism is characteristic, Wharton and Pierson state that the onset clearly distinguishes this form of pulmonary embolism (minor) from the postoperative inflammatory lesions and it is during the first days of the attack that the diagnosis should be made. Infarction occurs late in convalescence after an uneventful week or two, seldom as early as the third or fourth day. The attack occurs suddenly with pleuritic pain below the scapula, tachypnoea, and slight elevation of

Fig 10 Dog 83 Experimental pneumonia Section of portion of the lung not completely consolidated Alveoli and capillaries shrunken capillaries only slightly impaired Notice the presence of dilated vessels (precapillary arterioles) Compare with Figure 7

Fig 11 Dog 83 Experimental pneumonia Complete (gray) consolidation Circulation greatly impaired but not completely stopped Notice the great number of dilated vessels Compare with photomicrograph of Dog 82 shown in Figure 8

If we analyze the case histories of post operative pneumonia bronchopneumonia atelectasis and even more or less complicated bronchitis which all form a well defined group designated by Wharton and Pierson as "inflammatory pulmonary complications" we must conclude that they are certainly 'bronchogenous' and not of embolic origin. There are further arguments in favor of this opinion. First why are these lesions exceptional after operation upon the extremities, the head and even the mouth if they are of embolic origin and so frequent after operations upon the abdomen more particularly the upper abdomen? In 97 cases of pneumonia reported by Whipple 88 occurred after laparotomies. Cutler and his collaborators report that the incidence of pneumonia was 1.12 per cent after operations upon different parts of the body other than the abdomen 4.48 per cent after low ab-

dominal operations and 7 per cent and 8 per cent after operations upon the upper abdomen. Mandl's statistics on 1300 cases give 2.7 per cent as the incidence of pneumonia after operations upon the extremities, the head the mouth and the neck, and 10.5 per cent after upper abdominal operations under general anesthesia. Elwyn (46) reports on 0.7 per cent incidence after operation upon the extremities head, mouth, and neck, 6.29 per cent incidence after abdominal operations and 13.8 per cent after gastric operations. Head and Powers presented a clear explanation of these clinical facts by showing the variation of vital capacity after operation. They found that the greatest changes were produced in abdominal operations and the reduction was proportionate to the extent of the procedure and the proximity of the operative field to the diaphragm. The majority of authors who deal with post

Fig 8 Dog 8. Atelectasis. India ink Ringer solution injection through the jugular vein. Specimen of completely apneumatic portion of the lung. Notice that capillary circulation is greatly impaired but not completely suppressed. Dilated vessels (precapillary arterioles) are still more visible than in Figure 7 (Figures 6, 7 and 8 are taken under some enlargement.)

of these cases for the reasons given seems to be secondary to emboli; a careful study of the histories of these cases can leave no doubt about this point. I feel convinced that this fact would have been more apparent had the authors recorded their radiographic findings and the bacteriological examinations of the sputum, particularly for pneumococcus. In order to illustrate this statement I give here the histories of two of their cases. The first is diagnosed as pneumonia; the second bronchopneumonia.

I, a male 48 years of age with left nephropexy, lungs negative before operation. Operation for partial decapsulation and nephropexy were done under ether-oxygen anesthesia. Recovery was good. Twenty-four hours later the temperature was 103.6 degrees, pulse 143, respiration 40. Signs of consolidation were present at the right base. The sputum was negative for tubercle bacilli; white

blood cells on tenth day were 1,000. Recovery was by lysis on the eleventh day.

In female 50 years of age the lungs were normal but the heart showed a soft systolic murmur. Under ether anesthesia an operation was performed for an ovarian cyst. On the first day after operation there were dullness and bronchial breathing at the right base. The temperature was 101 degrees, pulse 100, respiration 38. Two days later consolidation of the entire back was present. There were rales but no dullness on the left side. The sputum was negative for tubercle bacilli but a great number of diplococci were found. She was discharged against advice.

In both cases the onset was within 4 hours of an aseptic operation. The right base was affected in both, in the second the whole right lung 48 hours after the onset. A roentgenogram in this latter case would probably have revealed the signs of atelectasis. Many diplococci were found in the second case. I do not see how these cases can fit into the symptomatology or pathology of embolism.

Fig. 14. Dog 251. Complete left atelectasis 24 hours after blocking left bronchus with balloon. Notice clear triangular area *T* due to encroachment of normal lung upon affected side and presenting a curious similarity to the enormous triangle described by Lord in pneumonia.

Fig. 15. Dog P 27. Left lobar pneumonia 22 hours after insufflation of 1 cubic centimeter of concentrated culture into left bronchus. Notice the clear area at the left base described under Figure 2.

monary artery succeeded in producing a gradual shrinkage of the affected portion of the lung with a noticeable displacement of the diaphragm only a week after and without infarction. Llwyn (46) also discards embolism as a factor in the production either of atelectasis or of postoperative pneumonia. He says that occasionally he has observed cases of pulmonary infarction following operation

but they were definitely diagnosed as such. Among his 89 cases of postoperative pneumonia none could definitely be said to have been caused by embolism from the operative field. Wharton and Pierson protest against the assertion made by authors who consider that the cause of any or almost any postoperative pneumonia is due to 'showers of minor emboli' and insist upon the fact that 'it is as a rule possible to establish a diag-

nosis between embolic lesions and inflammatory pneumonia.

It is not necessary to give further quotations and arguments against the embolic theory. I firmly believe that minor embolism as an etiological factor in postoperative pneumonitis cannot be admitted. It was necessary to insist upon this point in detail because in my opinion the embolic theory should be definitely discarded in order to clear the way for a better understanding of the etiology, nature and treatment of postoperative atelectasis and pneumonitis. In this way only can we avoid unwarranted conclusions concerning the treatment of pneumonitis and atelectasis.

It is not deemed necessary to discuss the opinions that chilling or irritation of the bronchial mucosa by anesthetics can by them

Fig 12 Dog B 47 Twenty four hours after blocking the right bronchus. Complete right atelectasis. Occluding balloon filled up with sodium bromide solution is clearly visible in right bronchus.

operative pneumonitis or atelectasis are not in favor of the embolic theory for either of them. Henle, in 52 autopsies in a series of 143 surgical pneumonias found only 5 cases of infarction. A C Whipple in 7 autopsies of 25 fatal cases of postoperative pneumonitis found no embolism. Furthermore in cases in which pneumonia or atelectasis and embolism existed together it was possible clearly to distinguish one lesion from the other. Churchill reports a case of embolism complicated by atelectasis in which the embolism (sharp pain, rise of temperature, loud crunching friction rub at the right base, blood streaked sputum) was followed after 4 days by signs of atelectasis. This case shows according to Churchill that "even when atelectasis accidentally follows embolism, the two conditions are distinct and can be readily recognized." Conversely, embolism may com-

plicate atelectasis as in Case 5 of Jackson and Lee. A colored man with primary carcinoma of the esophagus and extensive metastasis in the liver died suddenly after a sharp rise of temperature. At autopsy the findings were "a fresh wedge shaped hemorrhagic infarct in the left lung and complete atelectasis of the right lower lobe." It might be objected that the above facts concern atelectasis and not pneumonia. I shall answer this objection in the next part of this paper where atelectasis and pneumonitis will be compared. However in closing the subject of possible embolic origin of atelectasis I quote Churchill who aptly remarked: "We see no mechanism whereby an embolus can produce pulmonary collapse. Karshner and Ash have not been able to produce immediate deflation of the lung in minor embolism of this organ. Schlaepfer by ligating a branch of the pul-

common in both. It is difficult in their initial periods to distinguish atelectasis from pneumonia or even from bronchitis. As proof I quote the description of postoperative bronchitis given by Cutler and Hunt (32 p. 23): 'The onset of bronchitis is accompanied by cyanosis, excessive perspiration, the chest is often full of moist rales. It starts always within 48 hours after operation and subsides usually by lysis within 3 days to a week.' Cough is not a constant symptom in atelectasis and pneumonia. In a footnote on F. G. Blake's article on pneumonia in which it is said 'Cough is not frequent in the earlier stages of pneumonia. Blumer remarks: 'Turning the patient on the side with the affected side upward so frequently causes cough that I regard it as a diagnostic sign of some importance' (page 9). Is it not common knowledge that exactly the same thing happens in atelectasis? On this latter fact L. Sante based the treatment of rolling the patient back and forth.

Evolution. This is very similar in both diseases and lasts from 2 to 13 days, ending

Fig 19. Case 90744 New York Hospital. Left lower lobe pneumonia from the Medical Ward. Notice displacement of the heart and trachea to the left. Compare with Figure 18.

selves produce postoperative pneumonitis. As to the theories of *passive* or *active congestion* as principal causes the same question arises namely what is the mechanism of production of postoperative pneumonitis in these conditions? A study of the similarities between atelectasis and pneumonia will help us, I believe, to give a satisfactory solution of the problem of their production.

SIMILARITIES BETWEEN POSTOPERATIVE BRONCHITIS, ATELECTASIS, AND PNEUMONITIS

The kinship between these complications—bronchitis atelectasis and pneumonitis—more or less apparent when we study them clinically becomes striking when we investigate them experimentally. As Coryllos and Birnbaum have shown (27) it is impossible in a roentgenogram of a dog's chest to make a differential diagnosis between experimental pneumococcal lobar pneumonia and massive atelectasis. Figures 12, 13, 14 and 15 clearly prove this fact.

There are so many similarities between postoperative bronchitis atelectasis and pneumonitis that they cannot and must not

be considered as coincidences, they require a more careful analysis and investigation than has formerly been given them.

The similarities are *clinical*, *pathological*, and *etiological*.

CLINICAL

Atelectasis and pneumonitis appear within 24 to 48 hours after operations performed particularly upon the abdomen. In the literature the statistics on postoperative atelectasis of W. Pasteur, Armstrong, Scamger, Churchill, Scott (124, 125), Holmes, Mastics et al. (90), Jackson (69), Lee, Leopold (81, 82), Elwyn, Hirschbrock, Rugler, Mason, H. Santee, Bergamini and Shepard, Ball, Roland and Cheret, etc., clearly show a great predominance of abdominal operations as forerunners of the disease. In 134 cases of atelectasis compiled from the literature, the following incidence was found:

	Cases
Appendectomies—septic or aseptic	4
Hernias simple or strangulated inguinal or ventral	36
Gastric or duodenal procedures and exploratory laparotomies	6
Cholecystectomies	17
Hysterectomies or salpingectomies and caesarean sections	17
Thyroidectomies	3
Kidney operations	3
Rectal operations	2
Perineal operation	1
Injury of hip	1
Fracture of cervical spine	1
Fracture of pelvis	1
Tumor of thigh	1
Axillary abscess with streptococcus bacteremia	1
Total	134

It should be borne in mind that these statistics are incomplete since the diagnosis of atelectasis is still relatively infrequently made in the United States and even less frequently at Continental medical centers. It is interesting in this regard to quote Pasteur (101) who in reporting his statistics from the surgical service in Middlesex Hospital, says: "Mr. Simmonds (the surgeon) considers from the description given in the notes that 20 cases regarded as pneumonia were probably examples of massive collapse."

The onset. Within 24 to 48 hours after operation pain and dyspnea, a variable degree of cyanosis and elevation of temperature may appear. The above signs and symptoms are

V S A woman 20 years old gave no history of past or present respiratory infection, and a pre operative roentgenogram of her chest was negative. A left oophorectomy and right salpingo oophorectomy with routine appendectomy were performed for bilateral, multilocular adenocystomata. Ether anesthesia with gas induction was employed. During the operation the respirations were rapid, with excessive mucus. On the evening of the following day there was a sudden rise of temperature pulse and respiration accompanied by dyspnoea. Examination showed a limited excursion of the right chest with flatness to percussion and diminished breath sounds below the clavicle. The heart was displaced to the right. The next day the patient was improved and she raised a small amount of purulent sputum containing pneumococci and streptococci. Sonorous râles were present throughout the lungs and below the angle of the scapula. On the right there were bronchial breathing, egophony, increased voice sounds and normal tactile fremitus. A roentgenogram taken 2 days after the operation showed increased density of the right chest especially at the base and displacement of the heart and mediastinum.

Is not this case diagnosed "atelectasis" strikingly similar to an atypical case of pneumonia of the right base? Auscultatory symptoms of consolidation and pneumococci in the sputum were present. In other cases of the same author, pneumococci types 3 and 4 were found in pure culture. The sign on which the differential diagnosis between atelectasis and pneumonia was based was displacement of the heart and trachea to the affected side. But it has already been shown that this sign may as well be present in pneumonia, particularly in children and it is always present in experimental pneumonia in the dog (Figs 13, 15). At the onset of atelectasis, says L. Sante (119), the condition may resemble lobar pneumonia and "if alveolar absorption takes place rapidly and there is still some obstruction of the bronchi by secretion, displacement of the trachea may be present in pneumonia as a manifestation of atelectasis, under these circumstances lobar pneumonia in the resolving stage cannot be differentiated from massive collapse." Conversely when the upper lobe alone is atelectatic displacement of the heart may be negligible and deviation of the trachea the only symptom. Pratt and Bushnell say (107 p 139) "While the pneumonic process is still localized, the loss of expansibility of

the affected lobe tends to produce a displacement of the heart toward the lesion. Later in the disease when the hepatized lobe has increased in volume, it tends to push the heart away." However, they add, "such displacement is usually not well marked."

E. Jachet found in roentgenographic examinations that "massive atelectasis caused practically the same density of a lobe or the entire side of the chest as that seen in lobar pneumonia" but he adds, "it may be distinguished from the latter by the displacement of the heart to the affected side and elevation of the diaphragm." L. Sante expresses a similar opinion. S. Leopold (82), discussing the differential diagnosis between pneumonia and atelectasis, says, "This is the condition with which massive pulmonary collapse is most frequently confused, as evidenced by the experience of numerous observers who, after having their attention attracted to massive collapse have gone back over their records of 'postoperative pneumonia' and discovered that in some cases the symptoms, the physical findings, and roentgen ray studies, were typical of massive collapse. The symptoms pulmonary physical findings, and leucocytosis may be regarded for clinical purposes as so similar that on these findings a differential diagnosis is impossible. The displacement of the heart and mediastinal structure towards the affected side in case of massive collapse is the diagnostic point of differentiation." The massive degree of involvement in cases of collapse, the absence of the toxicity one would expect in lobar pneumonia particularly in the postoperative type, are of some importance when these cases are considered as a group but could not be very helpful in an individual case."

It would seem from the above that the only diagnostic physical sign between these two postoperative complications atelectasis and pneumonia, is on last analysis the displacement of the heart and the trachea to, and elevation of the diaphragm on the affected side in atelectasis. But even this sign is not at all pathognomonic. In several instances "inexplicable displacement of the mediastinum and its contents to the affected side and elevation of the diaphragm" have

Fig. 20 Right lobar pneumonia in monkey's lung. Posterior view (After Blake and Cecil)

by crisis or lysis. But there are even more striking similarities. The lobar localization in both atelectasis and pneumonia was the one which impressed the writer the most at the beginning of his experimental investigation on atelectasis. Why does this lobar distribution occur in atelectasis and in postoperative pneumonia as well as in medical lobar pneumonia? Little thought about this point and still less explanation of it have so far been given. We shall return to this question later.

The physical signs by percussion and auscultation are no less impressive by their similarities. At the beginning of a pneumonia there are dullness with slight tympanic resonance, and absence of breath sounds. In lobar atelectasis we have these signs throughout the disease. Likewise fine rales, bronchial breathing, and increased fremitus are apt to develop or be absent both in postoperative pneumonia and postoperative atelectasis. J. R. Bradford (13)¹ divides the physical signs of atelectasis into three periods: (1) signs of retraction and immobility of the affected side, weakness or absence of breath sounds,

and displacement of the heart often extreme, (2) weakness of the breath sounds has been replaced by loud tubular or amphonic breathing together with increased vocal fremitus, loud bronchophony, pectoriloquy, and transmitted spoken voice. (3) stage when the lung is expanding abundant rales may be present over the area where tubular breathing is marked.

The same author considers atelectasis as 'a possibility in pneumonia' and reports the autopsy of a case in which there was 'a pneumonia in the upper left lobe and atelectasis in the lower', and further he states that pneumonia may complicate atelectasis and then is limited to the affected lobe. Norris and Landis speak of massive atelectasis as a complication of pneumonia and Reynolds (1871) describing consolidation in newborn children insists on the point that the distribution of the affected lobules is in direct relation to the condition of the corresponding bronchial tubes. It is often impossible from the case histories to differentiate atelectasis from pneumonia. For illustration of the above statements, I give the history of a case called 'atelectasis' (Case 1 Churchill 21)

¹In W. E. Lee: *Ann. Surg.* 1914 LXXX 524

TABLE I—STATISTICS OF MASTICS AND OTHERS

Lobe	Number	Per cent
Right lower	5	50
Left lower	10	20
Right upper	2	4
Left upper	3	6
Right middle and lower	1	14
Right upper and lower	2	4
Right upper and both lowers	1	2

sinks in water. In both pneumococcus particularly group 4, is almost constantly present, and it is curious that this fact has not attracted more attention. Whipple has shown that in postoperative pneumonia "sputum as a rule, is a yellow mucus and usually shows pneumococcus, group 4 in both the pre operative and postoperative specimens. Cleveland expresses the same opinion. In atelectasis the sputum presents the same characteristics.

Churchill reports 9 cases of atelectasis and in practically every one in which an examination of the sputum was made, pneumococcus group 4, was found. In one case pneumococcus, type 3 was present—an unusual finding in postoperative pneumonia.

In the case of Hearn and Clerf which was bronchoscoped seven times within 36 days the secretion contained gram positive diplococci. In the cases of Lee, Tucker and Clerf the mucous secretion obtained by bronchial aspiration contained pneumococci, and when injected into the bronchus of an anesthetized dog, atelectasis was produced. On the other hand, in cases of medical pneumonia in the human, bronchoscoped in the services of Drs. A. Lambert and I. Conner by Dr. J. D. Hearn and myself, we constantly found the bronchus corresponding to the pneumoniae occluded with thick exudate as in atelectasis. After bronchoscopic aspiration of a few centimeters of exudate, often a great amount was expectorated by the patients exactly as in cases of atelectasis (24).

Another argument in favor of the identity of these two conditions is the similarity of localization. Table I shows the statistics of Mastics and others in 50 cases of atelectasis.

In Scott's statistics of atelectasis (40 cases) only the side is mentioned the right side was involved in 31 cases, or 78 per cent the left side was involved in 9 cases or 22 per cent.

TABLE II—STATISTICS OF ELWYN

Lobe	Number	Per cent
Right lower	35	55.5
Left lower	17	28
Both lowers	7	11
Right upper	1	1.5
Left upper and left lower	1	1.5
Right upper and both lowers	2	3.5

Table II shows the statistics on postoperative pneumonia of Elwyn (63 cases, following operations performed under local and general anesthesia).

The comparative study of Tables I and II shows clearly the striking similarities between these two conditions, so far as their localization is concerned.

ETIOLOGICAL

In order to avoid unnecessary repetition we will merely show that in the great majority of cases the two conditions cannot be differentiated from the etiological standpoint. A number of cases taken from different authors will illustrate this point. The following are two cases of Rigler.

CASE 4. Twenty-four hours after a bilateral salpingectomy the temperature rose to 100 degrees. The next day it was 101 degrees and patient had a cough was cyanotic and showed signs of consolidation of the right lung. Roentgenograms showed the right lung opaque, mediastinum markedly displaced to the right. On the third day, the temperature rose to 104 degrees with 15,000 white cells. The crisis occurred 10 days after the onset and 2 days later the right lung was clear and the heart in normal position. Two days later symptoms of empyema developed displacing the heart to the left side.

CASE 5. Typical right massive atelectasis 24 hours after salpingectomy until third day when rusty sputum appeared with distinct signs of consolidation of the right upper lobe. Roentgenograms showed upper lobe pneumonia with haziness of the medium and lower right lobes. There was a marked displacement of the mediastinum to the right and a very high right diaphragm.

Rigler thinks that in these cases pneumonia complicated atelectasis, that the first was a case of typical atelectasis, but because of the empyema which followed 2 days after crisis Rigler presumes that the elevation of temperature from 101 to 104.2 degrees on the third day must have been due to the development of pneumonia as a complication. I

been found in pneumonia Thoenes in 1922 reported 11 cases of lobar pneumonia in which roentgen ray examination showed displacement of the heart to the affected side, more particularly in early life St Engel pointed out that elevation of the diaphragm to the affected side in lobar pneumonia is of common occurrence Wallgren insisted upon displacement of the heart toward the affected side in unilateral croupous pneumonia in children Griffith (54) gives the history of a child less than a month old in which the diagnosis between atelectasis and pneumonia was impossible, and he concludes that lobar pneumonia may at times be capable of producing similar, if not perhaps as marked, roentgen ray appearances as seen in massive atelectasis The same author in a more recent paper (1927) reports 40 cases of pneumonia in young children Sixteen among them presented displacement of the heart to the affected side All the authors mentioned explained the displacement by compensatory hyperdistention of the healthy lung with the exception of St Engel, who is the only one to suggest that "it might be dependent upon a diminution of size of the affected lung caused by a reflex interference with respiration on the side"

Among roentgen ray plates of pneumonia at the New York Hospital obtained through the kindness of Dr W W Belden¹ were found a great number showing displacement of the heart and trachea to the affected side and in almost all, elevation of the diaphragm was found (Figs 16, 17 18 19) In a series of slides of Dr T C Roper¹ (prepared in 1915) dealing with evolution of lobar pneumonia in children, not only did I find displacement of the heart and elevation of the diaphragm to the affected side in practically every one of these, but, furthermore, there was a characteristic return of the structures to their normal sites as the diseased lung healed The roentgenograms given by O T Pickhardt in his paper on "Unresolved Pneumonia" are also of interest in this respect One can clearly see in this author's illustrations displacement of the heart to the affected side and homolateral elevation of the diaphragm (Figs 2

4, 6, and 8) with the return of these structures to normal position after healing of the lesion (Figs 3, 5, 6 13 in the paper of this author)

There is no doubt that displacement is not due to a primary compensatory emphysema or overdistention of the healthy lung compressing the consolidated lung A hyperdistention of the healthy lung certainly exists but this is secondary and due to the decrease in size of the affected lung The view that the pneumonic lung is decreased in size, contrary to what is generally believed and taught in textbooks (Fig 20), is supported by the fact that in uncomplicated lobar pneumonia there is never displacement of the heart toward the healthy side nor flattening of the diaphragm findings which one should expect if the diseased lung were really enlarged The idea that the pneumonic lung is larger has been perpetuated from one textbook to another, and from generation to generation, because the lungs are examined on the autopsy table after their extraction from the thoracic cavity and without the trachea having been previously clamped It is natural that under such conditions with the negative intrapleural pressure eliminated the healthy lung collapses readily whereas the consolidated lung cannot It is easy to verify this fact by removing the lungs of a person shortly after death from pneumonia, after having previously completely occluded the trachea with clamps One should carefully avoid undue manipulation of the healthy lung and proceed with dispatch because the air diffuses through the surface of a healthy lung very rapidly as Lichtheim has shown Figure 27 gives the relative sizes of consolidated and healthy lungs in experimental pneumonia in the dog

Thus the last and only remaining differential or "pathognomonic" sign between atelectasis and pneumonia would seem to be neither pathognomonic nor characteristic of atelectasis as is commonly supposed

PATHOLOGICAL

In the pathological examination we find marked similarities in pneumonia and atelectasis In both conditions the lung is airless, apneumatic consolidated fleshy friable, and

¹Personal communication

the ninth day after operation bronchial breathing was heard over the lower half of the right lower lobe. From this day on the breath sounds gradually became more distinct over the remainder of the lung and the bronchial breathing over the right base gradually diminished. The heart came back to its normal position after some time.

Elwyn (46) considers the above cases as of "uncommon occurrence." I do not agree with this opinion and consider these cases much more frequent than generally believed. If they are not reported more often it is because special attention had not been given to them. In these two cases of postoperative massive atelectasis, the middle and lower lobes were involved because of the occlusion of the right bronchus below the level of the upper bronchus, then because of the dislodgement of the "plug" the middle and lower lobes became aerated, with the exception of that portion of the latter dependent upon the first posterior bronchus which remained occluded. It is of no little importance that the persistence of the occlusion was due to increased virulence of the pneumococci; it is known that viscosity of the exudate and amount of fibrin depend upon the degree of virulence of the pneumococci. The simple atelectasis in that pulmonary territory corresponding to the first posterior bronchus was transformed into lobar pneumonia, or more exactly into a pneumococcal atelectasis because pneumococcal cellulitis developed. This sequence of phenomena was repeated in the second case of Elwyn (46) in exactly the same way.

If in the intrabronchial exudate instead of pneumococcus of low virulence staphylococci, streptococci, or anaerobes were present a suppuration or even gangrene of the lung might have ensued. A good illustration of this is offered by the following case of Churchill and Holmes.

In a female aged 31 years a curettage suspension of the uterus, ovariectomy and appendectomy were done under ether anesthesia. Immediately after there was dry cough and later green sputum appeared. About a month later the sputum became foul. Fourteen days after the onset she was admitted to the Massachusetts General Hospital presenting a dullness at the base of the right lung below the scapula, diminution of vocal and tactile fremitus and of breath sounds. A few moist rales

were present. The sputum was foul, about 7 ounces per day. Bacterial examination showed influenza bacilli and streptococci. Roentgenograms showed the mediastinum displaced to the right and the movements of the diaphragm markedly limited on the right side.

These case histories illustrate the striking similarities between postoperative atelectasis and postoperative pneumonia. They demonstrate the paramount importance in the various suppurations of the lung, of the obstruction of a bronchus with consequent suppression of the normal drainage of the corresponding bronchial tree, such drainage is the natural mechanism for self defense and sterilization of the lung.

THEORY

From experimental and clinical investigation, the conclusion is drawn that there are no differences between postoperative pneumonia and postoperative atelectasis other than those due to the type and the virulence of the micro-organisms infecting the occluding bronchial mucus. I am convinced that the determining factor in the production of this condition is the more or less temporary 'plugging' of a bronchus by mucus, which is followed by the absorption of the alveolar air and atelectasis of the corresponding lung. However the term 'plugged' must not be taken literally—no more so than the term 'corking' used by Chevalier Jackson (71). The obstruction of a lung does not depend only upon the consistency and viscosity of the bronchial exudate. It depends as well upon the expelling force of the lung. Very viscid and tenacious mucus may not be able to obstruct a lung which maintains unimpaired its means of defense, namely coughing, respiratory movements and activity of its ciliated epithelium. The cilia probably help break up the column of mucus and cough expels this mucus from the bronchus. On the contrary, very thin mucus may be able to obstruct a bronchus when the lungs are at a disadvantage—as they often are after operations because of suppression of the cough reflex by narcotics, pain, posture, splinting of the thorax, paralysis of the respiratory muscles or because of general weakness in

cannot agree with Rigler because there are a great number of cases of atelectasis with a temperature of 104 degrees, and more with a 15,000 white cell count. Shall we consider these cases as atelectasis or as pneumonia? We know that in almost every case of atelectasis, pneumococcus is present in the bronchial exudate, and often in pure culture. The fact that the development of pneumococcus empyema is unusual in atelectasis seems surprising and this is due, I believe, to the low virulence of the infecting agent and to the rapid liberation of the bronchi. In Case 5 of Rigler we have the same phenomenon as in the cases of Elwyn (46) given later. In this patient we have a clear cut case of postoperative atelectasis which because of the presence of virulent pneumococci in the exudate occluding the bronchus was transformed into lobar pneumonia. N. B. Gwyn, in 1926, reported cases of atelectasis complicating pneumonia.

CASE 1 A woman 60 years old with lobar pneumonia had complete consolidation of the right lobe. About the fifth day of the disease she was suddenly seized with dyspnea, prostration and cyanosis and the upper lobe which was formerly overexpanded was now apparently solid. The physical signs were those of a newly consolidated area, but the heart was displaced to the right, beating to the right border of the sternum. Clearing began in 6 hours and the heart returned to its normal position in 4 days.

CASE 2 Patient entered with signs of a small area of consolidation at the left base. During the night there occurred an attack of dyspnea and in the morning the involvement seemed more extensive. There was a marked displacement of the heart, the apex was felt in the left axillary line, the left chest was flatter than the right. Roentgenograms showed a typical picture of atelectasis. Healing occurred after a week with return of the mediastinum to its normal position.

CASE 3 A boy of 6 had pneumonia in the left lower lobe. Involvement of the left apex occurred at the end of 2 weeks without added distress. The chest was completely solid, sounds were tubular but varying. From day to day the presence or absence of rales was noted. The left chest was sunken and motionless. The right chest was overdistended and clear. The heart was displaced to the left and upward. The left diaphragm was elevated to the level of the third rib in front. The left lung was very solid behind, puncture gave no fluid. Three days later examination showed that resonance was appearing in the midback and that the heart was

lower in the chest. Roentgen ray picture revealed the heart in normal position, diaphragm lower.

In these cases atelectasis complicated an already existing pneumonia. How would it be possible to explain the pathogenesis of atelectasis in these cases by vasomotor or by reflex nervous obstruction of the bronchioles of the affected lobe or by embolism? I believe that in these cases a temporary obstruction of another bronchus occurred which produced an atelectasis of the lobe corresponding to that bronchus. If, in these cases, the bronchial obstruction had been of longer duration and the pneumococcus virulent enough to produce pulmonary cellulitis instead of simple apneumatoxis, we would have had an ordinary extension of the pneumonic process to the newly affected lobe. Here, on the contrary, has happened exactly what occurs in postoperative atelectasis where, although pneumococcus is present, lobar pneumonia does not develop, because of the rapid liberation of the bronchus from the mucous "plug." This same mechanism can easily explain the production of the so-called abortive forms of pneumonia. This opinion seems corroborated by the fact that pneumonia can complicate atelectasis as is shown in the following cases of Elwyn (46).

CASE 1 The day after a left herniotomy the patient developed a cough and had pain in the right chest. Breath sounds were absent anteriorly and over the right chest and below the third rib. There was marked dullness and diminished breath sounds below the angle of the scapula posteriorly. The heart was displaced to the right. These symptoms persisted for 4 days when dullness, bronchial breathing and rales over the lower half of the right lower lobe appeared. The roentgenograms showed a dense shadow over the lower half of the right lung and the heart and the trachea and mediastinum displaced to the right.

CASE 2 Colostomy was done for carcinoma of the ileocecal junction on June 20. A roentgenogram taken previous to the operation showed the chest to be normal. The same day the temperature rose to 102 degrees. The day following the operation a physical examination showed breath sounds markedly diminished over the lower two thirds of the right lung anteriorly and posteriorly. On percussion there was a tympanic note in front and dullness from the spine of the scapula to the base posteriorly. Roentgenograms on the third day showed heart and trachea displaced to the right and a very high diaphragm on the same side. On

many cases following abdominal operations, we were able to observe signs of consolidation over a part of the lobe, which disappeared in 20 to 48 hours, often during the examination, after a fit of coughing. In some of these cases a roentgen ray examination showed a high position of the diaphragm on the affected side." He considers that atelectatic areas are present most often after abdominal operations and that infection spreads to them due to a bronchitis existing before the operation or caused by the anæsthetic.

It is interesting here to quote Meltzer, who studied the pathogenesis of experimental pneumonia in the dog. He suggests that "in the human a previous cold may furnish a mucus secretion which might occlude several small bronchi and thus prepare a favorable ground for the pneumococci which secondarily infect this mucus secretion, under these circumstances, pneumococci develop rapidly and invade the surrounding tissues. Lee (1924) believed that collapse of the lung in varying degree is a constant phenomenon in any operative procedure and in traumatic or inflammatory injury of the heart and bronchi.

Czerny (34), in 1905, considered as the cause of postoperative pneumonia "retention of bronchial exudate in the bronchi" and created the term "retention pneumonia." The description he gives of it is absolutely identical with that found in "drowned lung" of Leopold (81) in atelectasis.

The relation between pneumonia and atelectasis was seen by these authors, but the nature and importance of this relation had not been grasped. The possibility of secondary infection of an atelectasis, says Ilwyn (46), "does not solve the question, but merely puts it back a step further. The question is how does the collapse of the lung arise?" Scott and Joelson (1927) in a rather prophetic statement, have said "An explanation of the origin of postoperative massive atelectasis will undoubtedly do far more than solve this clinical mystery, since it may prove to be a most important step in reducing the incidence of these fatal postoperative pulmonary complications now classified as pneumonia." But it is really astonishing

that the man who clinically discovered massive atelectasis, W. Pasteur (101), had the clearest foresight as to the significance of atelectasis. "I feel sure," he wrote in 1910, "that when true history of postoperative lung complications comes to be written, active collapse will occupy an important position among the determining causes."

I consider that atelectasis in its different forms multilobar (massive), lobar or lobular (patchy) due to pre operative or postoperative bronchitis, is not only the forerunner of postoperative pneumonia or bronchopneumonia, but that it is an initial and integral part of the disease syndrome. It is a manifestation of the role bronchial obstruction plays in the causation of pulmonary complications. Bronchial obstruction is the starting point of pneumonitis, lobar or lobular, and most probably also of abscess and gangrene as well. The particular condition arising will depend upon the infecting agents. So long as the bronchi are open and their drainage insured, the lung maintains asepsis by the mechanical means at its disposal—evaporation, expectoration, activity of the ciliary epithelium, and the antiseptic power of the mucus (Arling), but when obstruction occurs the fate of the parenchyma depends upon the microbes present in the occluding mucus. If they are of low virulence, there will be a slight degree of inflammation, a slight amount of exudate, and little or no fibrin. The air will be absorbed, and the walls of the alveoli will collapse completely, reducing to a minimum the size of the lung with marked displacement of the mediastinum, heart, and trachea and with elevation of the diaphragm. If the mucus be infected with more virulent pneumococci, then a condition called postoperative pneumonia (postoperative pneumococcal atelectasis) lobar or lobular, will develop. The amount of exudate will be greater and consequently the decrease in the size of the lung less marked and the displacement of the mediastinum less conspicuous. If pyogenic micro-organisms are present (staphylococcus streptococcus influenza bacilli etc.) abscess may result if the occlusion is sufficiently prolonged. If, finally, virulent anaerobes are present, gangrene may ensue.

wasting illnesses bedridden patients, etc. An example of the possibility of bronchial obstruction by thin mucus is given in the case of Harrington.

A man of 28 years was operated upon for right nephrectomy under ether anesthesia. Twenty four hours later typical atelectasis of the left lung appeared and was complete in 4 hours. The left lung was completely opaque the heart and the trachea displaced to the left and diaphragm visible because of the dense shadow. A bronchoscopic examination was made. Upon the introduction of the tube a thin serous secretion poured out of the trachea the consistency of the fluid was not thick as in the case observed by Tucker. Dyspnea and cyanosis subsided immediately after aspiration of the fluid. A roentgenogram taken 15 minutes after showed the heart in normal position and a marked decrease in the pulmonary density.

Pneumococcus is reported practically in every case of atelectasis and postoperative pneumonia in which bacteriological examination has been made. Furthermore, as A. O. Whipple has shown, this *pneumococcus*, group 4 is identical with *pneumococcus* isolated from the mouth of the patients previous to operation. This *pneumococcus* is generally of a low virulence so that the exudate will not be rich in fibrin. Wadsworth has clearly established that the amount of fibrin in the exudate is proportional to the virulence of the organism.

What may be the course of an atelectasis once established? There are various possibilities.

1. During a coughing spell the main column of mucus may be disrupted or expelled and the affected lung is rapidly aerated or there may be a partial expulsion and only partial aeration of the parenchyma. Another coughing spell will evacuate more mucus some bronchi will be freed and so on until the lung is completely aerated. The fact that aeration of the lung proceeds from above downward makes it easy to conceive the "creation of an airway" by disruption of the obstructing mass of mucus and consequent transformation of a complete obstruction into an incomplete one. By a subsequent occlusion of a previously liberated bronchus an already aerated portion may again be obstructed and become atelectatic. This explains the variability of the physical signs

The rapidity of the expulsion of mucus depends not only upon the condition of the patient and the expelling force of his thorax but also upon the amount of fibrin present in the exudate—an amount which we have already said was proportionate to the kind and the virulence of the microbes present. The investigation of Archibald and Brown of cough reflex, and the conclusions drawn by Lee, Tucker, and Clerf concerning the production of bronchial obstruction are of great interest in the elucidation of the mechanism of this obstruction.

2. If the obstruction is prolonged and the virulence of the pneumococci sufficient a pneumococcic cellulitis (as in medical lobar pneumonia) will follow. This in postoperative cases is generally mild and produces a pneumonitis comparable to the mild type of medical pneumonia (called *maladie de Woillez*). In this way the condition starts as atelectasis and continues to develop as pneumonia (cases of Elwyn). When the major part of the mucus exudate is expelled and only a few bronchi remain occluded we will have forms similar to those observed by Rigler (Case 5) with pneumococci in the occluded area becoming more virulent.

3. If the obstructing mucus is infected with pyogenic organisms, suppuration may follow if the obstruction is prolonged. If anaerobes are present gangrene may ensue. The origin of lung abscesses following thoracic resections, bronchopneumonia or pneumonias are due I believe in the great majority to the same mechanism. The abscesses following delayed or unresolved pneumonias are the most characteristic of this group.

Viewed from this angle the problems of postoperative bronchitis, atelectasis and pneumonia are greatly simplified. The relation between them has interested several authors. Elwyn (46) suggested that "the greater number of postoperative pneumonias were due to infection taking place in atelectatic or collapsed areas of the lung. In 194 after a careful study of all operative cases, he says (47) "attention was especially directed toward finding atelectatic areas of the lung in the first few days following the operation. In

to understand that under the combined effect of narcotics, pain, and posture, they are decreased, especially after operation upon the upper abdomen or after thoracic traumatism (J R Bradford) Also, as Head and Powers have shown, the vital capacity decreases considerably after operation on the upper abdomen For the same reasons the lesion appears within 24 hours after operation and clears up as soon as the means of defense of the lung are recovered

From these considerations, we can conclude that prevention of postoperative lung complications should be possible if we could prevent the formation of mucous exudate and the decreased ventilation of the lung especially that of the lower lobes How can this be accomplished? I believe that since the viscosity of exudate is dependent upon the virulence of pneumococcus group 4, every attempt should be made to decrease the virulence of this microbe Careful pre-operative cleansing of the mouth, a preliminary inspection by the dentist, and a mouth wash with optochin, hydrochloride, 1:500, repeated every 3 or 4 hours will be of great help Optochin is a powerful and specific bactericidal against pneumococci The internal use of optochin base has given some encouraging results (Morgenroth and Levy, A E Wright Baldwin and Rhoades, Walter, Cross) With Dr J Cline on the Second Surgical Division of Bellevue Hospital, I experimented with optochin base by mouth and the hydrochlorate salt by rectum, before and for 24 hours after operation without noticing any marked differences with the cases taken as controls I shall not insist upon the necessity to postpone if possible operation in the presence of a common cold or of a sinusitis The importance of these conditions for the development of postoperative pulmonary complications has been sufficiently emphasized (Whipple, Cleveland, Churchill etc)

I should like to lay emphasis upon another therapeutic agent, which seems to me thus far to exert a marked influence in the prevention of postoperative pulmonary complication This is the use of a mixture of carbon dioxide and oxygen, or even air It is not necessary to enter here upon the theo-

retical or experimental detail of this important question The results of the experimental work of Henderson and Haggard, Birnbaum and myself will be given in a paper to appear shortly¹ Suffice it to say that carbon dioxide seems to act in two ways first, by producing hyperventilation of the lungs, it prevents the deficiency in respiratory excursion which follows operation especially on the abdomen and thus provides the alveoli with the necessary amount of air for expulsion of intra bronchial secretion Second, it appears from our experimental data that carbon dioxide by decreasing the hydrogen ion of the exudate acts upon the pneumococcus to inhibit its growth and probably by favoring the proteolysis of the fibrin in the exudate Both of these actions have as an effect, besides the decrease in virulence of pneumococci, the liquefaction of the exudate and its easier expulsion Henderson and Haggard (60) in a preliminary paper insisted upon the importance of the last mechanism The results obtained by Scott and Cutler (1928), Sixe, Dzialoszynski (1927), Fischer (1928), and others show the real importance of this method in prevention of postoperative pulmonary complications

The authors mentioned used the carbon dioxide-oxygen inhalation with the idea of washing out the ether after anaesthesia, following the advice of Henderson and Haggard (62, 1921) and the brilliant results obtained by these authors in the resuscitation of carbon monoxide asphyxias (61, 1922) and alcohol intoxications (63, 1924) Henderson and Haggard (60) believed that prevention of lobar pneumonia in cases of carbon monoxide asphyxias by treatment of carbon dioxide inhalation was due to the rapid elimination of carbon monoxide But they could give no clear explanation of the exact mechanism of this action The experimental work of Coryllos and Birnbaum (27) brought the solution of this problem by showing the relation existing between atelectasis and pneumonia Hyperventilation acts in both diseases by relieving the obstruction, aerating the apneumatic lung and above all by re-establishing a free bronchial drainage

¹This paper has appeared in Arch Int Med 1930 xlv 28

TREATMENT

By the theory thus developed, the pathogenesis of pathological postoperative pulmonary conditions can be explained and the foundation laid for a preventive and curative treatment, based upon sound etiological principles. Bronchial obstruction cannot be produced unless two factors are present. The first is a more or less viscid bronchial secretion and the second the inability of the lungs to expel it. This second factor will depend upon the viscosity of the exudate and the degree of impairment of the means of defense of the lung. Consequently, the elimination of all or one of the factors named if this conception be correct, will prevent or cure postoperative complications of the lung (of non-embolic origin). Let us consider each of these factors separately.

1 *Bronchial secretion* It is known that mucus is abundantly secreted by the innumerable mucous glands of the bronchi (of 1 millimeter diameter and up) as a response to the slightest irritation of the bronchial mucosa, and that it is constantly pushed outward by the ciliary movements. The cilia can propel foreign particles at a rate of 0.5 millimeter per second. Dixon and Inchley described an ingenious apparatus the "ciliometer," by which this rate can be measured with precision. Under normal conditions, the amount of mucus secreted is small and the ciliary movement suffices for its elimination. But with the slightest irritation it increases considerably and its contact in increased amounts with the mucosa of the larger bronchi produces cough which contributes to its expulsion. The expelling force of cough is considerable. For this reason, it is almost impossible to obstruct the bronchi of a dog and produce obstructive lesions if the animal is not completely and deeply anesthetized, and this for several hours after the obstruction. For that purpose Coryllos and Birnbaum (25-29), and Lee Clerf and Tucker used amytal (iso amyl ethyl barbituric acid, Lilly) intraperitoneally for anesthesia in their experimental work. Even then cough was often produced when my obstructing balloon was being inflated in the bronchus, and it was necessary to use a small

piano wire spring device in order to avoid expulsion of the balloon. Deep respiration and thorough aeration of the bronchial airways and the alveoli insure against stagnation or accumulation of mucus with possible occlusion of bronchi. The inspiratory dilation of bronchi, the alternating respiratory currents of air, the ciliary movements, and the expulsive powers of coughing are the usual defenses of the lung against infection. To these must be added the antibacterial properties of the bronchial mucus.

But in case of bronchitis there is, besides increased secretion, a number of other modifications, prominent among which are a hyperemia of the mucosa with a more or less marked degree of edema and subsequent narrowing of the lumina of the bronchi. Moreover and this is to my mind the principal factor, bronchial inflammation allows group 4 pneumococci normally present in the mucosa of the mouth and throat to descend the air tract, their presence modifies the nature of the bronchial secretion, which now becomes richer in fibrin and much more viscid. A vicious circle is thus created, the increased viscosity renders expulsion of bronchial secretion more difficult, and its prolonged contact with the mucosa increases the inflammatory reaction of this membrane and consequently the amount of bronchial secretion. The motility of the epithelial cilia becomes more and more impaired. If now the cough reflex decreases in force or ceases altogether if the amplitude of respiration diminishes and if the patient is immobilized in one position it is easy to understand how bronchial obstruction may occur. The mechanism of cough described by Archibald and Brown gives a clear explanation of the production of patchy lobar or massive atelectasis according to whether the obstruction of a small lobar or common bronchus ensues. At the same time it explains how displacement of this mucus can create an airway and result in a temporary or permanent expulsion of the mucus with a temporary or permanent aeration of the involved lung.

2 *Means of defense of the lung* The means of defense of the lung have already been mentioned. In postoperative cases, it is easy

5 to 10 per cent carbon dioxide and oxygen. If special mixture tubes are not available, a rubber bag is filled with oxygen and carbon dioxide added to it. There is no danger in using mixtures of even 15 per cent carbon dioxide. If a special Henderson and Haggard inhalator (as used by Fire Departments) is available, the valve is fixed at 10 pounds. Immediately after the first few inhalations respiration is modified and respiratory movements become deeper. After a little experience, it is easy to regulate the amount of carbon dioxide and oxygen given, so as to maintain the patient in a condition of deep breathing. It is not necessary to prolong this inhalation over 3 to 5 minutes at a time. Every 2 to 3 hours, when the patient is in the ward, a tube of the mixture or a bag as described above may be used in conjunction with an anaesthesia mask or a nasal catheter, and carbon dioxide-oxygen is given for 2 minutes at a time. At the same time the patient's position is changed, and this, however severe the operation performed upon him may have been. The more severe and prolonged the operation (particularly if abdominal), the greater is the danger of a postoperative pulmonary complication, this later complication is a far greater danger to the patient than is the change in position. In cases in which consolidation has already developed the use of a tent or chamber with continuous oxygen and intermittent carbon dioxide administration is advisable. Finally in the cases of delayed atelectasis or when the lung appears drowned in its secretions and when cough and expectoration are neither present nor can be induced by rolling the patient from side to side, bronchoscopy should be used. It is a bold measure, at least it is considered such at the present time, but it may be a life saving procedure.

If the theory that postoperative bronchitis, atelectasis, bronchopneumonia and pneumonia are simply different stages or manifestations of the same morbid conditions be correct, then the treatment proposed to overcome bronchial occlusion and insure free drainage of the bronchial tree for 48 hours after operation (when the means of defense of the lung are impaired) will enable us to

avoid postoperative pulmonary complications. In cases in which these are already developed, the treatment described, by aiming at the cause of the complication, the pneumococcal (group 4) bronchitis, will help us avoid their extension and hasten recovery.

Experimental data to appear shortly will show that in experimental atelectasis in dogs, if we extract the obstructing balloon and place the animal in an atmosphere of air containing 5 to 7 per cent of carbon dioxide, the lung will be aerated very rapidly (15 to 60 minutes). Dogs with experimental pneumonia appear to have a far lower mortality rate if left in this atmosphere for a time varying from 6 to 36 hours.

It is not difficult to understand the aeration of the apneumatic lung after the relief of bronchial obstruction. But it is not easy to understand how pneumonic and consolidated lung will be aerated under carbon dioxide hyperventilation. This supposes the elimination of the occluding agent in pneumonia and it is precisely this mechanism which remains obscure. This point is now under investigation. We can state at present that under the influence of carbon dioxide inhalation the bronchial exudate appears to lose its viscosity, is transformed into a thin frothy secretion, which is more easily expectorated or aspirated by the bronchoscope or resorbed, and the lung can therefore drain and become aerated. In dogs which after several hours respiration of carbon dioxide 6 per cent air mixture, survive extremely toxic pneumonias, the change was quite rapid, the animals come so rapidly out of the toxic condition that one cannot help being impressed. This experimental work will be given in detail by Birnbaum and myself in collaboration with Henderson and Haggard in a forthcoming paper. At the present time laboratory and clinical investigations allow us to state that this method constitutes a means of preventing postoperative lung complications far more efficiently than any of the methods thus far employed.

The elimination of other factors favoring development of postoperative lung complications, namely narcotics and posture, should not be neglected. The patient's position in bed should be changed often if there is no other contra indication, a moderate Trendelenburg position is desirable. The use of atropine, which very probably after a suppression of secretion renders it more valid should be dispensed with.

Once a postoperative lung complication is established, carbon dioxide inhalation is indicated. We should not forget, however, that the liquefied exudate should be expectorated and the method of L. Sante (119), namely turning the patient on the healthy side several times a day in order to induce cough, must be used. We need not be afraid of the convulsive and the occasional asphyxiating cough which may follow the rolling of the patient upon the healthy side. I have never noticed any untoward effect from such cough. If the condition of the patient is such that he cannot expectorate and if after a reasonable time he does not improve, I consider that there should be no delay in aspirating the bronchial secretion by bronchoscope. We need not fear shock from such a procedure. I have already shown that even in toxic medical pneumonias, there is no shock after a skillfully performed bronchoscopy (24). The number of my cases in which carbon dioxide inhalation has been used as a curative procedure is not as yet large enough to allow definite conclusions to be drawn.

In a recent paper, Binger, Judd, Moore, and Wilder have shown that good results were obtained in the treatment of postoperative pneumonia by the use of oxygen inhalations. Judd and Passalacqua used oxygen inhalations, both as a prophylactic and curative measure. In a group of 180 unselected cases, there was no casualty although 43 patients already had a slight degree of pulmonary congestion and 32 patients had obvious signs of pulmonary consolidation.

From my own experience I consider the carbon dioxide and oxygen method superior to simple oxygen inhalation. The latter prevents anoxæmia whereas the former by increasing the ventilation of the lungs and very possibly by direct action upon pneumococcus and its liquefying effect upon the exudate strikes at the cause and not only at the symptoms of the disease.

TECHNIQUE

The technique I consider quite efficient is as follows. Immediately at the end of an operation (especially abdominal) and independently of the anæsthesia used, the patient breathes a mixture containing approximately

Chart 1 Representative curve of blood pressure, pulse, and respiration. Case 12 Appendectomy. Woman aged 63 years. In this case no supplementary anesthesia was used.

Chart 2 Combined spinal anesthesia and Sodium Amytal. Case 124 Subtotal hysterectomy. Woman aged 43 years. No inhalation anæsthetic necessary. Condition good. Convalescence very pleasant.

spinal anesthesia, smaller amounts must be given, and in these cases it is best to administer the drug by vein because the more rapid action permits more accurate control of the depth of unconsciousness.

Sodium amytal, as described is soluble and it may be administered orally, intravenously, intramuscularly, or by rectum. In all but two of the surgical cases listed in this report, the administration was by vein. By this route the 10 per cent solution at a hydrogen ion concentration of 9.8 should be injected at a rate not exceeding 1 cubic centimeter per minute, the action is immediate. When given intramuscularly the induction is delayed 10 to 40 minutes, but the effect is more lasting. We have never administered the drug intrapentoneally. In one case of intravenous administration where the solution was spilled into the tissues, a very sore arm resulted, so that we have not given any subcutaneously. By mouth and by rectum larger dosage is required.

ACTION

The exact localizing action of the barbiturates is not known. As Isenberger points out they probably act by depressing certain vegetative centers in the hypothalamic portion of

the diencephalon, but this is not established—any more than is the physiology of sleep.

INDUCTION

The induction of sleep is rapid and quiet, almost dramatic. During the intravenous administration of the first 3 to 9 grains the patient may remark that he is feeling sleepy, and if engaged in conversation he begins to slur his words, finally he may yawn, and drop off into a quiet sleep in the middle of a sentence, while the drug is still being given. As contrasted with inhalation anesthetics, we have observed an excitement stage in only one case, that of a chronic alcoholic who sang vulgar songs for several minutes before losing consciousness. Several others experienced brief coughing spells during the induction.

While with 3 to 9 grains the patient is asleep, with a few grains more he seems to be reflexly hypersensitive squirming, though asleep, to the slightest needle prick, thereafter, as the dose is increased, more profound anesthesia is produced.

REFLEX, BLOOD PRESSURE, AND PULSE CHANGES

The pupils become contracted and in some cases fixed so that they will not react to light.

EXPERIENCE WITH SODIUM AMYTAL AS AN INTRAVENOUS ANÆSTHETIC¹

J TATL MASON M.D. F.A.C.S. AND JOEL W. BAKER M.D. SEATTLE, WASHINGTON

From The Mason Clinic

ALTHOUGH for years the barbituric acid derivatives have been used for hypnotic purposes, it has only been since the preparation of the sodium salts of these derivatives that they have been applied in surgical anesthesia. The sodium salts are soluble and are tolerated in doses sufficiently large to be effective.

HISTORY

In 1924, Fredet in France reported the induction of general anesthesia by the intravenous administration of somnifene, and in 1927 Rumm, in Germany, reported the similar use of pernokton, both barbituric derivatives. In this country in 1916 Page and Coryllos by preparing the soluble sodium salt of iso amyl ethyl barbituric acid were able to inject dogs intravenously and intramuscularly to produce anesthetic relaxation. The dogs went "quietly and rapidly to sleep and awoke after a number of hours active and frisky, without nausea or vomiting." Page and Swanson showed iso amyl ethyl barbituric acid, or amytal, to be more effective and less toxic than barbital (Veronal). Subsequently Chambers, Milhorat, Hines and others have studied the effect of sodium iso amyl ethyl barbiturate upon animal metabolism when given in anesthetic doses and their observations are to be found in the literature of the past 4 years.

In February of this year Zerkas and McCallum, of the Medical Research Department of the Indianapolis City Hospital reported the successful induction with sodium iso amyl ethyl barbiturate of general anesthesia in man in about 300 cases and Lundy of the Mayo Foundation, reported in September at the Pan Pacific Surgical Congress 1000 cases surgical and medical, in which this barbituric acid derivative had proved of value. Of these latter cases in the surgical series, however 450 were hemorrhoidectomies in which the acid amytal tablet was given by mouth.

In this paper we wish to report our experience with sodium iso amyl ethyl barbiturate administered to 195 patients.

Amytal is the trade name of iso amyl ethyl barbituric acid. It is marketed in grain and one half tablets for soporific purposes. The sodium salt, on the other hand, i.e. sodium amytal, which is soluble, and with which the following report is concerned, is supplied in pure form, as a crystalline powder with companion ampules of distilled water. When ready for injection the salt is dissolved in the distilled water to give a 10 per cent solution at a hydrogen ion concentration of 9.8. For convenience in this report the sodium iso amyl ethyl barbiturate will be referred to as sodium amytal.

DOSAGE AND ADMINISTRATION

The dosage is still in the experimental stage. The lethal dose for man is unknown. As with all hypnotics, there is an individual susceptibility factor. This to us, seems of greater importance than the weight of the patient in determining the amount the individual should receive. Susceptibility can best be judged just as in giving inhalation anesthetics, by the color, blood pressure, pulse, and respiration changes as the drug is administered. Age and general strength are important considerations. Very old or debilitated patients may fall fast asleep after 3 to 4 grains have been given while young robust patients may require 7 to 9 grains before they lose consciousness. As a general guide in surgical cases we customarily administer double the amount necessary to put the patient barely to sleep. We no longer give over 22 grains to any patient at one time. This maximum dose may be used for surgery about the face, neck, or breasts, where for convenience or other reasons it is desired not to use supplementary anesthetic agents. Where it is desired to produce only a twilight stupor and retain the cooperation of the patient, as in regional and

¹Read before the Washington State Medical Association, Yakima, Wash. 1929. August 29-31 1929 before the King County Medical Society, Seattle, Wash. November 18 1929 and before the Thirty-Ninth Annual Meeting of the Western Surgical Association, Del Monte, Cal. December 12-14 1929.

along with a small amount of ether vapor in order to get sufficient relaxation. In these cases the dosage of sodium amytal has varied from 12 to 22 grains—except in a few very susceptible patients when we first started to use sodium amytal, where the deep cyanosis caused us to cut the dose very low. Since we see but few instances of this initial cyanosis now, we believe it to have been due in these early cases to relaxation and swallowing of the tongue or to an overdose of morphine before hand.

Probably the most satisfactory combination to both surgeon and patient is that of *spinal anæsthesia* and sodium amytal. The spinal anæsthesia relaxing the muscles ideally for the surgeon, the sodium barbiturate making the patient oblivious of the proceedings in the operating room and adding to his postoperative comfort. Unless thoroughly familiar with both sodium amytal and spinal anæsthetics the anæsthetist may find it easier first to establish the level of anæsthesia with the spinal anæsthetic and thereafter administer the sodium amytal, rather than the reverse procedure. For when the sodium amytal is given first the patient often proves hypersensitive and this makes the lumbar puncture difficult. Furthermore in using Pitkin's light spinocain the hypersensitivity necessitates constant guard afterward to prevent the patient from raising his head with consequent danger of respiratory paralysis from ascent of the light spinocain to the medulla. However, with studied judgment, the most satisfactory of all results may be obtained by administering in the room beforehand sufficient sodium amytal to put the patient barely in a twilight stupor such that he is free of anxiety yet can still be aroused to cooperate for the lumbar puncture. Later, after the spinal anæsthetic has set, more of the sodium amytal may be given to put the patient entirely to sleep (Table II).

In our endeavor to give the new drug with anæsthetic properties a fair experimental trial the surgeon has often had to work at a disadvantage because we have withheld auxiliary agents until they were absolutely necessary. In a number of cases the incision has been made and the peritoneum reached under sodium amytal alone, only to find it necessary to hold

up the operation until sufficient relaxation could be obtained with gas and ether. It is necessary, therefore, to understand the limitations of the drug, and to supplement it at the proper time with the proper anæsthetic.

This necessitates that the anæsthetist become familiar with the new combination of anæsthetics. Otherwise many exasperating and occasionally dangerous conditions may occur. The anæsthetist must become accustomed to the changes in the pupillary reactions, in the pulse rate, and in the general muscular tone. New guides to the depth of anæsthesia must be established. In several instances the fixation of the pupils, by preventing their dilatation with the dangerous depth of anæsthesia, permitted the supplementary anæsthetic to be pushed to the point of temporary respiratory cessation before the anæsthetist realized that too much ether had been given. In these cases a little oxygen and a few strokes of artificial respiration restored the patient.

ADVANTAGES

The chief advantage of sodium amytal in surgical management is the way in which it

PRELIMINARY MEDICATION

In all the surgical cases reported we have given morphine sulphate $\frac{1}{16}$ to $\frac{1}{4}$ grain with atropin sulphate $\frac{1}{150}$ grain one hour prior to the administration of the sodium amytal. In one half of the surgical cases we have followed Lundy's regimen of administering chlorotone 10 to 12 grains $1\frac{1}{2}$ hours before hand. In the cases receiving the preliminary chlorotone, sleep was induced with an average of a half grain less of sodium amytal, and the hyperæsthesia seemed to be less marked and of shorter duration. However the reaction time was neither lengthened nor shortened by chlorotone and the incidence of restless reactions was not reduced. We are therefore beginning to question the justification of adding chlorotone to the already complex combination of hypnotic agents.

SUPPLEMENTARY ANÆSTHETIC AGENTS

When we first started to use the drug we knew little about it and from the over enthusiasm of the earlier reports we were led to expect surgical anæsthesia unassisted by other anæsthetics. We soon proved to ourselves that this was inadvisable. As described above the patient becomes hypersensitive after a small dose of the drug then more relaxed as the dosage is increased. But with as large dosage as we feel it wise to use, we have in only 4 cases obtained satisfactory relaxation for abdominal surgery under sodium amytal alone. Two of these were women past 60 years of age and the other two while younger were of asthenic stature and debilitated by chronic illness.

The blood pressure in all but a few of our series fell, the systolic an average of 30 millimeters of mercury, the diastolic an average of 15 millimeters, during the induction of anæsthesia but returned to the normal level early in the operation or else was restored to normal by the administration of ephedrin. In one patient with hypertension and heart block, undergoing an operation for toxic adenoma of the thyroid the systolic pressure fell 100 millimeters of mercury during the administration of the first seven grains of the drug (Charts 1 and 2).

The pulse rate if elevated by emotional excitement was reduced during the induction of anæsthesia. In all other cases however the pulse appreciably quickened after injection of the sodium amytal an average of plus 15 beats per minute. The respirations become shallow and the respiratory rate slightly increased, but in a few cases the respiratory rate fell as low as 12 per minute. The color in all but a few cases has been uniformly good.

The types of supplementary anæsthetics selected are outlined in Table I. In all thyroidectomy cases receiving sodium amytal we have given smaller dosage 8 to 15 grains, in order that the patient might be made to strain and speak at the end of the operation to permit early recognition of hemorrhage or injury to the laryngeal nerves. Hence it had to be supplemented with either local novocain infiltration or light nitrous oxide and oxygen inhalations. For abdominal surgery nitrous oxide and oxygen had to be superimposed in some cases because of the squirming hypersensitiveness of the patient and in other cases

lungs at the end of the operation with the aid of carbon-dioxid-oxygen inhalations is advantageous regardless of the anæsthetic used.

Other complications are listed in Table III. Of the 14 cases in the series with postoperative vomiting, 4 were patients suffering from gall bladder colic, in whom pre operative nausea had been even more marked than was the postoperative nausea. 4 others had had extensive pelvic operations, another was a patient with peritonitis with distention, another had undergone both a cholecystectomy and a Judd operation for peptic ulcer—10 cases in which vomiting was rather to be expected. Of the 4 remaining 2 had had a thyroidectomy, 1 a radical breast amputation, and the last the removal of a stone from the kidney pelvis. All of these except the 2 patients undergoing thyroidectomy and the 1 having the breast amputation received supplementary ether.

The high percentage of catheterizations is deserving of comment. Fifty seven per cent of the females had to be catheterized as against 21 per cent of the males. This may be explained in part by the fact that we have a standing order on the wards for female patients receiving sodium amytal to be catheterized at the end of 12 hours if they have not voided—but for males only if in pain. This is necessary because of restlessness with the relaxed bladder, which cannot empty itself. Three cases of cystitis have resulted with this atonicity of the bladder and catheterization.

In relaxed cases the jaw may droop and the patient be suffocated from swallowing his tongue. So grave a calamity from this source almost befell one of our patients that we now keep a special nurse at the bedside until the patient is fully conscious.

LABORATORY FINDINGS

The following laboratory findings are merely a preliminary report and cannot be interpreted as representative of sodium amytal alone, because supplementary anæsthetics were superimposed upon the sodium amytal in the majority of cases, and because we have no control series of similar tests on patients undergoing operations under other anæsthetics. Before they can be so interpreted similar tests must be correlated to rule out the sepa-

rate influence of surgical shock and of the auxiliary agents used.

In 77 patients the average output of urine for the first 12 hours following operation (calculated from the nearest voiding time) was 315 cubic centimeters, for the first 18 hours 450 cubic centimeters, and in 21 recorded cases for the first 24 hours 630 cubic centimeters. In 72 patients the specific gravity of the first urine voided after the sodium amytal averaged 1.011 as against an average of 1.000 for the morning urine voided before sodium amytal. Alkaline urines became acid after the drug, and urines initially acid remained acid. As pointed out by Zertias, the excretion of urates in the urine is increased. Repeated urinalyses at varying intervals after the drug showed no albumin, casts, or red blood cells.

In 22 patients tested, the average blood urea and creatinin immediately after and 24 hours after the operation under combined sodium amytal and ether anæsthesia showed a slight increase over the fasting level before operation.

In 36 patients the average blood sugar taken immediately after operation under combined sodium amytal and inhalation anæsthesia showed an average increase of 26 milligrams per 100 cubic centimeters over the fasting level before the operation, and an average increase of 27 milligrams per 100 cubic centimeters when taken 24 hours after the sodium amytal. (This series excludes those patients receiving glucose intravenously.) Fifteen of 65 postoperative urines tested gave a positive sugar test. Since we have no blood sugar curves and urine analyses on control cases undergoing operation without sodium amytal and with other anæsthetics used alone, these tests are not conclusive but they do favor support of the findings of Hines, Boyd and Resse. These authors, working with dogs, concluded that sodium amytal interfered somewhat with the glycolytic function of the liver—a point to be remembered in administering the drug.

Red blood counts and hæmoglobin readings taken on 63 surgical patients (a) just before, (b) immediately after, (c) 24 hours after, and (d) 10 days after sodium amytal demonstrated no change except a lowering in two cases complicated by secondary hæmorrhage. Spectroscopic examination was not performed.

sparing the feeling and nerves of the patient. He is put to sleep in his room, remembers nothing of the dreaded trip to the operating room, reacts partially 2 to 13 hours after the so called "hypodermic," remains in a twilight stupor for 24 to 48 hours longer, and in the majority of cases experiences no nausea or vomiting.

Some of the patients who received sodium amy. tal had had previous operations under inhalation anesthetics and to hear their praise of the 'new anæsthetic' makes one appreciate the real anxiety some patients suffer before going to the operating room. All patients in the series were asked before leaving the hospital for their opinion of the sodium barbiturate, and every one of them, even those with restless reactions, was grateful for its administration, and many, especially those having been nauseated by ether at former operations, were enthusiastic in praise. Several patients requiring a second operation requested the sodium amy. tal.

Among its other advantages, only less important is the fact that the amount of inhalation anæsthetic is reduced by one fourth or more, the depth of ether anæsthesia is more constant, and if nitrous oxide and oxygen are used, the increased proportion of oxygen gives the patient a better color. In waiting for pathological reports on frozen sections, the supplementary inhalation anæsthetics may be temporarily discontinued without the patient arousing. It has been brought out that the sodium barbiturates successfully control

the convulsions, vasomotor disturbances, and respiratory difficulty of novocain poisoning and this is another advantage in its combination with local anæsthesia, where every now and then such a reaction has occurred. In breast amputations the shallow respirations facilitate surgery and may serve to diminish bleeding. In using the live cautery about the tongue and face, we have gotten sufficient relaxation without the use of other anesthetics.

DISADVANTAGES AND COMPLICATIONS

Some patients having received the larger dosage become very restless and thrash about the bed and react in a drunken delirium. (This is not true, however, when the drug is given intravenously in small doses.) In the average case of this kind the early administration of morphine and catheterization of the bladder will prove effective. (The bladder loses its tone and cannot empty itself.) Other patients lie motionless so long that there is danger of passive congestion and with the shallow respiration possibility of pulmonary oedema. Pulmonary oedema is the chief complication to be feared. Of two instances in our series one was fatal. This represents the only death in the series in part traceable to sodium amy. tal. The patient was an old luetic man, very toxic and debilitated, undergoing an exploratory operation for obscure abdominal cancer. He received 6½ grains of sodium amy. tal followed by drop ether. Postoperative pneumonia followed within 12 hours, and the patient died 8 hours after the onset, showing no resistance to the infection. Of course a case of this type is always a bad ether risk, and we cannot say that he would not have contracted postoperative pneumonia without the sodium amy. tal. However, sodium amy. tal does depress the respiratory center, and several cases of pulmonary oedema are already on record. It is evident that care should be exercised in the administration of ether to patients who have received sodium amy. tal and particularly in the case of the aged and debilitated. The other case of congestion cleared rapidly with the use of the oxygen tent and caffeine and promotion of deep breathing on the part of the patient. It should be recalled here that hyperventilation of the

was restless and the weakness and tremors consequent to the reduction of morphine did not seem to be helped by the drug

OBSTETRICAL CASES

In conjunction with Doctor Houston Doctor Windom, and others of the hospital's obstetrical staff we are beginning to employ the drug in obstetrical cases, but at present our series is limited to 7 cases, and we can give no opinion of value

CONCLUSIONS

Finally, our present impressions concerning sodium iso amyl ethyl barbiturate in surgical cases are as follows. We have come to employ it as a rapidly acting hypnotic rather than as an anæsthetic to take the place of ether nitrous oxide, novocain, etc. In operations about the nose and in using the cautery about the mouth and neck and in the removal of breasts with the cautery, we believe it of singular advantage, and, as mentioned in these cases supplementary anæsthetics have not been necessary, and sodium iso amyl ethyl barbiturate has served as a complete anæsthetic in itself. But to look upon sodium iso amyl ethyl barbiturate primarily as a hypnotic rather than as an anæsthetic is not to underestimate the advantages of the drug or its contribution to the comfort of the surgical patient. In highly strung patients psychic shock can equal surgical shock, and if by putting such a patient knowingly or unsuspectingly to sleep in his room we can reduce this type of shock we have added materially to

surgical management. We believe that by doing away with the anxiety of the trip to the operating room and the psychic suffocation of the ether mask, as much as by adding to the comfort of the patient after operation the sodium barbiturates have won a lasting place in anæsthesia

In the sodium salts of the barbituric acid series the internist has a more dependable hypnotic and a rapidly acting one as well as a control for eclamptic tetanic and strychnine convulsions. These derivative salts will prove a great asset in relieving pain and insomnia not responding to ordinary measures

We feel that there is no contra indication to the use of this drug where surgical interference is necessary except in case of extreme shock uræmic coma diabetes, or respiratory obstruction. It should be given cautiously to the very aged and to those very susceptible to morphine

We wish to thank Drs G M James H R Wesson and A L Carter for their assistance in administering the drug

MEDICAL CASES

In application to medical cases, as a pure and rapidly acting hypnotic, we believe the sodium barbiturates will prove of greater advantage than in surgery. With Doctors Palmer and Blackford we have studied the use of sodium amytal in 21 cases as listed in Table IV. Some of these received the drug by vein others by mouth and a few by rectum. In some of the cases we repeated the administration every 24 to 48 hours over several weeks time, with no apparent complications and without the patient acquiring a tolerance for the drug.

The case of pernicious vomiting of pregnancy had not improved with isolation, glucose injections, and sedatives. She was relieved for 2 days by the first sodium amytal injection (5 grains). Recurrences of vomiting necessitated repetition of the drug six times over 18 days before the patient was discharged on a full diet. She was a very grateful patient.

A patient with coronary occlusion who had gotten no relief from 2 grains of morphine, was relieved of the agonizing chest pain by 5 hours' sleep with sodium amytal awaking without any pain. A second case seen, not in the throes of the anginal attack but later with marked orthopnea and insomnia was also grateful to the barbiturate for several nights' sleep.

In the case of a primipara at term with rapidly recurring eclamptic convulsions two doses of sodium amytal (each 4 grains) con-

trolled the convulsions. At the time of the first injection pains were fairly strong and were coming every 5 minutes, the cervix was partially effaced but not dilated, and the fetal heart could not be heard. Four hours later a stillborn babe with rigid extremities, apparently dead some hours, was delivered. One hour after delivery the patient was thrashing about the bed, decidedly on the verge of another convulsion, so that although the pulse was weak and the blood pressure could not be read another dose of sodium amytal was given. The patient was quiet after this, and the blood pressure, pulse, and color improved with rest. However, 18 hours later the pulse became imperceptible and the patient expired.

A second patient experiencing several eclamptic convulsions within 12 hours following delivery of her baby had the convulsions controlled by 10 grains of sodium amytal intravenously. She made a recovery.

We have administered sodium amytal intravenously to 2 patients with tetanus. The first, a man in dire extremity with continuous convulsions, died, although the one injection of the sedative controlled the convulsions. The second a boy 12 years of age, admitted to the hospital in his first tetanic convulsion following 21 days after running a nail in his foot had the convulsions controlled by 5 grains of sodium amytal intravenously. The dosage was repeated in 2 hours and several additional times the next 4 days. Meanwhile large amounts of tetanus antitoxin were administered intravenously and intraspinally while the patient slept. This patient made a recovery and on leaving the hospital remembered nothing of his numerous treatments.

In two of the alcoholics we found large amounts of sodium amytal necessary to control the patient and that even then the sleep was only of 4 to 6 hours duration and the reaction violent. In the third alcoholic it produced a long quiet sleep. As an aid in the Townes Lambert treatment of one morphine addict it proved of no definite advantage. The patient slept 8 hours after 22½ grains of sodium amytal by mouth and 7 hours after repetition of the dose—the morphine having been reduced over a 4 day period before this from 5 grains daily to nil. But the reaction

ceivable that a diverticulum which contains all of the anatomical structures of the intestinal wall may form in youth or adult life and that subsequently, because of some muscular defect or inherent weakness, the mucosa protrudes between the muscle fibers and an acquired diverticulum results. Observers are not in complete agreement as to the exact situation of these diverticula in the circumference of the bowel. A cursory examination of the literature reveals wide divergence of opinion as to whether the diverticula occur more particularly in the weakest spot in the intestinal wall, which is opposite the mesenteric border, or whether they are associated more often with openings between blood vessels which come in from the mesenteric side. In the small intestine, acquired diverticula usually are constant in their relationship to the wall of the bowel, developing at the mesenteric attachment or a little above it. Usually they attain the size of about 1 centimeter in diameter, but occasionally they become many times larger. In the colon, on the other hand, diverticula are not constant in their relation to the mesentery, but may be found at any point along the circumference of the wall of the bowel, a fact which has added to the confusion as to etiology, particularly as it is affected by the relationship of the blood vessels and the longitudinal muscle bands. Keith is the chief advocate of the view that intracolonic pressure as evidenced by contracture of the *tæniæ* in the segment of bowel that is host to the diverticula, is the foremost etiological factor. His contention that this results in the formation of circular folds of mucous membrane in the colon, producing obstruction, and resulting in sacculations in the weak spots of the musculature, is not without other advocates, certainly it must be considered among the more satisfactory explanations of the mechanism of production of diverticula. The structural and anatomical influences in the formation of diverticula have received much attention, particularly the relationship of the blood vessels and the longitudinal muscle bands. Drummond called attention to these influences, and his observation that diverticula occur most commonly between the mesentery and longitudinal bands, and that after pene-

trating the muscular coats they follow the shields of the mesentery, has been our clinical experience.

The experimental production of diverticula is extremely difficult because of the conditions under which attempts must be made to reconstruct normal factors as they are in the viable bowel. Chlumsky, Philipowicz, Beer, and others have demonstrated by experiments on intestines of dogs that when injections are made into the small bowel while it still is viable, and before it has been removed from the animal, rupture occurs opposite the mesentery. Just the reverse is true when the bowel has been removed from animals and has been dead for a number of hours, then rupture is into the mesenteric portion. The spaces around the blood vessels, as they enter the mesenteric border of the bowel, are empty and non elastic. Consequently, they do not resist intracolonic pressure in the dead bowel, and their distention by injection of water is not comparable to normal distention, a dead bowel may not be dilated to the size one frequently finds clinically in *volvulus*. Furthermore, experiments of these same workers have demonstrated that the tear in cases of *ileus* usually is from the serosal side toward the mucosa. All of this evidence negatives the theory that the weakest portion of the wall of the bowel is in the mesentery and demonstrates conclusively that just the reverse is true, namely that the point of least resistance is opposite the mesenteric border. Beer in his experiments in 1904, refuted many of the hypotheses already advanced as to the production of diverticula and the relationship of constipation, venous stasis, and so forth, to their formation. He emphasized the fact that the supposed weakness at the mesenteric border does not exist and consequently cannot account for the production of all diverticula. He stated that there is some change in the resistant power of the intestinal wall, and that there is consequent muscular deficiency which probably accounts for the formation of false diverticula. Indeed, this hypothesis must be looked on favorably, since it will explain the production of diverticula in both mesenteric and non mesenteric portions of the bowel. According to his hypothesis, diverticula would

DIVERTICULITIS OF THE COLON¹FRED W. RANKIN, M.D., F.A.C.S., ROCHESTER, MINNESOTA

Division of Medicine, The Mayo Clinic

DIVERTICULOSIS, or sacculations along the lumen of the large bowel, is a condition uniformly asymptomatic save in a small number of cases in which inflammatory reactions are taking place secondary to the irritating processes. Because of obstruction or for other reasons fecaliths may not be discharged into the colon but may remain imprisoned, to cause a condition no longer recognized as unique, namely, diverticulitis.

Anatomically, the acquired diverticulum or diverticula for they are in most instances multiple and may be localized or scattered diffusely throughout the whole length of the large bowel or even throughout the entire gastrointestinal tract represent either a muscular defect or a protrusion of the mucosa through an attenuated spot in the adjacent underlying coats so that there are only two layers in its wall. These two layers are the peritoneum and mucosa, except in the occasional instance in which a true pouch with all the normal intestinal coats develops in adult life and possesses greatly thinned-out coats.

Klebs in 1869 directed attention to the etiological relationship of diverticula to the blood vessels in the intestinal wall. Preceding this contribution, Virchow, in 1853, is credited with having described certain inflammatory areas at the hepatic, splenic and sigmoid flexures of the colon which he termed "isolated circumscribed adhesive peritonitis". His consideration of their sequelae explained the symptoms, although he could not draw a clinical picture of the conditions, he believed that the symptoms usually were interpreted as relating to an inflammation in some other viscus. Graser, in 1898, and Fischer in 1899, again added to the knowledge concerning this condition from material obtained at necropsy. Graser, particularly, emphasized the predominant occurrence of diverticulosis in the pelvic

colon and called attention to the venous congestion without inflammation which occurred in such cases, a view which later experiments apparently has negated.

ETIOLOGY

The cause and method of production of diverticula continue to be controversial subjects, but the factors involved in the inflammatory processes of diverticulitis are most readily explained by obstruction at the neck of the diverticulum and its concomitant failure to empty. Whether or not the majority of diverticula are of the congenital or of the acquired type is not clear, and it seems that they may be designated as true or false just as accurately from the anatomical standpoint. When the sacculation is composed of all of the structures normally found in the wall of the bowel, arranged in normal sequence, true diverticula are the result, such are typified by Meckel's diverticulum or by the vermiform appendix, which is a normal vestigial pouch. Rarely, a diverticulum similar in structure to the true type may develop during the patient's lifetime, thus precluding its classification as congenital but it is usually the result of traction as reports of cases by Neumann, Nauwerck and Hanseemann would indicate. Their rarity makes unnecessary their inclusion in any general classification of diverticula either from the anatomical or the etiological standpoint. Those of the acquired or false type, which occur throughout the gastrointestinal tract may be satisfactorily nominated from the etiological standpoint as either "pull on" or "traction" diverticula. Concerning the traction variety first described by Rokitsky in 1861 and most commonly associated with the small intestine, Klebs deserves the credit for the suggestion that the pull on the bowel, by the mesentery produces the necessary place of lessened resistance. It is con-

¹Read before the Interstate Postgraduate Medical Assembly of North America, Detroit, Michigan, October 23 to 25, 1929.

cess formation or fistula, external or internal. It is not uncommon for a vesico intestinal fistula to result from diverticulitis after an abscess has been formed in the pelvis, or after the thickened sigmoid has become attached to the bladder and the process has extended slowly by necrosis. The abscess formation with localized peritonitis which so often gives rise to symptoms which simulate appendicitis save that they are present on the left side, is perhaps the most common complication of this disease. Rarely does a diverticulum perforate through into the abdominal cavity causing generalized contamination. We have seen this occur, but usually the perforation is slow and walled off and results in local, rather than diffuse, peritonitis. The obstruction which results from diverticulitis is peculiar in that it is due to extrinsic inflammatory reaction and contraction of the underlying coats of the bowel, in contradistinction to that produced by ulcerating carcinoma in which the contraction begins from within and progresses outward. The slow inflammatory change that produces stenosis following abscess formation, or occasionally without it, usually results in a fistula, and in our experience these fistulae have been extremely difficult of closure unless we resected the piece of bowel which contained the stricture. Closure with out resection almost invariably fails.

The exact relation of carcinoma to diverticula is questionable. There is no reason why a carcinoma should not develop in the mucous membrane of the diverticulum and this does happen occasionally but there is little evidence to support the view that carcinoma is the result of diverticulitis. Indeed, the association of the two lesions is so uncommon that one may question the diagnosis of carcinoma in association with diverticulitis except under the most extraordinary circumstances. Occasionally carcinoma and diverticulitis are associated and apparently one is able to demonstrate a carcinoma arising from a diverticulum or engrafted on a diverticulum but the percentage of cases occurring thus is almost negligible. We have several times resected the sigmoid for diverticulitis because there has been recent bleeding from the bowel, in the belief that carcinoma was engrafted on

the inflammatory process. With rare exceptions, we have been unable to demonstrate such a change. The so called mimicry of carcinoma, which diverticulitis has been accused of, is infinitely more theoretic than real. This seems the logical conclusion from a study of the 227 cases of diverticulitis in this series which actually required treatment, co existing carcinoma was found in only 4 cases and during the course of operation for carcinoma of the bowel in 679 cases, diverticulosis was present in only 4. If, in such a large group, the conditions are found co existent in only 8 cases, it seems reasonable to believe that the relationship is incidental rather than significant.

CLASSIFICATION OF DIVERTICULA

In order to evaluate more carefully the significance and importance of diverticula, we have used the following classification

- I Diverticulosis including that group of cases in which evidence of diverticula is found by roentgenographic examination or at necropsy and in which, from all available data the diverticula do not bear any relationship to the patient's complaints
- II Diverticulitis
 - 1 Acute
 - 2 Chronic
 - 3 Complicated
 - a Abscess formation
 - b Fistula
 - External
 - Internal {vesicocolic
enterocolic
 - Multiple
 - c Associated with malignancy

Ordinarily we consider acute, subacute, and chronic diverticulitis to be fundamentally medical problems and the complications essentially surgical. To serve as a basis for study, we have reviewed the cases of diverticula that occurred over a 5 year period, from 1923 to 1928. The patients in 48 cases of diverticulitis came to operation and 179 were treated by medical measures. After reviewing 234 cases in which diverticula occurred but

develop where the muscular weakness is localized to a small area of muscular tissue, the mucosa would be pushed along the lines of least resistance, the weakened muscle bundles parting, and the direction of the sacculation would be the course of least resistance on the mesenteric sides along the veins. He further stated that larger diverticula, likewise, could be explained in this manner, since larger areas of the musculature could be weakened and could allow the passage of the walls into a sac.

That no one factor produces diverticula seems the most likely conclusion of the study of the experiences of the many observers. It seems reasonable to assume, however, that the outstanding features of their formation have to do with inherent weakness of the wall of the bowel, in addition to increased intracolonic pressure, which results from constitutional or environmental causes. Certainly there must be some congenital predisposition in many cases, and undoubtedly obesity, venous stasis, and constipation, with their noxious cycle of intoxication and lowered resistance, play a part. To this one might add the questionable promoting factor of retrograde peristalsis, but with the mental reservation that there is little conclusive proof as to its actual, positive influence. Once the diverticulum is formed it becomes a bottle shaped process, with a narrow mouth and wide body, into which the fecal current projects itself and from which it is released reluctantly. There is consequent inflammatory change secondary to obstruction and stagnation and the rather constant pathological picture.

PATHOLOGY

The pathological processes which occur in the diverticula produce inflammatory changes with complications of perforation, stricture, and fistula in some cases. At first these changes are local, and, as they progress they often become extensive and complicated. One should recall, however, that in most instances diverticulitis does not develop on a basis of diverticulosis and that often, when it does develop, it is more likely than not to run a chronic uncomplicated course. Most often the pathological changes which require intervention or treatment occur in the pelvic por-

tion of the colon and in the rectum, probably because of the stasis which normally the fecal current undergoes in this portion of the large bowel. In addition, the character of the intestinal content, which is formed and hard tends to prevent emptying of the diverticulum, once it is packed, the right side of the colon and the small bowel normally housing fluid content, rarely are subject to impaction, obstruction and inflammation. The local inflammatory changes begin, of course, in the mucous membrane of the diverticulum, which undergoes atrophy, with subsequent round cell infiltration of the submucous coats, and lateral ulceration. These changes progress both in the wall of the bowel and in the mesentery itself, producing symptoms of inflammation or obstruction, according to the amount of encroachment on the lumen from the inflammation, perisigmoiditis, and mesenteritis. The changes in the diverticulum itself are aptly noted by Wilson in a description of a resected specimen, as follows: "The walls of the diverticulum consist of the following coats: (1) mucosa, markedly atrophied around the proximal end of the lumen where pressure has been greatest from the thickened gut walls, and fairly well preserved around the saccular portion, (2) submucosa, a strong fibrous coat, thicker in the proximal than distal portion, (3) muscularis, fibers derived from the circular coat of the sigmoid, and thickened by fibrous infiltration to twice the thickness of the same coat in the normal portion of the sigmoid; the muscularis in the wall, where penetrated by the diverticulum, was much thicker, and (4) a layer of fibrous tissue from the subserosa."

The changes in the coats of the diverticulum vary markedly from attenuation of the musculature to complete absence of musculature in the latter condition. The wall is made up mostly of mucosa and serosa. The chronic thickening of the mesentery, so frequently noted in diverticulitis, is the result of extension of an inflammatory process and at times of perforation into the mesentery. Usually there is marked thickening of the mesenteric attachment as well as contraction and of ten considerable tumefaction. Perforation of the diverticulum may produce local ab-

FIG. 1 Roentgenogram showing diverticula in the descending colon

FIG. 2 Large diverticula of transverse and descending colon

observed. On the other hand, diarrhea alone was present in 35 cases (11 per cent), and although it was not true diarrhea but usually more of a rectal tenesmus with the passage of a small amount of mucus, pus, and fecal material, it gave sufficient disturbance of the intestinal habit to call the patient's attention to its presence. In 2 cases in this series intestinal passage of apparently pure pus occurred, probably signifying the presence of an abscess which had ruptured into the lumen of the bowel in contradistinction to the usual course of penetrating the peritoneal coat.

Tumefaction was noted in 71 cases (31 per cent), and in a larger number a tender, easily palpable sigmoid was observed. Tumefaction more often than not, represents merely a gross inflammatory reaction around segmental diverticulitis. Its mere presence is not a particularly serious circumstance and is not to be construed as indicating the more serious presence of a malignant condition for in only 4 cases in which tumefaction was present was a malignant condition associated. On the other hand unless the tumefaction is

relieved by regression of the inflammatory process, obstruction, abscess, or a fistula is the result.

The presence of blood in the stool in diverticulitis is probably of small significance from a diagnostic standpoint, and although it was noted in 39 of the cases of this series, usually proctoscopic examination revealed the blood originating in the anal canal. In 20 of the cases bleeding was demonstrated to be around the anal canal by proctoscopic examination, and, consequently, in the presence of tumefaction a malignant condition was suspected, but as has been noted was found in only one of these cases. This is important since previously we have been rather inclined to look on bleeding in the presence of tumefaction and diverticulitis as a rather constant sign of a malignant process and have urged exploration on this account. However, we believe that although one should be on one's guard for carcinoma in the presence of diverticulitis particularly if blood in the stool is observed, although it is not a very reliable or trustworthy symptom.

TABLE I — INCIDENCE OF DIVERTICULUM
ACCORDING TO AGE

	Cases	Decades						
		20-29	30-39	40-49	50-59	60-69	70-79	80-89
Clinical series	481	1	19	80	91	154	40	4
Necr pos series	111	1		6	30	41	31	3
Total	592	2	19	86	121	195	71	7
Per cent		0.03	3	15	37	32	10	1

seemed unrelated to any of the patient's complaints, we felt that nothing significant was being shown and discontinued further analysis of diverticulosis. Hence this study includes the 481 cases mentioned, to which are appended figures from the necropsy service for this same period. In order to determine, if possible, the occurrence of diverticula, we secured information that there had been 24,620 roentgenograms of the colon, with a diagnosis of diverticula in 1,398 cases. This would suggest an occurrence of 5.67 per cent but this figure is not entirely accurate as it is all but impossible to make deductions for the number of re-examinations that were made. However in a figure this large, the error probably is not great and the figure may be of some significance because at necropsy of 1,925 cases (1924-1928) diverticula were found in 111 (5.2 per cent). It must not be held that 5 per cent represents the occurrence of diverticula for all ages, but refers more to a group of cases in which, for definite or even vague reasons, the colon was examined. The actual occurrence for all ages is probably less than 1 per cent, as estimated from the finding of diverticula in 2,310 cases in the course of 765,793 examinations (1916-1928).

The situation of the diverticula is of interest. They occur most commonly in the sigmoid, but they may be distributed throughout the colon, usually with decreasing frequency from the left to the right side of the bowel. In the series found at necropsy which is more accurate than clinical observation diverticula occurred in the sigmoid in only 29 per cent, in the sigmoid and other parts of the colon, in 68 per cent, and in any part but not in the sigmoid, in 3 per cent.

The question of the influence or significance of sex is small. In our series of 481 cases, 60

per cent were males, and in the series of 111 cases in which diverticula were found at necropsy, 70 per cent were males. The relation of age to diverticula is illustrated in Table I.

The fact that in the series of 111 cases in which diverticula were found at necropsy, all cases but one were in patients aged more than 40 years as were 461 in the series of 481 cases emphasizes the assumption that in patients aged more than 40 years the incidence of diverticula is about 5 per cent. It is not possible to estimate accurately the incidence of diverticulitis in relation to diverticulosis but an approximate figure may be obtained from the 1,398 roentgenographic diagnoses in which are included 65 additional examinations of the colon of various patients with diverticula. Hence, in about 1,300 cases of diverticula, 27 are considered to be cases of diverticulitis or approximately 17 per cent of the cases of diverticula seem to be productive of symptoms. This percentage obtained from clinical observations, is somewhat higher than that obtained from necropsy for in the 111 cases there were 16 cases of diverticulitis (14 per cent).

SYMPTOMS OF DIVERTICULA

Probably the most common symptom complained of is pain of some kind. Usually it ranges from an intermittent sharp pain probably secondary to formation of gas to a slow boring type of discomfort which is present more or less constantly. There is no typical pain in diverticulitis but the complaint is present in practically every case at some time during the disease. Usually it is situated in the lower left quadrant, or in the lower mid-abdominal section. Its reference depends largely on the accompanying complication which usually is attachment to or perforation of, another viscus. We have seen in the clinic 4 cases in this series in which the pain was referred to the right side but this is extremely unusual. Constipation as one would expect is a rather constant accompaniment of diverticulitis particularly when it has advanced to the complicated stage or when tumefaction with encroachment on the lumen of the bowel is present. In 142 cases (60 per cent of the series), constipation either alone or alternating with diarrhoea which was atypical was

Fig 4. In this patient the diverticulosis involved the entire colon.

Fig 5. Diverticula in caecum, descending colon, and sigmoid.

inflammatory tissue on the lumen of the bowel. Antispasmodic drugs, administered until the physiological effect is obtained, will modify the appearance at least of the former but will have little effect on the latter except to relieve concomitant spasm. These filling defects make the roentgenological differential diagnosis of diverticulitis and carcinoma confusing, but it can usually be accomplished by careful and painstaking observation. Differential points are the somewhat concentric contours of the segment noted in diverticulitis contrasted with the sharply irregular contours in carcinoma, the maintenance of mobility in the former, compared with the stark immobility of the latter and the relatively long segment of colon involved with diverticulitis whereas carcinoma usually involves a much shorter segment.

Proctoscopic examination is of relatively little value in the diagnosis of diverticulitis save when the lesion is extremely low and the distal portion may be visualized. In the medical group of 179 cases, proctoscopic examination was made in 83. Reports were as

follows: 60, negative for abnormality above the anus, 14, immobile or sacculated sigmoid, 4, pelvic mass, and 5, sufficient visualization to allow of a diagnosis of diverticulitis. Proctoscopic examination was made in 36 of the 48 surgical cases, with negative results in 9, immobile sigmoid was reported in 3, sigmoidal or pelvic mass in 9, and diverticulitis in 10.

The blood picture in diverticulitis is of some diagnostic value but is not of great significance. In 11 of the 48 surgical cases, the hæmoglobin was less than 70 per cent, and of these there was carcinoma in 2 cases and an associated bleeding duodenal ulcer in 1 case. Anæmia is an uncommon accompaniment of diverticulitis and when present, indicates usually either a long standing infection or possibly an associated malignant condition.

There is no absolute type of persons more prone to the development of diverticulitis than others, but there is a distinct tendency in a certain group of persons who conform to a common anatomical type: a middle aged man, preferably a physician, inclining toward corpulency and leading a sedentary existence,

Fig 3 Marked spasm proximal to sigmoid with multiple diverticula distributed throughout the sigmoid and descending colon diverticulitis of sigmoid

Symptoms referable to the bladder are common and represent, in most instances, a rather serious complication either attachment to the bladder or attachment to and perforation of the bladder. With a mobile sigmoid, which drops down into the extreme bottom of the pelvis attachment to the bladder is easily accomplished by direct extension of the inflammatory process. Not only is it the most available viscus to become involved but the situation of the involvement, which is usually at the lowest point on the bladder also renders surgical interference which is essential in many of these cases excessively difficult and dangerous. In the surgical group of 48 cases in this series, urinary symptoms were definite in 13 (26 per cent) and in 7 of these there were fistulae into the bladder with the accompanying passage of gas and feces through the urethra. Although this is not always essentially a surgical condition the danger of attending infection from the bladder renders any long standing vesico intestinal fistula a serious condition. The diagnosis of this complication is readily established by

cystoscopic examination, although one should always be able to suspect it from the knowledge of passage of gas or fecal material, or both, through the urethra. In one case of this series there was perforation into the ureter close to its juncture with the bladder and pyuria resulted with a ureterovesico-intestinal fistula.

DIAGNOSIS OF DIVERTICULA

Laboratory aid in the diagnosis of diverticulosis consists chiefly in roentgenological examination (Figs 1 to 5). Since the accurate diagnosis is made only by demonstration of the diverticula, and since their involvement in an inflammatory process gives characteristic roentgenological signs, the roentgenological examination holds first place among diagnostic procedures in the establishment of the diagnosis. In The Mayo Clinic the barium enema observed roentgenoscopically, is used exclusively in these cases, the barium meal is eliminated in an effort, of course, to prevent further intestinal stasis by the introduction of a large amount of barium proximal to the suspected lesion. Diverticula manifest themselves roentgenoscopically and roentgenographically as rounded, knob like projections from the lumen of the colon and show considerable variation in size. The sigmoid segment is the favorite site, and the diverticula become less numerous as the examination proceeds more proximally.

Roentgenological evidence of the presence of diverticulitis consists principally of the signs of extreme irritability that always are present with inflammation of a hollow viscus. These signs are spasm and hypermotility and they vary in intensity with the extent, severity, and virulence of the process. All degrees of spasm are seen from the mild type manifested by a sharp serrated appearance of the haustra in a somewhat narrowed segment of bowel to almost complete occlusion of the lumen. The filling defect almost universally encountered is either of one type or a combination of two types: a false filling defect resulting from spastic narrowing of the affected segment which may be so marked as to produce complete occlusion or a true filling defect resulting from encroachment of pericolic

TABLE II—TYPES OF OPERATION AND CAUSES OF DEATH IN HOSPITAL

Type of operation	Cases	Cause of death	Cases

carefully regulated. It is probable that some of the patients in the large remaining group concerning which later data are not available have suffered further trouble or have even suffered from complications. Yet, we believe that most of them will get along satisfactorily if they persist in the care of the bowels and the use of mineral oil.

SURGICAL TREATMENT

Surgical interference, because of the mere presence of diverticula or even in the early inflammatory stages of the disease, is perhaps not usually indicated and frequently is unwarranted. We believe it more essential to confine surgical operation, in this ailment to chronic complicated cases or to cases of the acute type in which the condition has progressed to perforation. The complications which arise and necessitate surgical intervention are (1) acute perforation, (2) abscess, (3) fistula whether external vesical intestinal or multiple, (4) inflammatory obstruction and (5) malignancy (Figs 6 and 7).

Fortunately acute perforation of a mobile segment of the colon where diverticulitis more frequently occurs is unusual. We have seen it in an occasional case in the clinic but it is less common than perforation into the free peritoneal cavity from carcinoma of the colon. Usually perforation from diverticulitis is not into the free peritoneal cavity but

Fig. 7 Multiple diverticula of the descending colon filled with feces

cause the inflammatory reaction most commonly draws to the sigmoid either loops of the small bowel or fixes the sigmoid to the lateral parietal peritoneum, bladder or anterior abdominal wall. Consequently penetration and abscess more commonly result. In acute perforation, the ideal type of procedure is to remove the offending diverticulum, close the opening and drain the peritoneal cavity. Our experience is small in this type of case and the mortality rate is high. Abscess however is not an infrequent occurrence and demands surgical intervention. Abscess may form against the anterior or lateral parietes and may perforate through the abdominal wall as we have seen it do in one case or it may perforate into a viscus. When it perforates through the abdominal wall a serious condition confronts both patient and surgeon. This usually is the result of long standing inflammation and is accompanied by obstruction from stricture.

We have found in a small proportion of these cases that the most usual operation demanded (Table II) has been removal of the affected sigmoid with end to end anastomosis following drainage by colostomy farther

Fig. 6 Carcinoma of the colon developing in the presence of a diverticulum

in whom with increasing years and a tendency to constipation, a syndrome develops of left sided lower abdominal irritation, possibly pain, and other symptoms associated with advancing inflammatory reaction. This type more often than any other inclines toward diverticulitis.

MEDICAL TREATMENT

The treatment of diverticulitis is preferably medical and usually only when complications occur is operation to be undertaken. The presence of a tumor, especially if associated with obstruction, arouses fear that the trouble is malignant and if the other clinical data, particularly the history do not tend to support the diagnosis of diverticulitis operation must be carefully considered. Medical treat-

ment in acute cases consists essentially of rest in bed, residue free diet at the onset icebags to the lower part of the abdomen and rectal irrigations with hot physiological solution of sodium chloride. As the condition subsides in the course of a few days a bland anticonstipation diet is instituted and mineral oil is given orally. In the use of the mineral oil we believe it preferable to administer only 4 to 8 cubic centimeters three times daily rather than 15 to 30 cubic centimeters once or twice daily. Excessive oil merely leaks through the rectum in many instances and gives rise to the desire to discontinue its use. Used in small doses this objection seldom arises and we consider the constant lubrication of the area of the diverticula of such importance as to necessitate continuation of the oil indefinitely. The hot irrigations are discontinued as soon as the inflammatory reaction subsides and the bowel begins to empty naturally. We are not sure of the value of tincture of bella donna but since it may help to relax the intestinal spasm it is administered in doses of a 0.33 to 1 cubic centimeter three times daily.

On the patient's dismissal constant diligence in the care of the bowels and daily use of mineral oil must be emphasized. Even in cases of diverticulosis this advice is indicated since it may minimize the potential danger of diverticulitis.

Data on the results of medical treatment are meager, of 37 patients who were treated medically only 2 later came to operation. One had gone along without incident for 6 months, only to suffer a recurrence which rapidly resulted in the establishment of a vesical fistula. The second patient had been under observation for 3 years and had been at the clinic several times for treatment of exacerbation of the diverticulitis. Each time the disease subsided but the patient failed to carry out anticonstipation measures at home. The patient wearying of trying to get along elected operation. Two other patients of the 37 had fairly severe recurrences but they were controlled by medical measures. The remaining 14 have been free or practically free of symptoms for 6 months to 7 years. It was not uncommon to have reference made to some pain and distress, if the bowels were not

10 Tumefaction associated with diverticulitis is common and usually is the result of inflammatory reactions, with or without formation of the abscess. In itself, it does not indicate associated malignancy.

11 The medical treatment of acute diverticulitis consists of watchful waiting while the patient is at rest in bed and is given irrigation of the affected segment of bowel with warm sodium chloride solution and other sedative solutions. As the process subsides anticonstipation diet and the use of small doses of mineral oil orally are given. A dietary regimen is highly essential and probably often prevents complications.

12 In a definite percentage of cases, diverticulitis tends to become complicated. The

most common complications are abscess, fistula, and perforation.

13 The treatment of the complications of diverticulitis is usually surgical, particularly of the internal fistulous formation in which a viscus, such as the bladder, is penetrated by the inflammatory process.

14 Primary resection in the face of complications and diffuse inflammation is accompanied by a relatively high mortality rate. The operation of choice is a graded procedure, consisting of drainage and subsequent resection and anastomosis.

15 Often prolonged drainage by colostomy permits complete recession of tumefactions and disappearance of clinical symptoms rendering unnecessary further intervention.

MALIGNANT TUMORS OF THE NAIL BED

R. H. JAFFÉ, M.D., CHICAGO

From the Department of Pathology, Cook County Hospital, and the Uehlein Memorial Laboratory, Grant Hospital.

In malignant tumors the early stages are often masked by a harmless appearance and insignificant symptoms so that they may be overlooked and the best chances for cure are lost. Those afflicted with benign tumors in the course of years become more less accustomed to them so that the transformation to a malignant stage is often overlooked until the new growth has advanced so far that there is little possibility for a successful removal. Beginning malignant tumors not seldom resemble inflammatory conditions and are mistaken for such, especially if they occur in places frequently exposed to slight injuries and, therefore, places in which infections and inflammations are common. This is well illustrated by a pigmented tumor which arises at the border of or beneath the nail. Located between nail and bone with little soft tissue to expand in the tumor destroys the nail and often is still of no considerable size even when the regionary lymph glands or distant organs have become invaded by metastases. Since pigmentation may be slight and secondary infections may change the appearance of the exposed surface, the easily bleeding granular

mass breaking through the nail suggests an innocent granulation tissue until microscopic examination reveals the true nature of the growth.

From a review of the literature it seems that the melanotic tumors of the nail bed are rare. Since the first description by Boyer in 1854 and Demargnay and Monod in 1855 only about 27 cases have been reported (Womack). Hutchinson has called the condition "melanotic whitlow" which indicates both the resemblance to an inflammatory lesion and the pigmentation. The majority of these tumors were found on the fingers, especially on the thumb (13 cases) while on the toes only 4 have been observed, namely 3 on the great toe (Jones 2 cases, Bonnet) and one on the little toe (Chauvenet and Dubreuilh). These tumors are very malignant and usually come under observation after metastases have developed in the regionary lymph glands or in the internal organs.

I recently had the opportunity of examining a characteristic subungual melanoblastoma of the great toe and since so little is known about this tumor and it may so easily

back in the colon, preferably in the transverse colon. Plastic operations usually are of no avail in this complication, and in the presence of acute or subacute inflammation certainly one should not undertake such a formidable procedure as resection. Consequently, it is usually wiser, we believe, to perform a drainage operation and allow the patient to return home for 2 to 4 months applying local treatment to the inflammatory area through the rectum and the colostomy opening. Often the recession is so marked that subsequent removal of the offending segment may be accomplished with little danger. Likewise, in the cases of rather acute diffuse diverticulitis with tumefaction in which one feels that resection should be done because of the extent of the disease and the obstruction present, we have found it most satisfactory to perform a drainage operation and to postpone removal of the lesion for a considerable length of time. In 1 or 2 cases, we have been favorably impressed by the great recession of the growth that has taken place after drainage. In fact we believe that frequently after colostomy has been done in a case of rather diffuse diverticulitis, and after the consequent "side tracking" has been carried on over a sufficiently long period, the recession will be sufficient to allow of omission of subsequent resection. Obviously one must be sure before closing the colostomy opening and abandoning the idea of further operation that there is no obstruction at the primary site of the disease.

Formation of fistula leading into the bowel or the bladder is a serious complication, particularly fistula leading into the bladder. Here the inaccessibility of the two openings makes the surgical procedure extremely difficult. Formerly we were inclined to attempt this type of procedure in one stage, closing the two openings and hoping for primary union. There is always a certain amount of infection around the field and thus a graded operation, namely colostomy first and subsequent attention to the fistula may be done with lower mortality and more satisfactory end results.

When carcinoma is believed to be present even though one may not be absolutely sure of it, resection is indicated. In any case of diverticulitis in which the diverticulum is

suspected of harboring a malignant process the diverticulum should be removed. The type of removal depends on the opinion of the surgeon in many cases, but in our experience a radical operation has been indicated in only a few cases in the presence of inflammation of any extent. The operation of choice is colostomy and subsequent removal of the growth after regression of the inflammatory reaction.

SUMMARY AND CONCLUSIONS

1 Diverticulosis is quite prevalent apparently occurring in about 5 per cent of persons who have symptoms referable to the large bowel but probably actually occurring in about 1 per cent of all persons.

2 Diverticulitis probably occurs in about 17 per cent of cases of diverticulosis and in most instances is chronic in its course and subject to exacerbations.

3 The etiology of diverticula is obscure but they are probably the result of several factors among them inherent muscular weakness in the wall of the bowel and environmental conditions, obesity and constipation.

4 Diverticulitis probably is the result of improper emptying of the bottle shaped sacculations, with subsequent inflammatory reaction, necrosis and occasional perforation.

5 The relationship of diverticulitis to carcinoma probably is incidental rather than actual.

6 In 227 cases reviewed in this paper, as treated at The Mayo Clinic a malignant condition was found associated in four only.

7 Diverticulitis occurs almost entirely in persons of middle age who are inclined to be corpulent and who lead sedentary lives. Diverticulitis usually runs a chronic course with several exacerbations and yields satisfactorily to dietary and medical treatment.

8 The outstanding symptom of diverticulitis is pain usually situated in the lower left portion of the abdomen and is frequently associated with constipation. Change in bowel habit is a confusing factor.

9 Bleeding is not commonly found among the symptoms of uncomplicated diverticulitis or diverticulosis. When it does occur an associated malignant condition is always suspected but frequently not found.

tumor. The latter was covered with a layer of fibrin necrotic cells and degenerated pus cells. In places the tumor tissue bordered directly on stratified epithelium.

The bone was not invaded by the tumor. It appeared rarefied with thin and scanty bony trabeculae and an ample marrow composed of fibrillar connective tissue with perivascular accumulations of plasma cells and lymphocytes (Fig 1).

Histological diagnosis: melanoblastoma of the nail bed. Rarefying osteitis of the terminal phalanx.

The papers dealing with the melanotic tumors of the nail bed say little about the differential diagnosis. There are several benign tumors which occur in this location and which will be discussed later. Occasionally a squamous cell carcinoma may arise in the region of the nail. Its clinical picture resembles that of the melanoblastoma as illustrated by the following case.

SQUAMOUS CELL CARCINOMA OF THE NAIL BED OF THE LITTLE TOE

A Russian Jew, 63 years of age, complained of pains in the little toe of the right foot which had been bothering him for several years. These pains had been present all the time but had become more severe during the past few months. The terminal part of this toe was found transformed into a dry, firm mass and the clinical diagnosis of senile gangrene of the little toe was made. Under local anes-

Fig 3 Subungual squamous cell carcinoma of the little toe. Note on the surface the remnant of the nail and the proliferation of the rete malpighi. $\times 24$

thesia the middle and terminal phalanges were removed. The wound healed *per primam* and the patient left the hospital after 5 days. There were no enlarged glands in the groin or elsewhere.

The specimen consisted of the little toe of the right foot enucleated in the joint between middle and basal phalanx. The nail was replaced by an irregular ulcer which extended over the upper part of the anterior aspect of the toe. The ulcer measured 25 by 12 millimeters in diameter and had slightly raised and scalloped edges. The floor was firm, dry, scaling and of waxy appearance. There were a few pinhead sized depressed areas which were purplish gray in color.

Microscopic examination. The dry and waxy tissue on the surface of the ulcer was revealed to be composed of a thick layer of hornified material which was invaded by degenerated pus cells. This material covered irregular branched and budding papillae which extended deep into the cutis and were surrounded by dense accumulations of lymphocytes and plasma cells (Fig 3). The papillae were composed of cells some of which had still retained their prickly shape while others were polyhedral with large and indented nuclei. There were many atypical mitotic figures. In the center of some of the papillae concentric rings of hornified material were present. The bone appeared unchanged.

Histological diagnosis: squamous cell carcinoma of the nail bed.

Fig. 1 Subungual melanoblastoma of the great toe. The nail bed is the site of a cellular tumor the surface of which is ulcerated. The tumor extends close to the bone which shows rarefaction of the trabeculae and fibrosis of the bone marrow.

be overlooked, a description of it seems to be warranted.

SUBUNGUAL MELANOBLASTOMA OF THE GREAT TOE

A white German woman aged 69 years complained of pain in the right great toe which had been noticed for 3 years. She attributed the pains first to a poorly fitting shoe. During the last year the toe became swollen and bled on several occasions. A physician who saw her about a year ago diagnosed an inflammation of the nail bed, made an incision and prescribed wet dressings. Since the wound did not heal but grew larger the patient went to the hospital for further treatment.

The examination revealed a well nourished woman whose past history is negative except for a rupture of the gall bladder several years ago. According to her knowledge there were no cases of carcinoma in her family. She had 3 children who are living and well. She complained of dyspnoea, shortness of breath, precordial pain and palpitation. The heart was slightly enlarged to the left. Blood pressure was 178/100, pulse rate 92. The urine showed a trace of albumin, a few pus cells and an occasional hyaline cast. Blood count showed red cells 4,800,000, hæmoglobin 75 per cent, white cells 7,400, leucocytes 62, lymphocytes 31, monocyte 5, and eosinophiles 2 per cent.

The nail of the right great toe was almost completely replaced by a soft, dark red and easily bleeding mass. The terminal phalanx was moderately swollen and slightly tender to touch. X-ray examination of the bone was negative. In the right groin there was a mass of enlarged lymph glands, the largest having the size of a hen's egg. Under local anaesthesia the terminal phalanx was removed. The patient had an uneventful recovery and left the hos-

pital after 8 days. The enlarged glands in the groin were treated with deep X-ray therapy and decreased in size. For the last 6 months they have remained stationary.

The specimen consisted of the amputated terminal phalanx of the right great toe. The nail bed was transformed into a roughly oval ulcer 24/27 millimeters in diameter. The edges were sharp, slightly indented and in places undermined for 1 to 2 millimeters. The floor of the ulcer was firm, finely granular of light purplish gray color and was covered with a thin, adherent, light yellow gray membrane. Near the posterior border there was an irregular deep brown line. Of the nail only a small fragment was left. It occupied the posterior medial part of the nail bed and measured 0.5 millimeters in diameter. A longitudinal section through the middle of toe showed the purplish gray tissue of the ulcer extending close to the bone and measuring 10 millimeters in vertical diameter. Its posterior part contained several deep brown areas up to 5 millimeters in diameter.

Microscopic examination. The nail bed was the site of a very cellular tissue extending close to the terminal phalanx from which it was separated by a thin layer of fibrillar connective tissue. Branched septa of connective tissue divided the tissue into spherical areas from 1 to 2 millimeters in diameter (Fig. 1). From the septa delicate fibers and capillary blood vessels extended into the cellular areas and subdivided them either into small irregular alveoli or narrow cords.

The cells of which the tissue was composed were large and of varying shape. They were round or oval or polygonal and by compression often assumed a spindle shape. These spindle shaped cells had the tendency to fascicular arrangement.

The cells possessed an ample clear cytoplasm and large round or oval nuclei. The largest of the cells contained two nuclei. The chromatin of the nuclei was finely granular and was evenly distributed. The nuclear membrane was distinct and there was either a small basophilic or a large oxyphilic nucleolus. There were from 3 to 5 mitotic figures to high power field.

The brownish discoloration in the posterior part of the tumor was due to the intracellular accumulation of dark brown pigment granules. The cells filled by the pigment were elongated and branched and the pigment granules which were of even size extended into their branches. In the clear round oval and polyhedral cells no pigment could be demonstrated. Pigmented and non pigmented cells often mingled with each other (Fig. 2).

The septa contained an occasional accumulation of lymphocytes and single pigmented cells. In these cells the pigment granules were lighter and of irregular size (phagocytized melanin). In none of the locations did the pigment give the iron reaction. It was slowly bleached by hydrogen peroxide.

There were regressive changes in the center of the larger alveoli as well as on the free surface of the

tumor. The latter was covered with a layer of fibrin, necrotic cells and degenerated pus cells. In places the tumor tissue bordered directly on stratified epithelium.

The bone was not invaded by the tumor. It appeared rarefied with thin and scanty bony trabeculae and an ample marrow composed of fibrillar connective tissue with perivascular accumulations of plasma cells and lymphocytes (Fig. 1).

Histological diagnosis: melanoblastoma of the nail bed. Rarefying osteitis of the terminal phalanx.

The papers dealing with the melanotic tumors of the nail bed say little about the differential diagnosis. There are several benign tumors which occur in this location and which will be discussed later. Occasionally a squamous cell carcinoma may arise in the region of the nail. Its clinical picture resembles that of the melanoblastoma as illustrated by the following case.

SQUAMOUS CELL CARCINOMA OF THE NAIL BED OF THE LITTLE TOE

A Russian Jew, 63 years of age, complained of pain in the little toe of the right foot which had been bothering him for several years. These pains had been present all the time but had become more severe during the past few months. The terminal part of this toe was found transformed into a dry, bony mass and the clinical diagnosis of squamous carcinoma of the little toe was made. Under local anes-

thesia the middle and terminal phalanges were removed. The wound healed *per primam* and the patient left the hospital after 5 days. There were no enlarged glands in the groin or elsewhere.

The specimen consisted of the little toe of the right foot enucleated in the joint between middle and basal phalanx. The nail was replaced by an irregular ulcer which extended over the upper part of the anterior aspect of the toe. The ulcer measured 25-12 millimeters in diameter and had slightly raised and scalloped edges. The floor was firm, dry, scaling and of waxy appearance. There were a few pinhead sized depressed areas which were purplish gray in color.

Microscopic examination. The dry and waxy tissue on the surface of the ulcer was revealed to be composed of a thick layer of hornified material which was invaded by degenerated pus cells. This material covered irregular branched and budding papillae which extended deep into the cutis and were surrounded by dense accumulations of lymphocytes and plasma cells (Fig. 3). The papillae were composed of cells some of which had still retained their prickly shape while others were polyhedral with large and indented nuclei. There were many atypical mitotic figures. In the center of some of the papillae concentric rings of hornified material were present. The bone appeared unchanged.

Histological diagnosis: squamous cell carcinoma of the nail bed.

The malignant tumors of the nail bed can be easily distinguished from the benign tumors because the latter do not break through the nail. These benign tumors are the subungual fibroma (Leduc and Suter), the Dupuytren's subungual exostosis, and a peculiar new growth the origin and nature of which has been much discussed. This tumor has been described under different names such as angiosarcoma, colloid sarcoma and perithelioma, and though its microscopic appearance is somewhat suggestive of a sarcoma the clinical course is benign. According to Masson, the tumor originates in the neuromyoarterial glomus which is arranged about the small arteries of the skin and is composed of smooth muscle fibers and nerve cells. The glomus tumors are non pigmented and consist of blood vessels, muscle fibers, nerve cells and nerve fibers. They are most frequently found beneath the nail (Masson, Martin and Dechaune, and Nicod) but occur also in other places of the extremities (Masson and Gery, Psodanoff). The subungual glomus tumor appears as a blue spot or nodule which is very painful. The pains are excruciating and radiating. The tumor does not destroy the nail, although it may produce a slight depression in the bone. Metastases have never been observed.

In order to distinguish the melanoblastoma from harmless granulomata, the demonstration of pigmented areas or of a pigmented line near the border is of great significance. This pigmentation though often very slight and visible only with the aid of a magnifying glass, secures also the differentiation from a squamous cell carcinoma of the nail the surface of which is dry and wavy.

The malignant tumors of the nail bed occur in higher age. No case of 'melanotic whitlow' has been reported in a patient under 35 years of age and most of the patients are in the sixties or seventies. In about half of the cases of melanoblastoma, a trauma is reported to have preceded the tumor for from 1 1/2 to 5 years. In 3 cases the melanoblastoma seems

to have started from a subungual pigmented mole.

Especially as far as the melanoblastoma is concerned, the prognosis is grave. Absence of local metastases does not exclude the involvement of internal organs (Chauvenet and Dubreuilh, Womack, 3 cases). On the other hand patients with enlarged regional lymph glands may survive the amputation of the toe or finger for several years. In the cases in which the lymph glands were not submitted for microscopic examination, it remained doubtful whether the enlargement was due to a metastatic invasion or to a chronic inflammatory irritation.

The treatment of the melanoblastoma of the nail bed is the early radical operation. Most authors agree that X ray or radium are contra indicated. The average length of life after the diagnosis is made is 14 months.

CONCLUSIONS

Ulcerative lesions of the nail bed in elderly persons which do not show any tendency to heal should be examined carefully for a possible melanoblastoma or squamous cell carcinoma. In distinguishing the melanoblastoma from benign granulomata and squamous cell carcinoma, the demonstration of pigmented areas which may be very small is of great importance. In this location the carcinoma shows a dry and wavy surface.

THE ABSORPTION AND TRANSIERENCE OF PARTICULATE MATERIAL BY THE GREAT OMENTUM¹

GEORGE M. HIGGINS, Ph.D., ROCHESTER, MINNESOTA

Division of Experimental Surgery and Pathology

AND

C. GRANT BAIN, M.D., ROCHESTER, MINNESOTA

Fellow in Surgery, The Mayo Foundation

FUNCTIONS of the omentum such as the elaboration of peritoneal fluid, the absorption of particulate materials or the production of antibodies, have long been known. Ever since Aristotle attributed to the great omentum a function to protect abdominal viscera from the cold, each succeeding scientific generation has contributed its experimental data to our knowledge of the part the organ plays in regulating body economy. Although the literature on the anatomical, physiological, clinical, and surgical significance of the omentum is enormous, complete and exact data concerning it must yet be compiled.

The removal of isotonic solutions and numerous suspensions of particulate material from the peritoneal cavity has been a favorite subject for study since von Recklinghausen described stomata within the mesothelium of the coelom through which such particles may be removed. Any study of the method of removing foreign particles from the peritoneum, the type of cellular response to invading organisms, and the routes of drainage from the peritoneum, must of necessity include the reaction manifested by the greater omentum.

Whenever foreign particles such as India ink, trypan blue, or whole blood, are introduced into the peritoneal cavity, a polymorphonuclear leucocytic reaction follows within the first few hours; mononucleated cells appear in abundance only after 24 to 48 hours. McJunkin (1925) recognized three types of cells determined by the manner in which they take up neutral red in supravital staining. Whether these cells in large part are derived from the omentum has not been determined.

The large number of histocytes which abound in the normal omentum leads one to the opinion that this organ may be the source of many of the peritoneal exudate cells and

yet experimental evidence does not thus far warrant such a conclusion.

The literature reporting the cellular response within the peritoneal cavity to any irritation is enormous, and we shall not attempt to review it here. Generally, these exudate cells which arise following peritoneal injection have been attributed to the mesothelium lining the cavity, the reticuloendothelium of the spleen and lymph nodes, the specialized vascular endothelium of the liver, and the greater omentum.

Using a new finely particulate graphite suspension Higgins and Graham (1929) undertook a study of the role of the diaphragm in the removal of foreign particles from the peritoneal cavity in the dog. Special emphasis was placed on the lymphatics of the diaphragm and the routes of absorption through the anterior mediastinum. Higgins, Beaver, and Lemon (1929) continued the study of absorption through the diaphragm of dogs which had been previously subjected either to unilateral or to bilateral phrenic neurectomy. Diaphragmatic paralysis, which follows section of the phrenic nerve, merely retards the rate of absorption but it does not render the diaphragm any the less effective for the removal of injected material from the peritoneum.

During this study of absorption through the diaphragm we were impressed by the speed with which the great omentum in these animals absorbed and fixed the graphite particles. It was apparent at once that the mesothelium covering the omentum reacted far more intensively than the other surfaces of the peritoneum. Poynter (1928) stated that the peritoneum covering the omentum is different from that which covers the visceral and parietal surfaces. Furthermore we have noted, in our study of the relation of the omentum to diaphragmatic absorption, that

animals from which the omentum had been partially resected were not able to withstand the effect of graphite within the peritoneum and usually died within 2 to 3 weeks following an injection. In experiments on dogs that had been subjected to partial resection of the omentum some time before peritoneal injection graphite particles appeared on the pleural surface of the diaphragm following injection as rapidly as in the intact animal. Rubin (1911), however in studying absorption of indigocarmine from the peritoneal cavity of cats from which the omentum had been resected previously noted marked delay in the appearance of the dye in the urine from that which takes place in a normal animal. From our studies it seemed evident that the great omentum was essential to adequate protection but that it did not bear any relation to the absorption of particulate material through the diaphragm.

Restoration of an organ is rather positive evidence that it is essential for the well being of the organism. Its restorative capacity is great and surgeons have noted that at a second laparotomy following earlier partial resection of the omentum it has been restored to its earlier proportions. Arnaud (1928), in the most recent work on the omentum, stated that in both guinea pigs and dogs complete regeneration following resection has taken place in 5 to 6 weeks.

In our study on the absorption of graphite from the intact peritoneum the abundance of black particles within the omentum and the gross appearance suggesting a system of drainage from the organ to the gastric and hepatic regions naturally prompted the inquiry as to whether the omentum could remove absorbed materials and, if so, whether such drainage passes by way of the diaphragm to the thorax. We were interested to know whether material engulfed by the omentum was removed through definite channels carried by way of the blood stream, or perhaps remained as isolated foreign substances within the organ itself.

It is difficult to study the absorptive mechanism of the omentum apart from the other closely related structures of the peritoneal cavity, because the omentum must be

withdrawn from the cavity entirely or be isolated in such a way as to be independent of the adjacent organs. Shipley and Cunningham (1916) were perhaps the first to make a histological approach to the study of omental absorption, and they overcame the spatial difficulty by withdrawing the omentum from the cavity of the body and immersing it in a fluid or suspension, the absorption of which they wished to study. In this way all other drainage routes from the peritoneal cavity were necessarily excluded. In order to maintain anaesthesia over periods sufficiently long to permit adequate absorption, decerebrate animals were used so that mechanical difficulties were largely overcome. In this way the omentum could be easily immersed in various solutions and suspensions and studies were made on the rate and the routes of absorption by the omentum in animals so prepared. In certain of the animals, Shipley and Cunningham previously had ligated the thoracic duct in the neck attempting thereby to determine whether or not the lymphatic system was concerned in absorption by the omentum. Their results were unchanged by the ligation of the thoracic duct. In this connection however it must be recalled that should drainage from the omentum pass by way of the diaphragm into the anterior mediastinum a large portion of the lymph will enter the blood stream by way of the right cervical duct so that ligation of the thoracic duct would not be a completely effective control. They concluded that absorption of both solutions and suspensions is by way of the omental veins and that granular material may be recovered from the portal vein and liver within a very short time following immersion in the solution. They stated that lymph vessels if present within the omentum do not play a part in the removal of particulate material. Likewise Poynter (1935) in studying the functions of the great omentum, is convinced that the removal of foreign particles is accomplished by the omental and the portal veins. Poynter did not mention a lymphatic system but he demonstrated crystalloid and various particles and granules in the portal vein within a few minutes following peritoneal injection.

Fig 1 Side view of the body of a cat showing the position of the subcutaneous pouch the isolated portion of the omentum contained therein and the relation of the abdominal viscera to the isolated omentum

In our earlier study on peritoneal absorption, we were unable to recover graphite particles from the liver for a considerable period following peritoneal injection. Furthermore, in sections of the omentum taken at various times following peritoneal injection fixed in Zenker and formol solution and stained with hematoxylin, and with eosin azure we were unable to recognize any graphite particles in any of the omental blood vessels. Numerous particles were adherent to the surface mesothelium and a considerable portion of free graphite was present within the layers, but most striking perhaps was the exceedingly large number of histocytes packed with the phagocytosed particles.

These earlier observations prompted us to try a series of experiments in which we could isolate the omentum from the peritoneal cavity and thus study absorption as carried on by the omentum alone, apart from other adjacent organs and under conditions approaching the physiological. We hoped, too, to determine whether the lymphatics of the diaphragm and the anterior mediastinum had a part in drainage from the omentum as well as in drainage directly from the peritoneal space.

EXPERIMENTAL METHOD

Cats were used in this study. In order to avoid the necessity of decerebration and exposure of the omentum to atmospheric condi-

tions we isolated the distal two thirds of the omentum in a pouch formed within the ventral abdominal wall (Fig 1). With the use of Narath's modification of the Talma Morison operation under ether anesthesia and sterile technique an incision about 4 centimeters long was made in the abdominal wall slightly to the right of the median line. By dissecting away the intervening fascia, a pouch of considerable proportions was made between the integument and the layers of muscle. The muscle tissue was incised in the median line, a small incision was made through the peritoneum and the great omentum was carefully withdrawn through this incision and gently placed in the pouch previously prepared between the integument and the abdominal muscles. Caution was observed to avoid any undue manipulation such as tension on the stomach spleen and the transverse colon. In the cat the omentum is extensive and in this way a considerable portion (approximately two thirds) may be withdrawn and thus isolated from the peritoneal cavity. Sutures were inserted around the opening in the peritoneum fixing it firmly to the omentum, so that there might be no spatial continuity between the pouch beneath the integument and the peritoneal space. The skin was then closed. This gave an operative hernia of the omentum. The animals speedily recovered from the operation and in 4 to 5 days ample

animals from which the omentum had been partially resected were not able to withstand the effect of graphite within the peritoneum and usually died within 2 to 3 weeks following an injection. In experiments on dogs that had been subjected to partial resection of the omentum some time before peritoneal injection, graphite particles appeared on the pleural surface of the diaphragm following injection as rapidly as in the intact animal. Rubin (1911), however, in studying absorption of indigocarmine from the peritoneal cavity of cats from which the omentum had been resected previously noted marked delay in the appearance of the dye in the urine from that which takes place in a normal animal. From our studies it seemed evident that the great omentum was essential to adequate protection, but that it did not bear any relation to the absorption of particulate material through the diaphragm.

Restoration of an organ is rather positive evidence that it is essential for the well being of the organism. Its restorative capacity is great and surgeons have noted that at a second laparotomy following earlier partial resection of the omentum it has been restored to its earlier proportions. Arnaud (1928), in the most recent work on the omentum stated that in both guinea pigs and dogs complete regeneration following resection has taken place in 5 to 6 weeks.

In our study on the absorption of graphite from the intact peritoneum, the abundance of black particles within the omentum and the gross appearance suggesting a system of drainage from the organ to the gastric and hepatic regions naturally prompted the inquiry as to whether the omentum could remove absorbed materials and if so whether such drainage passes by way of the diaphragm to the thorax. We were interested to know whether material engulfed by the omentum was removed through definite channels carried by way of the blood stream, or perhaps remained as isolated foreign substances within the organ itself.

It is difficult to study the absorptive mechanism of the omentum apart from the other closely related structures of the peritoneal cavity, because the omentum must be

withdrawn from the cavity entirely or be isolated in such a way as to be independent of the adjacent organs. Shipley and Cunningham (1916) were perhaps the first to make a histological approach to the study of omental absorption and they overcame the spatial difficulty by withdrawing the omentum from the cavity of the body and immersing it in a fluid or suspension, the absorption of which they wished to study. In this way all other drainage routes from the peritoneal cavity were necessarily excluded. In order to maintain anesthesia over periods sufficiently long to permit adequate absorption decerebrate animals were used so that mechanical difficulties were largely overcome. In this way the omentum could be easily immersed in various solutions and suspensions and studies were made on the rate and the routes of absorption by the omentum in animals so prepared. In certain of the animals Shipley and Cunningham previously had ligated the thoracic duct in the neck attempting thereby to determine whether or not the lymphatic system was concerned in absorption by the omentum. Their results were unchanged by the ligation of the thoracic duct. In this connection, however, it must be recalled that should drainage from the omentum pass by way of the diaphragm into the anterior mediastinum a large portion of the lymph will enter the blood stream by way of the right cervical duct so that ligation of the thoracic duct would not be a completely effective control. They concluded that absorption of both solutions and suspensions is by way of the omental veins and that granular material may be recovered from the portal vein and liver within a very short time following immersion in the solution. They stated that lymph vessels if present within the omentum do not play a part in the removal of particulate material. Likewise Poynter (1938) in studying the functions of the great omentum is convinced that the removal of foreign particles is accomplished by the omental and the portal veins. Poynter did not mention a lymphatic system but he demonstrated crystalloid and various particles and granules in the portal vein within a few minutes following peritoneal injection.

not due to graphite within the blood vessels but to the heavily laden histocytes and free graphite particles which have accumulated around them. Although the graphite is closely packed around the blood vessels, we have never identified a single graphite laden cell or free graphite particle in the blood stream of the omentum in the early periods. Figure 3, the omentum of a dog, represents rather accurately the relations which maintain between the circulation of the blood and the graphite laden histocytes at 3 to 6 hours after peritoneal injection. The peritoneal portion of the omentum in an animal 3 hours after an injection was far less heavily infiltrated than the portion within the pouch and yet an abundance of black material could be detected grossly, up to and including its attachment to the spleen. Sections show that the graphite hitherto at the surface is now within the mesothelial layers and is largely contained within phagocytes, although much free graphite is profusely scattered throughout both the ascending and the descending limbs of the omentum.

The rate of absorption through the isolated omentum is by no means constant for all animals. A cat killed at 6 hours following an injection may not show greater absorption than one killed at 3 or 4 hours so that individual variations may occur. This however, may be due in part also to operative procedures. In general, exploration 3 to 6 hours following a graphite injection into the subcutaneous pouch will show absorption by way of the omentum sufficient to blacken grossly the mesothelial structures related to the spleen and the pancreas inside the abdominal cavity.

Following these early stages the animals were allowed to live for longer periods after the injection had been made into the subcutaneous pouch. Studies were made of the routes of drainage and the site of the absorbed graphite at 12, 20, 24, 36, and 48 hours after injection. Without giving exact details for each animal we wish to report the sequence of absorption and drainage which these experiments have demonstrated.

In each successive experiment all portions of the greater omentum and its normal attachments within the peritoneal cavity were pro-

Fig. 3 The omentum of a dog 6 hours after an injection of graphite into the peritoneal cavity

gressively more heavily infiltrated (Fig. 4). In the descending limb of the omentum, the color deposits may be readily traced around the pancreas and thence into the hepatoduodenal ligament. Furthermore, the gastrosplenic ligament becomes progressively more heavily infiltrated and frequently considerable deposits of graphite are observed along the greater curvature of the stomach, especially toward the duodenum. Within the area of the liver, the gastrohepatic ligament (Fig. 5) and the duodenohepatic ligament are heavily infiltrated with black particles. Likewise that portion of the lesser omentum which covers the caudate lobe of the liver is invariably stippled with pigment. The black particles are not on the outside of these ligaments and investing omentum. Sections show that they are definitely beneath the mesothelial layer and occur either as free particles or in wandering histocytes. We have never positively identified any channels of any sort through which the graphite passes in these hepatic ligaments. Microscopically, there seems to be a diffuse distribution of the graphite granules. Forty-eight hours after an injection it is easy to follow the course of the black granules from the hepatic ligaments and the lesser omentum to the coronary ligament of the liver and thence to the central tendon of the diaphragm. We have not studied sections of the coronary ligaments and yet they are invariably speckled black, and, as far as our observations go, represent the only demonstrable course whereby

Fig. 2 Portion of the omentum within the subcutaneous pouch 3 hours after an injection of graphite

time for the wound to heal, 1 to 3 cubic centimeters of the graphite suspension was injected into the pouch containing the isolated portion of the great omentum. Care was exercised in this injection, the needle being introduced through the integument into the posterior region of the pouch to avoid actually injecting the omentum. Following these injections animals were killed at successive intervals: the isolated portion of omentum, the peritoneal portion of omentum, the gastrohepatic omentum, the diaphragm, the anterior mediastinum, and the liver were examined for evidence of absorption of the graphite. Fourteen experiments were considered successful. Careful necropsy was performed at intervals following injection ranging from 30 minutes to 48 hours. These form the basis for the conclusions presented in this report.

EXPERIMENTAL OBSERVATIONS

One of the functions of the great omentum is the elaboration of fluid with marked coagulative properties. Arnaud (1928) recently demonstrated the secretory activity of the omentum in guinea pigs by inserting into the abdominal wall a window of transparent cellophane so that he could observe the movements and responses of the omentum. He concluded that the omentum is the source of large quantities of a serous fluid which possesses marked coagulative properties. Our observations bear out these conclusions in that foreign particles in contact with the omentum become at once adherent, held by a coagulum to its

mesothelial surface. Within a few minutes following an injection of graphite into the abdominal pouch the omentum is well speckled with particles which may be washed off only with considerable difficulty. The proximal portion of the omentum within the peritoneal cavity is already faintly gray in places, suggesting graphite, and sections show that the black particles have extended along the mesothelial surface and are still largely adherent. A few very fine granules lie beneath the surface layer. Thus far a phagocytic reaction has not been marked, for only occasionally we encountered phagocytic cells just beneath the mesothelial surface containing only a few black particles.

In a cat killed 3 hours after an injection of 3 cubic centimeters of the graphite suspension into the subcutaneous pouch absorption by the omentum was well advanced (Fig. 2). The fluid then within the pouch contained many polymorphonuclear leucocytes with black granules, but whether these arose from the omentum or came from other sources as a result of irritation is as yet unknown. Diapedesis through the mesothelium into the surrounding area was not extensive, and we are inclined to believe that more stress is placed on this early activity of the mononuclear phagocyte of the omentum than actual evidence would warrant. Whereas we have noted these phagocytic histocytes within the mesothelium in actual migration, we have never seen them so packed with particles in these situations as they are along the blood vessels. It is probable that by far the major phagocytic activity takes place within the tissue of the organ rather than outside the mesothelial layer. At 3 to 4 hours after injection the histocytes along the blood vessels are literally packed with graphite so much so that their nuclear structure is often concealed. In their early phagocytic response these cells may be readily identified by their eccentrically placed nuclei, usually of kidney or horse shoe shape. At this period too fibroblasts, which are usually non-phagocytic or only slightly so, have engulfed many graphite particles. Figure 2 shows the extent to which absorption by the portion of the omentum within the pouch has progressed. The major routes of blood vessels appear black.

disprove the existence of a lymph draining system within the great omentum. The demonstration of such a system is exceedingly difficult, since numerous spaces abound in histological sections which make any adequate interpretation impossible. Suzuki (1910) concluded that the omentum regularly possesses a rich supply of lymphatics. Koch (1911), studying both normal and pathological material, supported Suzuki in his contention. Broman (1914) and Crouse (1915) likewise attributed lymphatics to the omentum. Caspary (1918), using the silver nitrate preparation methods, disclosed extensive lymphatics along the larger blood vessels of the omentum in rabbits, cats, dogs, and man. On the other hand, Shipley and Cunningham (1916) and Seifert (1923) were unable to demonstrate lymphatics in the omentum. Marchand (1924) and Poynter (1928) stated that lymphatics are present only in fetal life and for a short time after birth, when they soon disappear. Seifert (1927), however, stated that while he was not able to demonstrate lymphatics in the free portion of the fetal omentum, he could discern them along the attachment to the greater curvature of the stomach.

Our study is not essentially concerned with the presence or absence of lymphatics of the omentum. We were more concerned with the question of fixation of injected foreign particles and especially with their removal to other regions of the body. Although we have made no attempt to disclose lymphatics in the omentum, our observations lead us to conclude that the removal of the absorbed particles is essentially a function of the lymph drainage rather than the blood vascular system. In each animal experiment, we have studied sections of the great omentum which were made from the portion isolated within the subcutaneous pouch and that within the peritoneal cavity but we have never been able to demonstrate any graphite particles in the blood stream. Furthermore we have studied fixed sections of the liver of the cats shortly after injection of graphite and as late as 48 hours after injection and we have failed to identify the black granules within the phagocytic cells. The von Kupffer cells are actively phagocytic and should the graphite have en-

tered the portal vein through the omental circulation, one would expect to identify the particles in these cells lining the sinusoids. We did identify a few mononuclear cells with graphite particles in the sinusoids of the liver of the cat 48 hours after injection, but these were lying free in the blood stream and in our opinion were histocytes that had probably entered the blood stream by way of the anterior mediastinum and the thoracic duct. The fixed or littoral cells were always devoid of the black particles.

Relatively soon following a graphite injection into the pouch, the secretory function of the omentum is early manifested by the abundance of black particles which are firmly adherent to its mesothelium. The extensive vascularity of the organ probably accounts for the large quantities of this serous fluid that is secreted. Within a few minutes these black particles make their way into the omentum where the hitherto inactive histocytes begin their function of phagocytosis. The actual migration of histocytes back and forth through the mesothelium is not frequent and we are inclined to believe that the more extensive phagocytosis occurs within the omentum and not without. The transfer of the free particles into the omentum is very rapid, and one may only conjecture that a return of a certain amount of the fluid into the omentum carries the particles beneath the mesothelium.

After granules have entered the omentum and phagocytosis has occurred, the histocytes accumulate along the larger blood vessels of the organ. Thus these blood vessels appear black in the omentum removed a few hours after an injection. The lumina of these blood vessels are devoid of either the graphite or the graphite laden cells, and the endothelium is likewise clear. The histocytes with graphite granules are closely massed along these vessels and the evidence leads one to conclude that they move along if not in channels, in spaces, surrounding but not connected with the blood vessels (Fig 6). Occasionally, we have noted in our sections an endothelial pattern or space suggesting a lymphatic vessel both with and without graphite and devoid of erythrocytes (Fig 7). These areas have been identified in close proximity to blood vessels and although

Fig 4. The peritoneal portion of the great omentum 48 hours after an injection into the pouch. Large numbers of histocytes may be noted. The blood vessels shown are devoid of free graphite or graphite laden cells ($\times 400$)

Fig 5. The gastrosplenic ligament 48 hours after an injection into the subcutaneous pouch. The blood vessels are devoid of graphite ($\times 500$)

the graphite may reach the diaphragm. The peritoneal cavity is always clear and we are unable to explain the presence of graphite in these structures on any basis except one involving a direct continuity of drainage from the greater omentum to the diaphragm.

The peritoneal surface of the diaphragm in a cat killed 48 hours after a graphite injection into the subcutaneous pouch presented a picture somewhat similar to that encountered when particles were injected directly into the peritoneal cavity. Strands of black granules accumulated between adjacent bundles of muscle radiated from the central tendon toward the costal margins of the diaphragm. Sections of the diaphragm showed that these particles were beneath the mesothelial surface massed in the intermuscular spaces some within the sub-erosus lymphatic plexus and some without. Free graphite was rarely if ever seen in a serosal cell of the diaphragm. The evidence leads us to conclude that free particles, as well as phagocytic histocytes, work their way assisted by circulating fluids under the mesothelial surface and thence into the extensive lymphatic plexus of the diaphragm.

The passage through the diaphragm is unquestionably by way of the lymphatics and we have demonstrated graphite in the collecting channels on the pleural surface, in the sternal lymph tracts and in the anterior mediastinal lymph nodes. From the central tendon of the diaphragm therefore the

drainage routes toward the anterior mediastinum are identical with those in absorption directly from the intact peritoneal cavity.

COMMENT

These studies support very definitely the hitherto recorded observations that the great omentum readily absorbs and removes foreign particulate material. They further show that its secretory activity and its adhesive and absorptive functions are by no means severely impaired when the omentum is withdrawn from the peritoneal space and carefully isolated within a pouch in the ventral abdominal wall.

Our observations are not in accord however with other recorded observations concerning the manner in which these absorbed materials are removed. The lymphatic distribution of vessels within an organ is the system to which the function of absorption and conduction is usually attributed. The existence of a lymphatic vessel system or lymphatic vessels lined by common endothelium within the great omentum of the adult animal continues to be a question of uncertainty. Ranvier (1896) demonstrated lymphatic channels in the great omentum of newborn kittens but he maintained that they disappeared before the animal reached adult age. Lymphatic vessels have been described in the omentum of infants. Subsequently scientific opinion differed and today considerable literature is available which attempts to confirm or

this lobe is the only one covered by the lesser omentum. The distinct infiltration of the ligaments of the liver, all a part of the lesser omentum, rather clearly point to a mesothelial conducting mechanism. The circulation of a fluid containing the free particles and the graphite laden histocytes throughout the extent of the lesser sac are not plausible explanations for the movement of the pigment. The continuity of the lesser sac with the greater peritoneal cavity through the foramen of Winslow would permit a circulation of the granules into the peritoneal space, a phenomenon never encountered.

A further note on the anatomical relations will facilitate an interpretation of the drainage to the central tendon of the diaphragm. If we follow the course of the mesothelium covering the lesser sac, we may observe that it conforms essentially to our pattern of drainage. Starting with the greater curvature this mesothelial layer covers the dorsal surface of the stomach, and extends from the lesser curvature upward to the liver covering the caudate lobe. It is now reflected onto the diaphragm and forms the dorsal layer of the coronary ligament. Thence it passes over the dorsal part of the diaphragm to the vertebral column, descends and covers the ventral border of the pancreas and forms the dorsal wall of the lesser sac and is continued posteriorly to form the inner layer of the great omentum. These anatomical relations rather clearly show how absorption of particulate graphite reaches the diaphragm. As stated the coronary ligament is always heavily infiltrated with graphite in the animals 48 hours after injection. Anatomically the ligament is composed of two layers, a ventral layer composed of peritoneum of the greater sac and a dorsal layer composed of the peritoneum of the lesser sac. The ventral layer of the coronary ligament appears to be less stippled in these drainage experiments than the dorsal layer. This explains we believe the absence of graphite in the serosal surface of the ventral portion of the diaphragm which is anatomically a part of the mesothelium lining the greater peritoneal sac. We believe that most of the graphite enters the diaphragm by way of two closely related routes. One of these is along

Fig. 8. A diagram of the relations of the fetal omentum to the abdominal cavity.

the posterior wall of the stomach (the anterior wall of the lesser peritoneal sac), thence through the gastrohepatic ligament to the coronary ligament and into the diaphragm. The other route is by way of the pancreas to the crura of the diaphragm along the posterior wall of the lesser sac and then into the diaphragm. The radial distribution of graphite, so frequently seen beneath the peritoneal surface of the diaphragm, occurs by migration along the intermuscular fascia from the site of contact of the diaphragm with the superior recess of the lesser peritoneal sac. Thence, the graphite particles enter the subserous lymphatic plexus of the diaphragm, pass through the partition and enter the collecting channels on the pleural surface. Thus the drainage from the great omentum is by way of those lymphatic channels of the diaphragm and the ventral mediastinum, rather than through the cisterna chyli, and the thoracic duct. There are then, two systems of drainage from the abdomen: one associated with the gastrointestinal tract passing through the mesenteries to the cisterna and the other associated with the omentum and the diaphragm passing through the ventral mediastinum to the cervical lymph ducts.

We do not wish to state that all particles absorbed and fixed by the great omentum are transferred to other parts of the body. We are well aware that the omentum following absorption of particulate graphite from the peritoneal cavity will remain black for many

Fig 6 The omentum of a dog 6 hours after pentoneal injection. The accumulation of the histocytes and the free graphite around the blood vessels is shown. The blood stream is devoid of graphite particles ($\times 1000$)

they resemble the lymphatic distribution around the portal vein we still hesitate to ascribe to them a lymphatic potentiality.

It may be that the conditions within the omentum are not unlike those within lymph sinuses and myeloid tissue. Maximow stated 'As the lymph sinuses are lined with flattened histocytes so the large venous sinusoids of the myeloid tissue also have a wall consisting not of common endothelium but of flattened histocytes which cannot be separated from the reticular histocytes of the tissue and which show the same functions in an especially high degree: storing of colloidal dyes, phagocytosis of particulate matter, transformation into free macrophages.

Omitting the details of its early development from the dorsal mesentery, the great omentum is formed of four layers of mesothelium, two comprising the ascending limb and two the descending limb of the organ. The cavity within this omentum, the lesser sac, largely obliterated in the adult, is continuous with the peritoneal cavity by way of the foramen epiploicum or foramen of Winslow. Thus the peritoneal sac with which we are concerned includes, besides the ommental bursa or the cavity of the great omentum, the cavity of the lesser omentum as well. The lesser omentum is a double layer of peritoneum which extends from the lesser curvature of

Fig 7 The accumulation of graphite-laden histocytes into structures that resemble lymph channels in the omentum. Closely related blood vessels are not shown ($\times 375$)

the stomach and the duodenum to the liver, the caudate lobe of which it covers. The duodenohepatic ligament and the gastrohepatic ligament are parts of the lesser omentum. If the two layers comprising the ascending limb of the great omentum are traced forward they enclose the stomach and again unite along the lesser curvature to form the lesser omentum reaching to the liver.

If we are to judge by the distribution of the graphite within the omentum following absorption from the subcutaneous pouch, we must conclude that drainage is to a great extent restricted to the mesothelial layer lining the lesser sac. In tracing the course of drainage around the spleen and to the greater curvature of the stomach by the black deposits in the mesothelium we have noted that the route to the lesser omentum is always over the dorsal surface of the stomach to the gastrohepatic ligament and not over the ventral surface. Furthermore, the ommental covering of the duodenum and the lobe of the pancreas are always heavily speckled with the black pigment, whereas the mesothelial attachment of the colon is less involved. Accordingly we conclude that the mesothelial lining of the lesser peritoneal sac is the layer more largely involved in the drainage of these foreign particles from the great omentum. The fetal relations of these mesenteries shown in Figure 8 will clarify our explanation. The caudate lobe of the liver is the only part of this organ ever speckled with graphite and

POSTCONCEPTION PELVIC IRRADIATION OF THE ALBINO RAT (MUS NORVEGICUS) ITS EFFECT UPON THE OFFSPRING

DOUGLAS P. MURPHY, M.D. F.A.C.S. AND MARGUERITE DE RENYI, M.D. PHILADELPHIA

From the Gynecologic Hospital Institute of Gynecologic Research and the Department of Anatomy University of Pennsylvania

THE findings in two recently completed clinical studies indicate that pelvic irradiation employed during pregnancy is very likely to arrest the development of the fetus. The fact that of 76 full term children irradiated *in utero* 18 were microcephalic—while still other developmental defects were exhibited by some of the remaining ones—definitely points in this direction.

Experiments upon a variety of the lower animals by different observers (1) confirm these clinical findings, although few of these studies were made upon mammals. Irradiation of fertilized animal ova and of immature animal young appeared to be followed in a large proportion of cases by a rather wide variety of physiological and anatomical disturbances e.g., early death, weakness under development, and very high frequency of gross structural deformities. These disturbances seemed to vary with the kind of animal treated, the amount of irradiation employed, and the time of the treatment in relation to the date of fertilization and to other factors.

One of the objects of the present study was to check the results of the other observers in this field. The rat was chosen for our experiments because most of the earlier investigations had been concerned with animals lower in the developmental scale making them less important as a means of evaluating the results of human irradiation.

The desired end of the experiment was to find out whether embryonic irradiation in non-lethal doses would or would not be followed by the birth of young exhibiting gross structural abnormalities.

The irradiation was given with equipment of the mechanically rectifying type, energizing a broad focus Coolidge tube. The roentgen machine was calibrated with a Wulf ionometer; the latter in turn calibrated in Germany with the proposed international 'R' unit. The operating factors were as follows: 127 kilovolts (peak), 5 milliamperes, 30 centi-

meter skin target distance, and 6 millimeters of aluminum. One hundred and eighty milliamperes minutes (m a m.) of exposure gave 800 R units of intensity.

The animals were treated as shown in Figure 1 strapped to the small concentrically arranged tables. The cephalic half of each animal was protected by a lead plate 2 millimeters in thickness. The Coolidge tube target was directed at the central point of the circular base upon which the small tables were fastened with adhesive plaster, the skin target distance (30 centimeters) being measured from the target to the level of the rats' backs.

With this technique, 120 animals were subjected to from 1 to 6 exposures, varying in strength from 45 to 360 milliamperes minutes (200 to 1600 R).

Gestation in the rat consumes from 22 to 23 days. Of the 120 treated animals, 34 cast litters within less than 22 days of their last roentgen exposure, i.e., the embryos in these cases had received at least one roentgen exposure.

The litters of these 34 animals varied in size from 1 to 11, the most common being 2, with an average size of 3.6 young. In 1

Fig. 1. Showing circular base and 4 concentrically arranged tables used for the purpose of holding unetherized adult rats in position for uterine irradiation. Each table is in turn strapped to the circular base. Note the sheet of lead protecting the upper half of the body.

months We do affirm, however that a considerable portion of the materials so absorbed, especially the finer particles, may be removed promptly to the diaphragm and thence to other portions of the body, through a mesothelial conducting mechanism operating by way of the omentum

SUMMARY

A method is described for the study of absorption by the omentum isolated from all structures within the peritoneum Studies have been made on the degree of absorption by the isolated omentum from the subcutaneous pouch at frequent intervals, ranging from 30 minutes to 48 hours after an injection Lymphatic vessels within the omentum have not been demonstrated conclusively and yet absorption from this organ is essentially by way of the lymphatics of the diaphragm and the mediastinum It was not possible to demonstrate either free particles or graphiteladen histocytes in the omental blood vessels, following an injection into the subcutaneous pouch Following phagocytosis of the graphite particles by active mobile histocytes these cells accumulate along the blood vessels and pass toward the gastric and splenic attachments of the great omentum The routes of drainage from the distal part of the omentum follow essentially the mesothelial lining of the lesser peritoneal sac From the gastrosplenic ligament drainage follows around the dorsal surface of the stomach along the lesser omentum to the caudate lobe of the liver and thence along the coronary ligament of the liver and the central tendon of the diaphragm to the anterior mediastinal lymph nodes

litter and in more than one litter. Furthermore, no such similar defects were observed in more than 600 control young examined during the previous 2 years. In addition, Dr. Helen Dean King of the Wistar Institute of Anatomy and Biology (from which Institute the mother animals were secured) reports that she has never observed any such defects in the more than 125,000 rats recorded in her laboratory.

SUMMARY AND CONCLUSIONS

- 1 The litters of 34 female albino rats, irradiated when pregnant, have been studied.
- 2 In 5 of these 34 litters one or more young exhibited either clubbing of feet or absence of toes.
- 3 The frequency with which defective young were produced appeared to vary directly with the degree of exposure.

4 Though no definite conclusion can be drawn from the observations set down in the present paper, due largely to the scantiness of material available for analysis, it is significant that the deformities observed among the young of animals irradiated when pregnant have not been duplicated in a series of 125,000 non irradiated control animals.

The authors are very greatly indebted to Mr. J. L. Weatherwax, physicist of the Philadelphia General Hospital, for his kindness in calibrating the roentgen machine.

Note the apparent difference between the degree of development of the hind legs and that of the fore legs in respect to the size and shape of the feet and the depth and length of the digital grooves

group of 35 control litters the most common size was 7 young

Grossly defective young were cast by 5 of the 34 irradiated animals. The number of these young appeared to be in direct proportion to the degree of the irradiation. For instance, of the 90 young born of 20 animals which had received only 45 milliamperes minutes (200 R) of exposure, not one was found defective. On the other hand 12 animals exposed to 90 milliamperes minutes (400 R) (twice the above amount) cast 3 litters (one each) containing defective offspring while each of 2 litters exposed to 180 milliamperes minutes (800 R) or 4 times the smallest exposure exhibited one or more defective young. If these 2 latter groups are considered as a single group, it will be observed that of the 14 animals receiving 90 milliamperes (400 R) or more 5 (a percentage of 35.7) gave birth to defective young.

These litters comprised a total of 13 offspring, of which 2 were known to be alive at birth but died within a few hours. The remaining 11 were either stillborn or were killed by their parents or died natural deaths before being observed. Of the whole group of 13 young, 6 exhibited developmental defects of the extremities.

Of the 5 animals casting litters containing defective young 4 gave birth to a total of 10 offspring all of which were at least externally, well formed except for a foot deformity exhibited by 5 of them.

The foot abnormality exhibited by these 5

Fig 3 Showing a rat which had been irradiated while *in utero*. Note the rudimentary development of the second toe on each fore foot. The dark area around the eye is due to a conjunctival discharge.

young (Fig 2) was characterized by lack of the normal depth of the digital grooves. In 4 of the 5 animals only the hind feet were affected while the fifth one exhibited the defect in all 4 feet. In addition, where the digital grooves were absent or distorted the entire foot was deformed so as to appear clubbed. In a number of instances the end of the extremity was perfectly smooth, similar in appearance to an amputation stump of long standing. In those instances in which only the hind feet were affected the fore feet appeared to be perfectly normal in every respect.

The fifth litter consisted of only one young shown in Figure 3. This animal appeared to be perfectly healthy and lived until the end of the experiment. Its fore feet however had only 3 well developed toes each with the normal site of the missing toe marked by a rudimentary bud which suggested an arrest of development.

For a number of reasons it is believed that the abnormalities which have just been described and which are depicted in the two accompanying photographs are the result of the embryonic irradiation. The clinical findings suggest this as does also the earlier experimental evidence advanced by other workers. In the case of the present experiment the defects varied (at least in frequency) with the degree of the embryonic exposure. The same defect was observed several times in the same

anginal pain. The physical signs of myocardial insufficiency may be present in varying degrees. These include evidence of pulmonary oedema, (rales at the lung bases), hepatic enlargement, and oedema of the extremities.

During the past 3 years at the request of Dr. Young we have studied the various circulatory problems encountered in patients undergoing prostatectomy in the James Buchanan Brady Urological Institute of the Johns Hopkins Hospital. This operation is most often necessary at an age at which the changes described above are well advanced. Urinary obstruction, which it is calculated to relieve, carries with it a series of strains upon the circulation, and some of the postoperative complications are prone to bring about myocardial insufficiency. Such obstruction, with the resultant impairment of renal function produces a condition which, at the time, may be indistinguishable from chronic nephritis with nitrogen retention and hypertension. With the relief of the obstruction these disappear—unless, as in some cases, chronic nephritis and urinary obstruction coexist—but until then the systolic discharge of the heart is opposed by an increased resistance, alone sometimes sufficient to cause symptoms of myocardial failure.

A factor of considerable importance in contributing to circulatory failure is the interference with adequate rest. Frequency of urination, particularly as it occurs at night may so disturb sleep that the patient becomes well-nigh exhausted. Infection, even though localized to the genito-urinary tract, throws an additional burden upon the circulation, particularly if it be accompanied by fever.

Pre-operative care. It has become increasingly apparent that the frequency and severity of postoperative cardiac complications may be lessened by adequate pre-operative preparation. Rest is a most important pre-operative measure. To this end as well as to relieve the frequency of voiding and to restore the renal function catheter drainage should be established. Sedatives, luminal or even opiates should be employed when necessary. In many cases cystoscopy must be delayed until adequate rest has been obtained.

Fluids. Urinary obstruction with its resultant functional renal impairment and

nitrogen retention necessitates the administration of large quantities of fluid. And yet any degree of congestive heart failure is to be regarded as an indication for restricting the fluid intake. When both conditions are encountered one can steer only a middle course. It is impossible to follow the same scheme for every patient. The degree of circulatory insufficiency must be determined by careful examination in each case, and the fluid limit established accordingly. In our experience it is unwise to force fluids at once in large amounts, following the patient's admission, if signs of myocardial insufficiency be present, but more advisable to increase gradually the fluid intake after 1 or 2 days' rest and digitalization. In general, too, in any patient showing signs of myocardial failure, the administration of fluids by the intravenous route is to be undertaken with caution. Recently we have adopted the following method.¹ A large transfusion needle is inserted into one of the veins in the forearm and strapped in place by adhesive so that it will not slip out. The arm is then so fastened to a board that the patient cannot bend the elbow. Through the needle normal salt or 5 per cent glucose is injected continuously by a drop method quite similar to the Murphy drip and so regulated that the patient receives not more than 100 to 200 cubic centimeters an hour. In this way large amounts of fluid may be given so slowly that the heart is not embarrassed by the increase in volume of the circulation.

What are the danger signals? How can one know that the limit of fluid tolerance is being reached? This again must be decided for each case but the most valuable sign is an increase in the number and extent of rales at the lung bases. In many such cases moist rales are audible at the lung bases on admission but are usually scattered. When large numbers are audible over the lower back on both sides fluid, should be restricted to 2,500 cubic centimeters or less, depending upon the urinary output.

Diet. Patients with oedema should receive a diet poor in salt—10 gram or less daily. In cases with impaired renal function the

¹A similar method was described by Matas. *Ann Surg* 1924, **183**: 643.

THE CIRCULATORY COMPLICATIONS OF PROSTATECTOMY

E COWLES ANDRUS M.D. AND EDWIN P. ALYEA M.D. BALTIMORE, MARYLAND
 From the James Buchanan Brady Urological Institute and the Medical Clinic of the Johns Hopkins Hospital

ANY operative procedure upon a patient during the sixth decade of life or thereafter is undertaken in the face of a diminished circulatory reserve. In the younger individual, in the absence of cardiovascular disease, the circulation, with the aid of its compensatory mechanism, is adequate to meet the most varied demands. With advancing age, however, coincident with degenerative changes in the blood vessels and myocardium, its functional reserve gradually decreases. The arteries become more or less sclerosed, irregular plaques are formed in the intima and may involve the medial coat. Diminution in the caliber of the vessels and impairment of the elasticity of their walls result. The changes in the myocardium are somewhat more varied. In the individual fibers histological alterations, pigmentation, occur which make it possible to distinguish an old fiber from a young one. Furthermore, the myocardium may show hypertrophy or fibrosis. The first is the normal response to the increased work required to maintain an adequate blood supply through narrowed inelastic arteries. Unless the valves are damaged or due to emphysema the resistance in the pulmonary circulation is increased this enlargement is confined to the left ventricle. Secondly, the aorta dilates, chiefly in the region of its base and arch. The second change, myofibrosis, is due to one or both of two factors: first, to the normal increase in interstitial connective tissue and wasting of muscle fibers, which occur with age; second, to localized or diffuse muscular degeneration and its replacement by fibrous tissue incident to impairment of the blood supply to the myocardium. The latter is augmented by any sclerotic narrowing of the coronary arteries either at their origin in the aorta or along their course.

Whatever may be the anatomical results of such changes the inevitable physiological effect is an impairment of the capacity of the heart to meet increased demands. The heart's

efficiency depends upon the integrity of its metabolism, this presupposes an adequate blood supply to the myocardium in proportion to the load placed upon it. The circulatory requirements under normal conditions can, in the majority of cases, be supplied but unusual demands (overexertion, fever, hypertension etc.) cannot be borne without some evidence of circulatory insufficiency.

Physical examination of the senile heart frequently presents the following clinical picture: the impulse is often obscured by overlying emphysematous lung and when visible or palpable it is usually displaced somewhat to the left. The relative cardiac dullness is enlarged particularly to the left and downward and the retrosternal dullness in the first and second interspaces, is widened, corresponding to the dilated aorta. The heart sounds at the apex are distant and feeble, and are often accompanied by a blowing murmur (functional mitral insufficiency). Over the base the aortic second sound may be sharp but in the absence of hypertension, is not greatly accentuated. More characteristic is a systolic murmur in the second right interspace sometimes transmitted upward. This is produced supposedly, either by arterio-sclerotic stiffening of the aortic cusps or by the relative disproportion in the diameter of the normal aortic orifice and the dilated arch. The cardiac rhythm may be normal but is often interrupted by ventricular extra systoles. Rarely auricular fibrillation may be present.

In the absence of myocardial insufficiency, such patients present few symptoms referable to the heart. They are conscious of limitation of their capacity for physical work and occasionally complain of palpitation. This latter symptom is sometimes lacking even in cases showing numerous extra-systoles. As the circulation becomes overtaxed however more obvious symptoms develop: fatigue, breathlessness while talking, dyspnea on slight exertion, and orthopnea. Finally a small proportion of these patients complain of typical

(or 1 to at most 2 gram daily) During the first 2 days after operation this is usually best administered by injection—digifoline 1 to 2 cubic centimeters Hyperventilation is a most important postoperative measure The interference with respiration caused by abdominal distention may sometimes contribute to circulatory failure It should, therefore, be prevented as far as is possible and vigorously combatted as soon as it appears Certain drugs, and particularly morphine, contribute to distention by relaxing the intestine Schlesinger's solution and pantopon are less liable to foster distention and at the same time are efficient sedatives After prostatectomy any treatment per rectum—enema or passage of rectal tube—is to be avoided on account of the danger of embolism Turpentine stoupes, pituitrin or eserine are usually effective in dispelling distention To avoid hypostatic pulmonary congestion these patients are turned frequently in bed

Uncomplicated cases are permitted to sit up in a chair for a half hour on the fourth day after operation Activity is gradually increased and supplemented by, at first light and then more vigorous massage When first allowed up many of these patients develop oedema of the feet, ankles, and lower legs This is particularly true of those who have, for one reason or another, been confined to bed for some time In the majority of instances this is an evidence of local, rather than general, circulatory insufficiency The return of venous blood from the lower extremities is, in no small measure, dependent upon the tone of the leg muscles As this develops, the oedema often disappears Massage and graduated exercises contribute to this In an occasional case it is necessary to provide elastic stockings to be worn while walking during the early days of convalescence

The most alarming postoperative complication is acute cardiac dilatation In this condition the myocardium becomes suddenly unable to accomplish an adequate systolic discharge Symptoms and signs of failure rapidly develop, the patient becomes cyanotic, the pulse rapid and thready, the blood pressure falls the pulse pressure is reduced, pulmonary rales become evident and the liver is engorged

The heart is often demonstrably enlarged, the sounds feeble, and a gallop rhythm is frequently audible The cause of dilatation is not always evident immediately It is theoretically due to increase in the myocardial load beyond the optimum limit in proportion to its blood oxygen supply

The most common factors causing acute cardiac dilatation are pulmonary embolism and coronary occlusion The incidence and results of the former have recently been reported by Thomas and Alyea¹ The abrupt blocking of a greater or lesser portion of the pulmonary circulation suddenly increases the resistance to the output of the right ventricle The added anoxæmia contributes to the failure of the myocardium by impairing its oxygen supply Coronary occlusion, by depriving a portion of the myocardium of its arterial supply, may bring about acute and alarming symptoms of dilatation If the occlusion involves a large vessel, death is the inevitable result If, however, it occupies one of the terminal branches, compensation may later be restored Coronary occlusion is attended by symptoms and signs of cardiac dilatation and by moderate fever and leucocytosis

The patient is often conscious, restless, and extremely apprehensive A sedative, usually morphia, should therefore, be given at once If the patient has not been previously digitalized this should be accomplished as rapidly as possible, best of all with strophanthin The fall in blood pressure is due only in part to peripheral vascular relaxation, it is the result chiefly of the decreased systolic discharge on the part of the heart For this reason adrenalin should be used cautiously, it may only increase the load upon an already overburdened ventricle Caffeine is, under these conditions, a far more rational stimulant than adrenalin

Finally an abnormal rhythm, auricular fibrillation, or, more rarely flutter, may so interfere with the output of the heart as to cause symptoms of circulatory failure This may be present upon admission or may develop suddenly following operation The ventricular rate can be controlled with

¹ Thomas and Alyea, South. M. J. 1929, vol. 237

tention of salt may contribute to the accumulation of *œdema*

Hyperventilation With advancing age the thoracic cage becomes more and more rigid as the costal cartilages ossify. At the same time the lungs themselves undergo characteristic changes. The alveolar septa waste and the alveoli coalesce, producing the so called senile emphysema. The residual air is increased, the vital capacity is diminished and expansion is limited. Upon auscultation the breath sounds are distant. If the patient has been recumbent prior to examination, dry, crackling rales are audible at the end of inspiration. These are due to the reopening of alveoli compressed in the recumbent position and are to be distinguished from moist rales which are pathognomonic of pulmonary congestion. The circulation in the lung is impeded by any considerable degree of atelectasis and is enhanced by normal pulmonary ventilation. Aside from its effect in reducing the incidence of postoperative pulmonary infection, as reported by Scott¹, hyperventilation has been found effective in relieving hypostatic congestion both pre-operative and postoperative, in older individuals. This may usually be accomplished voluntarily by the patient, in some cases it must be induced after operation by causing him to inhale a mixture of 5 per cent carbon dioxide in oxygen.

Digitalis As has been so often stated the indication for digitalis is myocardial insufficiency, the routine administration of this drug is not only useless but unwise. It should however, be given to any patient showing signs of congestive failure, and in adequate quantity, i.e., 15 grams standard leaves per 100 pounds body weight, or an equivalent amount of some standardized preparation. This is best administered in divided doses over a period of 48 hours or more, except in cases of acute failure, to which it may be given more rapidly. After the maximum therapeutic effect has been obtained, digitalis should be continued at 0.1 to 0.2 gram daily to replace the amount normally excreted. If the patient has received this drug prior to admission digitalis must be administered in smaller doses and a longer period allowed for digitalization

in order to avoid intoxication. The development of acute dilatation calls for an increase in digitalis dosage, or, if the patient has not been fully digitalized previously, for strophanthin (0.5 to 1.0 milligram intramuscularly). In cases showing numerous ventricular extrasystoles the combination of digitalis with diionine may often restore the normal rhythm more quickly than does digitalis alone. This is given in capsules (folia digitalis 0.1 gram, diionine 0.006 gram) and continued up to the therapeutic maximum for digitalis.

Operation The circulatory strain resulting directly from an operation is due to one or both of two factors. The first is reflected in a reduction of the vital capacity, and is particularly marked in abdominal operations. The normal vital capacity falls steadily during the sixth and seventh decades of life and after until at 80 it is but 45 to 50 per cent that of the normal at 30 years of age. Perineal operations have been shown to be accompanied by little or no reduction in the vital capacity,² a fact which we have repeatedly confirmed. As regards the perineal operation, the chief circulatory strain may be due to the second of these factors, i.e., the anæsthetic. Here the choice is often a nice one. Aside from increasing the frequency of postoperative pulmonary complications general anæsthesia, ether or nitrous oxide, is attended by a degree of anoxæmia and secondary circulatory changes which must be regarded as dangerous in elderly patients. Herein lies the advantage of caudal or spinal anæsthesia. Except in occasional, very apprehensive, patients with symptoms of angina pectoris, we have used caudal or epidural anæsthesia, injecting 20 cubic centimeters of a 3 per cent solution of procaine into the sacral hiatus. Morphia (16 milligrams) is given the night before operation to insure rest and again just before operation. Caudal anæsthesia is attended by a fall in blood pressure varying from 10 to 50 millimeters mercury in about 50 per cent of the cases, by a rise of 10 to 30 millimeters in 30 per cent, and by no pressure change in the remainder.

Postoperative treatment Digitalis should be continued after operation in doses just sufficient to maintain the therapeutic effect

¹Scott, W. J. M. J. Am. Med. Ass. 1919 xcii 202

adequate doses of digitalis. In the case of flutter the rhythm may be restored to normal by means of quinidine after digitalization.

CASE REPORTS

G. P., aged 77 years, admitted to the hospital December 4, 1928, complaining of urinary frequency and urgency which had been present for 4 years. Three years ago he began to have pain over the upper precordium and in the left upper arm following exertion or a heavy meal. Examination in October 1926 revealed benign prostatic hypertrophy with residual urine 400 cubic centimeters. He often felt faint but he never lost consciousness. The diagnosis at this time was arteriosclerosis, cardiac hypertrophy and dilatation and angina pectoris. Blood pressure was 170-90. These symptoms persisted up to time he was last admitted to the hospital.

Physical examination disclosed a large man with arcus senilis, lungs clear throughout. Heart rhythm was regular, rate 80. Impulse was visible in fifth left interspace 11.5 centimeters from midline and was localized and forceful. Relative cardiac dullness measured in first interspace 3.0 centimeters left, and 3.5 centimeters right, in second interspace 3.0 centimeters left and 3.0 centimeters right, in third interspace 6.5 centimeters left and 3.0 centimeters right, in fourth interspace 11.0 centimeters left and 4.0 centimeters right, in fifth interspace 13.0 centimeters left and 4.5 centimeters right. At apex sounds were loud and there was a faint systolic murmur. Over mid and upper portions of the precordium there was another systolic murmur, loudest over the aortic area and transmitted upward into neck vessels. The second aortic sound was loud and ringing. The retinal arteries were narrowed and tortuous. The radials and brachials were palpably thickened. The liver was not enlarged. No edema was present in extremities. Impression: Benign prostatic hypertrophy, arteriosclerosis of peripheral and coronary vessels, dilatation of aorta, cardiac enlargement, angina pectoris.

Patient was prepared for operation over a two week period with rest and digitalis. He got out of bed once and fainted. Blood pressure taken immediately thereafter was 130-80. Perineal prostatectomy was performed December 18, 1928, by Dr. Young. Ether anesthesia was used. Systolic blood pressure during operation varied from 150 to 180. Immediate convalescence was uneventful.

Three weeks after operation patient awakened at night with pain in his left arm. He insisted upon arising next day. That evening he complained of constant dull pain in the upper precordium and left arm, he became apprehensive. Examination showed slight cyanosis and the heart not demonstrably larger than before. Sounds were faint, the apical systolic murmur louder, a presystolic gallop rhythm was audible over the entire precordium. Liver edge 2 centimeters below the costal margin. Patient was confined to bed, sedatives were administered and

digitalis dosage increased for 5 days. Gallop rhythm and pain gradually disappeared. During the week following this attack patient had a fever of 100 to 101 degrees and leucocytosis 10,000. He remained in the hospital 3 weeks after the cardiac attack and then rested at a hotel in the south. Massage and graduated exercise were begun after 2 weeks and were continued after his discharge from the hospital. He returned 4 months later. At this time the physical examination showed the same conditions as were present when he entered the hospital for the first time.

This case illustrates the occurrence of minor coronary occlusion in a patient who had had symptoms of angina pectoris for several years. Operation was undertaken with considerable apprehension and then only after 2 weeks' preoperative treatment and because it seemed absolutely necessary. The choice of ether anesthesia was made for two reasons: (1) The history of syncopal attacks and the observation of one such associated with a fall in blood pressure which made it seem unwise to risk the lowering of pressure frequently associated with caudal or spinal anesthesia, and (2) the excitable temperament of the patient. It was felt that during an operation under local anesthesia, this latter might cause a dangerous rise in pressure.

D. G., aged 76 years, admitted to the hospital in March 1928. His complaint was urinary frequency of 10 years duration. Urinary retention was noticed 6 years prior to admission; during that period the patient catheterized himself. A large vesical calculus was discovered by cystoscopy in January, 1928. Patient was short of breath and had precordial discomfort upon exertion, cramps in the lower legs were brought on by walking. He gave no history of angina pectoris.

Physical examination disclosed a pronounced arcus senilis and clouding of the lens in each eye. Respiratory movements were limited by the rigid thoracic cage; respiratory rate 28 per minute. The pericardial note was resonant over both lungs and over the upper portions it was tympanic in quality. Fine moist rales were audible over both bases. Examination of the heart showed impulse visible 9.5 centimeters from the midline in the fifth left interspace. Relative cardiac dullness: first interspace 2.5 centimeters left, 5 centimeters right; second interspace 3.0 centimeters left, 2.5 centimeters right; third interspace 4.5 centimeters left, 3.0 centimeters right; fourth interspace 8.0 centimeters left, 4.0 centimeters right; fifth interspace 11 centimeters left, 4.0 centimeters right. Heart sounds were distant. Systolic murmur at apex was transmitted outward over the aortic area; the systolic murmur was trans-

mitted upward. Ventricular extrasystoles occurred every third cycle. Blood pressure on admission was 100-100. Blood urea 0.64 grams per liter. Vital capacity on admission was 800 cubic centimeters. All superficial arteries were palpably thickened and radial arteries contained calcified plaques in their walls. The retinal arteries were irregularly narrowed. Liver edge palpable 1 centimeter below the costal margin. Slight edema was noticeable over both ankles and tibiae.

The bladder was drained with a retention catheter. 4,000 cubic centimeters of fluid were administered daily. Patient was kept in bed except for 2 hours daily in a chair. He received 12 doses of digitalis leaves 0.1 gram and diionine 0.006 gram within the first 3 days. Digitalis leaves were then continued 0.2 gram daily. Upon the twelfth day after admission the blood pressure had fallen to 160-75 and blood urea to 0.40 gram per liter. Vital capacity at that time was 1,000 cubic centimeters. The liver had decreased in size. edema of ankles had disappeared. The respiratory rate was 16 per minute. The excretion of phthalein rose from 60 per cent to 80 per cent over a 2 hour period. The ventricular extrasystoles were still present.

Perineal prostatectomy was done by Dr. Young, caudal anesthesia being used. Digitalis was continued at 0.1 gram daily. The patient was confined to bed for 4 days and then allowed to sit up for increasing periods during the subsequent 10 days.

This case presents the problem involved in a patient with advanced arteriosclerosis, moderate hypertension and a low vital capacity who required removal of the prostate for the relief of urinary obstruction. Upon admission there was evidence of myocardial insufficiency. This disappeared as did also the hypertension under pre-operative treatment of 12 days' duration. The patient underwent operation without any circulatory complication.

E. S. aged 72 years was admitted to the hospital June 16, 1928. He had suffered from frequency and difficulty of urination for 6 years. He had been frequently catheterized during the last 5 years. Breathlessness was noticed on exertion but there were no symptoms of angina pectoris. The extremities were not edematous. The lungs were clear on percussion and auscultation. The cardiac borders were within normal limits; there was no cardiac enlargement; the sounds were of good quality; no murmurs and rhythm was normal. Blood pressure was 140-90. Urological examination showed a benign prostatic hypertrophy. On June 18, 1928, perineal prostatectomy was done by Dr. Young, caudal anesthesia being used. An attack of acute epigastric discomfort on the fourth day after operation was followed by pain in lower right axilla accentuated by deep

inspiration. Pain was relieved by sedatives and strapping of chest. The next morning movements of right side of the chest were limited on inspiration, there was a small area of dullness in right lower axilla with suppression of breath sounds over this region. No rales and no friction were noticed. Diagnosis: Pulmonary infarction. X-ray examination showed infiltration and pleurisy at the right costophrenic angle. Three days later pain was again noticed in the right chest. Temperature rose to 102.2 degrees and for the next 5 days ranged from 99 to 101 degrees. After the second attack of pain examination showed a large increase in the area of dullness in the right lower lobe. Patient was disoriented and weak, blood pressure was 100-75 with gallop rhythm at 140 per minute. Three days later bright red blood appeared in the sputum. Cardiac rhythm was now irregular. Patient received 1.2 grams of powdered digitalis in 2 days and 0.2 gram each day following for 2 weeks. X-ray examination 7 days later showed pneumonia at the right base. Blood streaked sputum persisted for 2 weeks. Temperature gradually fell to 99 degrees. White blood count was 11,400. Signs of thickened pleura at the right base were noticeable for a month. After the patient had sat up in chair his ankles became markedly edematous. Cardiac rhythm continued to be entirely irregular, pulse deficit 50 per cent. There was no edema of the lungs and edema of the extremities disappeared in 1 week. An electrocardiogram showed an auricular flutter. Patient was given 1.0 gram digitalis in 24 hours, followed by 0.8 gram quinidine. The next day a normal sinus rhythm supervened. A week following this the patient was discharged from the hospital with a normal sinus rhythm, no edema of the extremities or of the lungs.

In this case convalescence was interrupted by pulmonary infarction, acute cardiac dilatation and auricular flutter. With absolute rest, sedatives, and digitalis the patient recovered from the effects of the pulmonary infarction and the signs of circulatory collapse disappeared. The rhythm of the heart reverted to normal under quinidine.

SUMMARY

1 Hypertrophy of the prostate, requiring operative removal, usually develops at an age at which the functional circulatory reserve is already diminished.

2 Proper pre-operative care, the use of caudal anesthesia, and careful postoperative observation do much toward avoiding circulatory complications of prostatectomy.

The authors are indebted to Dr. Hugh H. Young for permission to study these cases on his service.

SIMPLE, NON-SPECIFIC ULCER OF THE COLON

MAURICE E. BARRON, M.D., F.A.C.S., BOSTON
 From Surgical Department of Beth Israel Hospital, Boston

SIMPLE, non specific ulcer of the colon is an ulcerating lesion which is not due to the action of any specific organism such as specific ulcer of tuberculosis, syphilis ulcerative colitis, dysentery, typhoid fever, or to the local action of any chemical agent and which is not secondary to or above a malignant tumor causing constriction.

In September, 1928, I published a paper entitled "Simple, Non specific Ulcer of the Colon." The article was a study based on 50 cases collected from the literature and observations on 3 personal cases.

I directed attention to the fact that simple ulcer, analagous to gastric or duodenal ulcer, may occur on any part of the alimentary canal from the oesophagus to the rectum and that the gross and histological characteristics of this lesion are similar in every way to the so called peptic ulcer.

Ulcer of the stomach in association with ulcer of the duodenum or in association with ulcer of the jejunum, ileum, or colon, in the same patient has been observed by some investigators (2, 3, 4). In the series which I studied the combined lesions, ulcer of the stomach and of the colon occurred in 4 cases.

Since the presence of ulcers occurring both in the stomach and duodenum in the same patient is not rare and we are ready to accept the etiology in both ulcers to be the same, it is rational to believe that simple ulcers occurring in the stomach and in other segments of the gastro intestinal tract in the same patient have a common etiology. Because of my findings and the observations of others where the lesions occurred both on the stomach and colon, I am led to believe that there is probably a common etiology. If this is true, it would seem that simple ulcer of the colon must be a manifestation of the same general disease as peptic ulcer, and therefore we must look to causes other than local for the production of these lesions.

Of 53 cases that have been reported in literature since 1837, the pre-operative diag-

nosis of appendicitis was made 11 times, first appearing in literature in 1910. Since 1910 there have been 23 cases reported, of which number the diagnosis of appendicitis was made 11 times—almost 50 per cent. In 10 of the 11 cases, the ulcer occurred either in the cæcum or the ascending colon. The diagnosis of ulcer, when the lesion occurs in the right half of the large bowel is very difficult to differentiate from that of appendicitis. Recently I saw and operated on another patient with a perforating ulcer of the cæcum where a diagnosis of appendicitis was made.

Mrs. C. P., female, age 61 years, white, entered the Surgical Service of the Beth Israel Hospital on April 5, 1929, with a complaint of severe pain in the right lower quadrant. Her family and past history were essentially negative except for mild diabetes mellitus for past 6 months. About 1 week ago she began to have pain in right lower quadrant. Pain gradually became worse and continued for about 1 week being moderately severe until day of admission when suddenly the pain became much more severe. There was no nausea or vomiting. There was no elevation of the temperature or increase of pulse rate until today when there was a slight elevation of temperature. The bowels were regular with catharsis and she had a bowel movement today. She has had a chronic cough for many years but with no expectoration. Menopause occurred 12 years ago—there is no dysuria or hæmaturia. Patient has been on insulin and regulated diet. There never has been any jaundice and there was no history of any previous digestive trouble.

Physical examination disclosed well developed obese woman of 61 years lying in bed complaining of considerable pain in the right lower quadrant. The skin was moist and warm and the face flushed. There was nothing else of note except marked tenderness over the right lower quadrant and some spasm and rigidity of the muscles in this region. The costovertebral angles were not tender—abdomen was tympanitic throughout—no definite mass could be made out over the tender area. A provisional diagnosis of acute appendicitis was made and immediate operation was advised. The results of urine analysis were negative. White blood cells 11,000. Temperature 100 degrees F. pulse rate 100 respirations 24. Blood pressure systolic 155 diastolic 90.

Operation was done April 5, 1929. Under local anesthesia a McBurney incision was made. There escaped a slight amount of a seropurulent exudate.

The cæcum was found indurated and adherent to the parietal peritoneum. The vermiform appendix was found to be much smaller than normal almost obliterated and could not possibly have accounted for the inflammatory reaction within the peritoneal cavity and the patient's clinical condition. It was removed however in the usual manner. Since the cæcum was found to be indurated and adherent it was impossible to continue the operation without the aid of a general anæsthetic. On account of the patient's condition nitrous oxide and oxygen was used. The cæcum was then freed and an indurated mass about the size of a silver half dollar found in the posterior lateral aspect. The induration corresponded to an isolated ulcer, the center of which revealed a perforation about the size of a lead pencil in diameter from which was escaping intestinal contents. There was no evidence of any other ulcer or enlarged glands and it was felt that this was a non-malignant ulcer and there was nothing to suggest this being a tuberculous ulcer. A small piece was taken from the edge of the perforation for histological examination. The perforation was sewed with fine chromic catgut. The serosa of the cæcum was sutured over the closure with linen. The abdomen was then closed in the usual manner and two cigarette wicks were placed to the right iliac fossa.

Patient made an uneventful convalescence and she was discharged well on April 22, 1929. The operative wound was well healed throughout.

Pathological report. Source of specimen appendix biopsy of inflammatory mass in cæcum. Specimen consists of a roughly pyramidal piece of tissue 1.2 centimeters in height and 5 millimeters broad at the base. The lower 4 millimeters is yellowish white and moderately firm and seems to be fat. The remainder is uniformly softer and pink. Two sides of the pyramid are smooth and appear as if cut with a knife. The other two sides are granular and the angle between them is blunt. At the apex of the pyramid is a tiny notch. Accompanying the specimen is an appendix which measures 7 centimeters in length. The proximal 5 centimeters is 0.5 centimeter in diameter and soft to palpation. The distal 2 centimeters is represented by a thin fibrous cord 1.5 millimeters in diameter. The serosal surface is rough everywhere, but shows no exudate. When sectioned the lumen of the proximal part is found to be patent and to contain a small amount of bloody material. The distal lumen cannot be entered. The wall of the proximal part is slightly thickened especially near the line of excision.

Microscopic section of the tissue from the edge of the ulcer shows the base of the pyramidal shaped tissue to be composed of fat, the fibrous tissue septa of which are infiltrated with inflammatory cells, a large proportion of which are lymphocytes. There are also a few eosinophiles. Several broad septa are markedly edematous. As the depths of this fat layer are approached, this cellular infiltration becomes more marked and here a few polymorphonuclears are intermingled with the other cells. The

remainder of the tissue extending from the fat to the tip of the pyramid is more or less alike and consists of very loose edematous fibrous tissue containing very few fibroblasts and a fair number of young capillaries. It is very heavily infiltrated with polymorphonuclears and some lymphocytes. There is also a moderate number of eosinophiles here, and a few endothelial leucocytes. Many of these cells are necrotic and have pyknotic nuclei and there is considerable nuclear debris sprinkled throughout. Several spots show complete necrosis and take a uniform granular acidophilic stain. There is no indication of the original layers of the cæcum except that near the tip of the pyramidal piece there are again some fat cells embedded in the inflammatory tissue and here are a few arterioles and this might be taken to be the remains of the submucosa. There are no epithelial cells recognizable anywhere and no evidence of carcinoma. No amebæ are found after careful search and there is no evidence of tuberculosis anywhere. There are a few small areas of fresh hæmorrhage, but no old changed hæmoglobin to indicate previous hæmorrhage.

Section of the appendix shows the distal tip to be composed of a mixture of smooth muscle and fibrous tissue with only small knots of lymphocytes. No mucosa is seen anywhere. Proximal to this, the muscularis is thin and fibrosed for a considerable distance although the mucosa is of good thickness. The mucosa here shows considerable eosinophilic infiltration and scattered areas of lymphocytic infiltration are found in the muscularis and serosa. Diagnosis: chronic inflammatory tissue from cæcum chronic obliterative appendicitis.

I felt it would be of considerable interest to ascertain whether there was any interference with the motility of the cæcum as a result of the operation or any gross evidence of pathology in the colon that might be revealed by X-ray studies. Therefore, following discharge from the hospital the patient was advised to have gastro-intestinal studies. The following is the report.

May 13, 1929. There was no obstruction to the passage of the barium enema. The base of the cæcum was slightly dilated. There were no filling defects but a moderate redundant sigmoid.

May 22, 1929. The œsophagus was normal. The stomach occupied a medium position. It appeared to be definitely narrowed near the pyloric end of the stomach but this narrowing is probably due to spasm. The first portion of the duodenum was large but filled normally. At the 6 hour examination the head of the meal was in the distal portion of the transverse colon (normal motility). At 24 hours the large bowel almost completely emptied. Plain films of the gall bladder region showed a slight suggestion of the outline of the gall bladder but no evidence of stones. Plain film of the urinary

tract showed some definite hypertrophic changes in the lumbar spine. There was nothing abnormal noted in the genito urinary tract.

SUMMARY

A case of a simple, non specific ulcer of the colon which perforated is reported. The gross and histological characteristics of this ulcer seem to be analagous to that of peptic ulcer, and therefore the question arises as to whether an ulcer occurring on the colon is not a local manifestation of the same general disease that peptic ulcer is. There is nothing in the past or present history of this patient that would suggest the cause to be mechanical, such as a decubital ulcer due to constipation. When the ulcer occurs on the right half of the

colon it is difficult to differentiate this lesion from appendicitis. However, since in the vast majority of cases both conditions require immediate operation it is important to remember that when the appendix appears more or less normal or does not give evidence of a sufficient inflammation to produce the clinical picture, the cecum and the ascending colon should be explored for the possibility of an ulcer.

CLINICAL SURGERY

FROM THE HESSISCHE HEBIMMEYERANSTALT, MAINZ

THE THEORY AND PRACTICE OF INTRA-UTERINE CHARCOAL TREATMENT IN GYNECOLOGY AND MIDWIFERY

DR H. NAHMMACHER, MAINZ, GERMANY

THE favorable results reported by Benthin of Koenigsberg, and Geller, of Breslau led us to employ charcoal intra uterinely in gynecological and obstetrical cases and we have been able to obtain the same favorable results as reported by these authors

Before responding to an invitation to test and recommend a new preparation or treatment—especially when good therapeutic precedures are already in existence—one must be convinced of the value of the new method and of its freedom from danger. In particular, one must understand the effect of the preparation—in the present instance, charcoal—and must then consider whether the new method of treatment (intra uterine charcoal treatment) offers any great advantages over methods already available

For the better understanding of intra uterine charcoal treatment I should like to preface my remarks with some brief observations on the importance and advantages of charcoal as a therapeutic agent

The use of charcoal in medicine is probably not uncommon. Even in olden times wounds and internal affections were treated with adsorbent substances. The most important quality of medicinal charcoal is because of its porous structure and consequent great surface energy, its high power of adsorption, i.e., of fixing other substances. To this property charcoal owes its great use. The adsorptive capacity is manifested either in the adsorption of wound secretions or in the adsorption of bacteria and their toxins. The latter is of very great importance

To gain a clear conception of the processes to which the name of adsorption phenomena is applied it is necessary to have recourse to the department of physical chemistry especially of colloid chemistry in which the phenomena of surface energy are of great importance. I would refer in this connection to the paper¹ by Franz

Koenig on "The Importance of Medicinal Charcoal in Therapeutics and the Nature of Adsorption." In this paper a short sketch is given of the conception and nature of adsorption, and also of the practical employment of charcoal in medicine, i.e., of adsorption therapy. The range of indications of which is very extensive. For us as medical practitioners, these pharmaceutical details are of infinite value in enabling us to obtain for ourselves a satisfactory explanation of the mode of action of the application of charcoal. Adsorption depends upon (1) the extent of the surface energy, i.e., the size of the free surface, (2) the surface tension between adsorbent (charcoal) and liquid and (3) the surface activity of the liquid.

While, as a result of the adsorption of wound secretion it is made much more difficult for bacteria to live on the drained tissue surface, it is true that as a result of the adsorbent fixative action on bacteria and on the poisonous properties of bacterial toxins, adsorption into the blood stream is very greatly retarded, if not rendered altogether impossible. Weidmann has shown that charcoal powder has an adsorbent action even on bacteria in the blood. It is absolutely necessary, therefore, in cases of poisoning for example, that the quantity of charcoal should be sufficient to reduce the quantity of poison present to below the lethal dose. Van Amstel has demonstrated that the maximum dose of charcoal to be administered at once in man is 40 to 50 grams.

In addition to the great adsorptive power just described, the astringent action of charcoal plays a not inconsiderable part.

Is the local application of charcoal likely, it may be asked to produce any injurious or detrimental effects? All the publications on the subject show beyond doubt that this is not the case. Geller and others have proved that no harmful action on the cells appears as the result of the application of charcoal but that, in virtue of the property already mentioned, of abstracting fluid, a stimulant

¹Pharm. Ztg. 1925 No. 102

action is actually exerted on the tissues, which leads to hyperæmia

The very fact that charcoal possesses such great therapeutic powers makes necessary especial care in selecting preparations of charcoal for medicinal use, such preparations must be of high standard. It is well known that the ordinary medicinal charcoal preparations on the market show very great differences in adsorptive capacity. The suitability of charcoal preparations for medicinal use is dependent not on the source (animal or vegetable) but solely on the method of treatment of the charcoal.

Up to the present charcoal and, consequently, adsorption therapy have been used only in the treatment of the gastro-intestinal canal diseases such as acute poisoning with metallic salts, poisoning with organic poisons, poisoning produced by meat, fish, sausages, pre-eaten foods, infectious diseases (cholera, dysentery, etc.) and intestinal auto-intoxication, hyperacidity and gastric ulcer (of special value in the latter on account of the acid binding and ferment inhibiting action of charcoal), excessive gas formation (postoperative intestinal paresis) and the presence of large numbers of bacteria. Recently, however, charcoal therapy has been used, by means of intra uterine application in gynecology and obstetrics. Favorable results following the intra uterine application of charcoal in metritis were first reported in veterinary medicine.

In what conditions in human gynecology and obstetrics is the charcoal treatment indicated? In abortion, especially febrile abortion, in puerperal endometritis, and in cesarean section after rupture of the membranes. The conservative treatment of septic abortion first inaugurated by Winter, of Koenigsberg is now generally recognized as correct.

The process of recovery is hastened by the intra uterine application of charcoal by reason of the preventive and curative action of the charcoal. The determining factor in the success of the treatment is its application at the earliest possible moment, provided the process is still substantially localized in the uterine cavity and provided sufficient charcoal in the form of granulated charcoal pencils which, from the colloid chemical point of view, approximate most closely the ideal powder, is introduced into the cavity of the uterus (insufflation of powdered charcoal is dangerous and therefore unsuitable for use in this treatment). The task of the charcoal thus introduced is to prevent, or at the least render difficult the occurrence of any absorption from the residual fluid of the uterine cavity, heavily charged with bacteria

and toxins, into the tissues or the blood and lymph apparatus. Such absorption, or the entry of the poisonous substances into the cells is prevented or hindered by a protective layer, difficult of penetration, which is formed by the dissolved particles of carbon.

It is necessary to use a quantity of charcoal sufficient, after expansion, to fill the whole cavity of the uterus and to cover the decidua completely. Further bacterial invasion is thereby made impossible.

As already mentioned, it has been demonstrated by Geller that no injury to healthy, regenerated mucous membrane cells occurs as the result of too abundant application of charcoal in the case of a local focus in the uterine cavity.

The germicidal action is, indeed, heightened by the fact that in consequence of the abstraction of water from the tissues, a stimulant effect leading to hyperæmia is simultaneously exerted on the healthy tissues. From these considerations and collected experiences it is sufficiently evident that intra uterine charcoal treatment offers great therapeutic advantages over the measures hitherto generally employed.

With uterine irrigations, a method now only rarely used, we obtain at most a temporary diminution of bacteria. The irrigating fluid is immediately evacuated, partly through the return flow catheter, partly through the cervical canal. Its action on the foci of infection is therefore of short duration. There is moreover the danger of injury to the mucous membranes by the rigid catheter. Such injury makes a place of lessened resistance sufficient to enable bacteria to break through the leucocytic defense. A further danger is that the bacteria infested contents of the uterus may be washed upward into the fallopian tubes and possibly into the abdominal cavity.

Swabbing of the uterine cavity with ether and iodine, intravenous infusion of dextrose and tamponage of the infected uterine cavity remain to be mentioned. The latter is supposed to act by absorption and at the same time serve as a means of escape for the uterine contents. Attempts have also been made to fight bacterial infection of the uterus by means of intravenous injections of trypanflavin, argochrome and collargol solutions, etc. Irradiation of the infected and metritic uterus with X rays has likewise been employed therapeutically. All these methods of treatment are so variable in their results—while some are not wholly free from danger—that none of them can be called fully effective. All have their good and bad points. These factors of danger and variable results do not exist with charcoal therapy.

For charcoal therapy we make use of the pencils of granulated charcoal, measuring 3 and 5 centimeters in length and about 4 to 5 millimeters in thickness, which have been placed at our disposal by E. Merck, of Darmstadt. These pencils, which are prepared from pure, compressed granulated charcoal—kaolin is unsuitable on account of its forming lumps—are very convenient in form but are very easily broken. Gentle manipulation is necessary, as indeed is the case in all intra uterine procedures. The fragility of the pencils has at the same time, however, the advantage that the least attempt, during their insertion, to overcome any resistance (narrow cervical canal, acute angled inflexion) by the use of force is met by the immediate breaking of the pencil, so that we are, as it were, debarred from causing injury.

What happens to the pencils in the cavity of the uterus? In the bacteria and toxin laden residual fluid of the uterus they begin to effervesce and to dissolve, at the same time exerting their therapeutic effect (inhibiting bacterial growth). They find themselves in a medium in which their disintegration is complete. That disintegration may, in isolated instances, be incomplete is shown by the fact that fairly large particles of charcoal are sometimes expelled again. Even after the lapse of 10 to 12 days we have found small remnants of charcoal in the posterior vault of the vagina. This fact has no influence on the favorable effects of the treatment. I shall again refer to these processes. The solution of the pencil can be facilitated by dipping it two or three times in distilled water before inserting it. By this means the outer parts of the charcoal pencil are softened and more rapid intermingling of the charcoal with the uterine contents is obtained. The insertion of the moistened pencils demands particularly delicate manipulation as they are very much more fragile, on the other hand by reason of the softened outer covering of charcoal, the possibility of injury and lesions of the mucous membrane is nil from the very beginning.

The processes which attend the interaction between the disintegrating charcoal pencil and the infected uterine fluid can be illustrated by preparing a fluid chemically similar to that contained in the uterus and treating it with the charcoal pencil in a vessel of some sort. To the accompaniment of effervescence and decrepitation, a thick, black pasty mass is produced, in which some solid particles of charcoal may remain undissolved.

In these experiments *in vitro*, which exhibit to us in some measure the intra uterine processes, there is missing however, the action on the charcoal pencil of the uterine contractions, which are

of great value in effecting the solution of the charcoal and its union with the bacteria infected contents of the uterus.

INDICATIONS

In the remainder of this paper I wish to speak of the range of indications for charcoal therapy and of the technique practiced by us.

Our treatment of abortion is strictly conservative, provided hemorrhages do not call for our interference. We regard every febrile abortion as intentional, produced by external interference. The same may be held true of afebrile cases, only here the operator has proceeded with rather more cleanliness.

In numerous trials we have been able to prove experimentally that the granulated charcoal introduced into the poison containing media (before any toxic action on the tissue appears), prevents their extension and continuance. We speak of a "direct prophylactic action," by means of which many severe affections, and even death, can be avoided. The possibilities of this direct prophylactic action led us to insert one or two charcoal pencils, also in every case of fever free abortion which for any reason had to be actively terminated, always on the supposition that a local infection might be present. This prophylaxis is of still greater and more effective value in those cases which are admitted with temperatures of up to 38 degrees C (100.4 degrees F) and which it is necessary for us to terminate. We found in almost all cases that the temperature fell to normal in at most 24 hours and, what is worthy of note, that convalescence was uninterrupted and entirely free from fever so that it could be assumed that the bacteria in the uterine cavity had been killed. In cases of febrile abortion, there is often during convalescence a subfebrile temperature extending over several days, and indicating in most cases an endometritis. The result of charcoal therapy is to eliminate this temperature and to secure a convalescence free from fever, and its success in this respect is the greater in proportion as the treatment is commenced early, i.e., before toxic damage to the tissues has set in.

There is a further field in which this direct prophylactic intra uterine application of charcoal is indicated—cases of abortion which are admitted to the hospital with high fever and severe local infection. The possibility of securing better results in treating these cases by means of charcoal, is also mentioned by Benthin who suggests that the infected uterine contents be rendered germ-free, or bacterial growth prevented at least, by inserting charcoal pencils as a first measure, before the infected case is actively terminated. In

similar cases we have begun by inserting charcoal pencils, and have been able in 24 hours at most to see whether the desired effect has set in, as evidenced by fall of temperature, improvement in the general condition, and almost immediate cessation of any malodorous discharge that may be present. A critical examination of each individual case must naturally precede treatment, for we can expect to influence the bacteria by means of intra uterine charcoal therapy only when the pathological process is strictly localized in the uterine cavity. After this direct prophylactic preliminary treatment, we can be sure of having a uterine cavity which is in some measure free from bacteria, so that less danger is involved in subsequent active procedures. Cases treated in this way have confirmed in practice our theoretical conclusions. The further course was in all cases free from fever, the fall in temperature critical. In these cases a part is played not only by the adsorbent and astringent action of the charcoal, but also by the charcoal pencil as a foreign body. The uterus reacts with contractions, so that placental remnants which have become purulent are partly detached if not entirely expelled. As soon as detachment occurs the dissolved charcoal can immediately exert its therapeutic powers at the site of adhesion, and so prevent further ascent of the bacteria.

Puerperal metritis is also very favorably influenced by intra uterine charcoal therapy, so that we now include this condition among our indications for the treatment. As soon as evil smelling discharge and subfebrile temperatures set in, the patients are treated for 5 to 6 days with ergotin or gravitol (either 20 drops thrice daily or better, a double dose of one of these medicaments on each of 3 successive days) and with the ice bag the head of the bed is also raised 25 centimeters so as to facilitate escape of the discharge. If no improvement is obtained by these means, we introduce charcoal into the uterus on the seventh day under the strictest aseptic precautions. In all cases a reduction in temperature was obtained on the next day, and on the second day at latest the temperature fell to normal. The fetid odor disappeared at once. In over 90 per cent of the cases it was unnecessary to insert charcoal pencils more than once a fact which says much for this method of treatment. In several cases of pyometra we were able to bring about complete recovery, with lytic fall of temperature only after several applications of charcoal. Even in these cases however, the evil lochia odor—often very unpleasant both to the patient and her neighbors—disappeared immediately after the very first applica-

tion a result which has a considerable influence in improving the patient's general condition.

As a result of our experience, I should like to extend the range of indications still further and include therein a class of cases often complicated by prolonged wound suppuration. These are cases of cesarean section after rupture of the membranes. We cannot know how far an infection of the uterine cavity has taken place. Our statistics of cesarean section for the ten years from 1918 to 1928 showed one abdominal abscess in cases of operation before rupture of the membranes, 10 abdominal abscesses in cases of operation after rupture of the membranes and almost always an endometritis with fever, which in most cases lasted over a week.

Accordingly, in such cases we insert several (3 to 5) granulated charcoal pencils into the uterine cavity after expulsion of the placenta. It is here quite impossible to cause even the slightest injury, as the uterine cavity lies open. I regard this method as the safest way of obtaining local prophylaxis of the uterine cavity. In swabbing with ether, tincture of iodine or dry swabs there is the great danger of transferring bacteria from one part to another.

Prophylaxis against an infection which is still invisible is also in any case a less severe and less dangerous proceeding than the treatment of an evident infection of the endometrium. From this therapy we have as yet seen no disadvantages but only advantages.

We, therefore employ charcoal pencils

- 1 In cases of infected abortion before or after clearing out, according to the condition of the patient.

- 2 In cases of puerperal endometritis—not before the seventh day of the puerperium.

- 3 Prophylactically, in cases of cesarean section after rupture of the membranes.

TECHNIQUE

The technique of intra uterine charcoal therapy is very simple. The necessary instruments (2 specula, 1 hooked forceps, 1 bullet forceps and 1 long tweezers) are previously boiled before insertion of the specula the orifice of the vagina is cleansed and then the vagina washed out with aluminium acetate. The portio vaginalis is exposed and the anterior lip of the os uteri hooked. The external os uteri is cleansed from mucus and blood. The charcoal pencil is grasped at one end with a dressing forceps dipped two or three times in sterile water and then carefully inserted through the cervical canal to beyond the internal os uteri. The cervical canal is almost always so

wide open that the charcoal pencil can be introduced without difficulty. We do not agree with Benthin in his recommendation of dilatation when the os uteri is occluded. According to the severity of the case and the size of the uterine cavity, two or three pencils may be introduced, and then distributed in the cavity, the first more toward the right, the second more toward the left tubal angle, and a third if necessary in the middle. Generally, however, one pencil of 3 centimeters in length is sufficient. After removal of the dressing forceps one hears the crackling and effervescence already mentioned as taking place when the charcoal pencil fixes the uterine contents. The crushing and mixing of the charcoal are greatly assisted by the muscular contractions which, as previously noted, are produced by the charcoal pencil in its capacity as a foreign body. In order to prevent immediate escape of the charcoal paste or foam through the cervical canal a thin strip of gauze is placed in the cervix with one end projecting from the vaginal orifice. After the lapse of 3 to 4 hours the gauze is withdrawn, and it can then be assumed with safety that intermixture of the charcoal and the uterine contents is complete, and that the walls of the uterine cavity have become covered with the charcoal suspension. As I have already mentioned, comparatively large particles of charcoal are found in some cases in the posterior vaginal vault. The undissolved portions of charcoal are expelled by the uterine contractions. The fact that fairly large particles of charcoal may remain undissolved is capable of explanation as follows: (1) there may be an excess of charcoal in proportion to the size of the uterine cavity, i. e., the uterine contents are saturated; (2) some parts of the charcoal pencil may be too strongly compressed or may be lying more in the cervical portion of the uterus and so cannot be completely dissolved by the bacteria containing residual fluid. An excess in the amount of charcoal introduced is never to the disadvantage of the treatment, as one can then be sure that the whole uterine cavity is uniformly filled, i. e. is lined with a coating of charcoal capable of exerting an adequate adsorptive action. The thicker the wall represented by this coating the greater will be its fixing effect.

To the details already given I would add that those of our cases which come within the indications mentioned have not simply been subjected to treatment with charcoal alone. In many cases naturally our previous methods of treatment have had to give way to charcoal therapy to enable us to get an accurate view of the effects of the application of charcoal alone. The cases thus

treated almost all led to the desired result. We have, indeed, obtained the impression that we considerably shortened convalescence without detriment to the permanence of the recovery. When we were in position to judge the results of charcoal treatment alone, we assisted the process of healing by means of ergotin or gravitol and the ice bag. The decisive factor in bringing about the rapid and favorable results, however, was the charcoal alone.

Unlike Benthin we have not strictly limited our range of indications, but have tried to obtain conclusive proof in as wide a variety of cases as possible, of the great therapeutic powers lying dormant in charcoal. Our observations give us ground for placing our favorable results on a level, in every respect with those of Benthin and Geller. These authors conclude their discussion with an appeal for further testing of the method. I should not like to close my paper without repeating this appeal for critical consideration of the results obtained shows the treatment to be worthy of trial. Everything new, however, is met with a certain skepticism. "Warum denn in die Ferne schweifen, wenn das Gute liegt so nah!" Why should I still further overload a sick body with high molecular intravenous solutions, why should I wash or swab out the cavity of the uterus and thereby run the risk of producing injuries or of facilitating a further ascent of the pathological process? The reported results of the charcoal treatment both in human and in veterinary medicine, are so favorable that they cannot be rejected at once with a decisive "No." The intra-uterine application of charcoal is completely free from danger, the medicament is very cheap and the period of illness is greatly shortened. The symptoms are instantaneously influenced, never for the worse. The body responds with an immediate improvement in the patient's general condition and in the local process with a fall in temperature and in the pulse rate.

INTRAVENOUS CHARCOAL THERAPY

What I have said so far relates only to local—intra uterine—charcoal treatment. I should like now within the framework of this paper, to touch upon the subject of intravenous charcoal therapy. This first came into use simultaneously with the intra uterine treatment, in veterinary medicine.

A suspension of charcoal was injected intravenously in septic affections. This intravenous application of charcoal was first adopted in human

¹ Why then go abroad seeking afar when the good lies close at hand.

medicine—and with very good results—by Wedekind, at the I Medical Clinic University of Cologne (Prof Kuelbs), for the purpose of actively attacking tuberculosis. In his summary, Wedekind says "By the intravenous administration of very small amounts of charcoal dust, even severe exudative and proliferative forms of human pulmonary tuberculosis can be brought in a short time to induration. A pre requisite for this form of therapy is that too great portions of the lungs should not already have undergone ulcerative disintegration, and that the body should still be capable of reaction. Relatively recent processes are most capable of recovery."

"No aggravations attributable to the treatment were ever manifest. Symptoms of intoxication did not appear. This influence of charcoal dust on the course of tuberculosis is explained by the activation of the reticulo-endothelial defensive apparatus which it produces, and in particular by the mobilization of the connective tissue histocytes of the lungs."

Another very interesting anatomico-physiological study of the action of intravenous charcoal therapy in pulmonary tuberculosis is one by H Gickler, which appeared in the *Beitraege zur Klinik der Tuberkulose*.

I have purposely referred to these papers in some detail because in part they provided us with factors for comparison with the observations made by us in the intravenous application of charcoal in sepsis, and in part gave us an explanation of processes which are exceedingly important in the problem of the treatment of sepsis. As I have here touched on the subject of sepsis, I should like to mention the paper published by Louros and Scheyer on "streptococcal infections, the reticulo-endothelial system, their relations and their amenability to therapy." The two authors sum up their very interesting observations as follows: "From the investigations described it appears that in animal experiments it is possible by means of injections of charcoal to exert a favorable in-

fluence on the outcome of a streptococcal infection, in one third of the cases, this result being attained by way of a general improvement in the functioning of the reticulo-endothelial system and in particular by a heightening of the phagocytic activity of the reticulo-endothelial system, especially toward introduced bacteria. The charcoal acts first by altering the hydrogen ion concentration of the media in the direction of an acidity which checks bacterial growth (Dresel). The charcoal then exerts its chief action as an adsorbent and serves as a vehicle for the bacteria to the phagocytosis of which it stimulates mechanically the reticulo-endothelial system. The action is to be regarded as purely non specific, and appears to be particularly favorable by reason of the fact that the mechanical stimulant effect on the reticulo-endothelial system is combined with the physical phenomenon of adsorption and with the physico-chemical phenomenon of alteration of the hydrogen ion concentration."

So far as our experiments and experiences up to the present, in the intravenous charcoal treatment of sepsis allow of comparison, we can say that much valuable investigation can still be done in this department. At all events, the cases of sepsis which we have so far treated in this way have provided us with a plan of work, for the carrying out of which a large number of interesting experiments of very varied nature are necessary. Some of these representing in themselves a complete field of work. We shall report on these matters elsewhere.

LOCAL ANÆSTHESIA IN ABDOMINAL SURGERY¹

PROFESSOR ALEXANDER W. WISHNIEWSKY, KASAN, U. S. S. R.

Director of the Surgical Clinic

I BELIEVE that the ideal anæsthesia in surgery will be that which will cause the patient's organism no insult outside of the operative field. Local infiltration anæsthesia comes closest to this ideal. However, the classical infiltration anæsthesia of Reclus with the concentrated solutions of cocaine could not be accepted as harmless for the organism. Work with concentrated solutions is based upon the principle of osmosis and diffusion and in this respect the solutions are not constant in their effect. This fact has contributed greatly toward the disrepute in which infiltration anæsthesia has fallen and even the brilliant investigations of Braun who introduced novocain and adrenalin in local anæsthesia have helped little to make popular such means of inducing anæsthesia.

My method of inducing local anæsthesia consists in the injecting, layer by layer of large quantities of a 1 per cent solution of novocain in Ringer's solution from which bicarbonate of soda is removed with the addition of 2 minims of adrenalin to each 100 cubic centimeters of solution. Large amounts of solution are used for injection into the various anatomical layers of the operative field as a result large serpentine anastomosing infiltrations are formed which block the nerves by direct contact and pressure rather than by diffusion. Occasionally the solution is injected slightly away from the immediate operative field but always close to it. The tissues may be incised immediately upon injection without the need of waiting for diffusion of the drug.

No single one of all the various methods of local anæsthesia is applicable to all types of surgical operations within the abdominal cavity. It is true that local anæsthesia is frequently used in performing complicated surgical procedures in the peritoneal cavity. However there is no single well systematized method of inducing local anæsthesia that may be used in all major operations within the abdomen. Mikulicz and Schleich introduced the method of using infiltration anæsthesia for the abdominal wall but after the peritoneal cavity was opened they continued the operation without further anæsthesia. Finsterer, Farr and others suggested that mesentery and

ligaments which are to be handled during the operation be anæsthetized by means of injections of novocain. Laewen and Siegel worked out the technique of paravertebral anæsthesia, while Kappis and Braun that for splanchnic anæsthesia. The latter method has become popular although nitrous oxide is used with it.

I shall describe here the method of local anæsthesia which is being used in my clinic in abdominal surgery. My method is a further development of a combination of infiltration anæsthesia and mesenteric anæsthesia. That local anæsthesia by injection into the mesentery as suggested by Farr and Finsterer is far from being satisfactory is easily seen from the difficulties usually encountered in its use. I have witnessed situations in which the surgeon is lost in an effort to locate a point for the injection of the novocain into the mesentery, and each time the needle was inserted the surgeon ran the risk of puncturing a blood vessel. Years ago I had the same difficulties but of course, with growing experience I have learned to master such situations. However, I have been struck by the fact that the technique used for this type of anæsthesia is purely casual in character and that the method of procedure is without system or definite plan. The results of my surgical work changed radically after I worked out systematically the details of producing local anæsthesia, and I wish to describe here the technique I have worked out in producing anæsthesia in relation to the various important abdominal organs.

TECHNIQUE

The stomach. I shall consider here the method of producing anæsthesia in a patient requiring resection of the stomach. Such an operation is a supreme test not only because of the difficulty of the operation itself but because of the condition of the patient.

1. The midline along the proposed line of incision is infiltrated with novocain after which the subcutaneous layer is infiltrated. Infiltration must be sufficient to cause a true swelling of about two fingers breadth since only then will the anæsthesia be effective for a period of about 3 hours. The incision is made and the midline dissected (Fig. 1).

medicine—and with very good results—by Wedekind, at the I Medical Clinic University of Cologne (Prof Kuelbs), for the purpose of actively attacking tuberculosis. In his summary, Wedekind says "By the intravenous administration of very small amounts of charcoal dust, even severe exudative and proliferative forms of human pulmonary tuberculosis can be brought in a short time to induration. A pre requisite for this form of therapy is that too great portions of the lungs should not already have undergone ulcerative disintegration, and that the body should still be capable of reaction. Relatively recent processes are most capable of recovery."

"No aggravations attributable to the treatment were ever manifest. Symptoms of intoxication did not appear. This influence of charcoal dust on the course of tuberculosis is explained by the activation of the reticulo-endothelial defensive apparatus which it produces, and in particular by the mobilization of the connective tissue histocytes of the lungs."

Another very interesting anatomico-physiological study of the action of intravenous charcoal therapy in pulmonary tuberculosis is one by H Gickler, which appeared in the *Beitraege zur Klinik der Tuberkulose*.

I have purposely referred to these papers in some detail, because in part they provided us with factors for comparison with the observations made by us in the intravenous application of charcoal in sepsis, and in part gave us an explanation of processes which are exceedingly important in the problem of the treatment of sepsis. Finsterer, Farr and others suggested that mesentery and

ligaments which are to be handled during the operation be anesthetized by means of injections of novocain. Laewen and Siegel worked out the technique of paravertebral anæsthesia while Kappis and Braun that for splanchnic anæsthesia. The latter method has become popular although nitrous oxide is used with it.

I shall describe here the method of local anæsthesia which is being used in my clinic in abdominal surgery. My method is a further development of a combination of infiltration anæsthesia and mesenteric anæsthesia. That local anæsthesia by injection into the mesentery as suggested by Farr and Finsterer is far from being satisfactory, is easily seen from the difficulties usually encountered in its use. I have witnessed situations in which the surgeon is lost in an effort to locate a point for the injection of the novocain into the mesentery and each time the needle was inserted the surgeon ran the risk of puncturing a blood vessel. Years ago I had the same difficulties but of course with growing experience, I have learned to master such situations. However, I have been struck by the fact that the technique used for this type of anæsthesia is purely casual in character and that the method of procedure is without system or definite plan. The results of my surgical work changed radically after I worked out systematically the details of producing local anæsthesia and I wish to describe here the technique I have worked out in producing anæsthesia in relation to the various important abdominal organs.

TECHNIQUE

The stomach. I shall consider here the method of producing anæsthesia in a patient requiring resection of the stomach. Such an operation is a supreme test not only because of the difficulty of the operation itself but because of the condition of the patient.

1. The midline along the proposed line of incision is infiltrated with novocain after which the subcutaneous layer is infiltrated. Infiltration must be sufficient to cause a true swelling of about two fingers breadth, since only then will the anæsthesia be effective for a period of about 3 hours. The incision is made and the midline dissected (Fig. 1).

Fig 1

2 The midline is then injected in such a way as to infiltrate the preperitoneal fat. It is essential to direct the needle under the anterior sheath of the rectus muscle on either side of the midline.

3 After the incision of the midline the parietal peritoneum is anesthetized. The preperitoneal tissues are retracted and novocain is injected about the parietal peritoneum and especially into the posterior sheaths of the recti on either side (Fig 2).

4 The peritoneum is incised and the transverse colon is delivered into the wound turned up, and the inferior surface of its mesentery exposed. An avascular point close to the root of the mesentery is chosen for the first injection. The subsequent injections are so made into the borders of the area which has become oedematous from the first injection that on one side the injected fluid spreads behind the posterior parietal peritoneum downward toward the root of the mesentery of the small intestines, and on the other side expands throughout the root of the mesocolon thus separating both leaves of the peritoneum and extending upward toward the peritoneal envelope (serosa) of the duodenum (Fig 3). The spreading of the fluid toward the root of the mesentery of

Fig 2

the small intestines makes it essential to keep the intestines out of the way. This point is not taken care of in the usual method of administering splanchnic anesthesia. When the transverse colon is turned downward at this stage of the procedure the oedema caused by the injection is easily seen. This oedema is shimmering through the superior peritoneal leaf of the mesocolon especially on the right side where it is not covered by the gastrosplenic ligament. Supplementary injections into the borders of these oedematous areas are easily made and the danger of puncturing a blood vessel is avoided. As a result the duodenum is bathed so to say in the injected fluid which readily spread beneath its serosa (Fig 4). The mesentery of the stomach is then injected along its lesser curvature in a direction toward the cardia. The gastrosplenic ligament is divided and immediately the upper leaf of the mesocolon comes into view. Several more injections are made here and the fluid

Fig 3

gradually expands toward the pancreas and appears behind the parietal peritoneum at the level of the lesser curvature. Finally the plica gastropancreatica and the gastrosplenic ligament are infiltrated. It is now possible to perform any variety of resection of the stomach (Fig 5).

Bile ducts. The principles described underlie my method of administering local anæsthesia in surgery of the bile ducts. The novocain is so injected that infiltration is extensive and rapidly spreads along exact anatomical paths. An oblique subcostal incision is made after injection of the abdominal wall in layers. The parietal peritoneum is anesthetized the injection being started well beyond the line of incision. The transverse colon

is delivered and the right half of its mesentery from the root to the periphery is injected. The colon is then turned forward and downward. By pulling down the hepatic flexure slightly, one can easily see between the leaves of the mesocolon the injected fluid spreading toward the posterior abdominal wall. One continuous injection is made into the margins of the oedematous area until the free edge of the hepatoduodenal ligament becomes infiltrated. Then the colon and omentum are replaced in the abdominal cavity, a large gauze pad directed toward the kidney is inserted to pack off the intestines, and the injection of the gall bladder proper is begun.

If the gall bladder has an anatomically intact

Fig 4

serosa, a subserous injection of the solution is made until the fluid is seen to have spread toward the ducts and there to have joined the edema caused by the previous injections of the hepatoduodenal ligament. The injected fluid easily separates the gall bladder from its liver bed. Such an injection contributes greatly to the ease with which a subserous cholecystectomy is accomplished. If the gall bladder is shrunken, scarred or tensely packed with stones, one is forced to fall back upon scattered individual small point injections, even though the field of the ducts proper remains completely anesthetized from the previous systematic serpentine injections (Fig. 6).

Spleen. A freely movable spleen without adhesions can be easily removed after the line of incision through the abdominal wall has been anesthetized, but when the spleen is adherent it is necessary to administer a strictly systematic anesthesia, not unlike that used for operations on the stomach and bile ducts. After the abdominal cavity is opened through a left oblique subcostal incision the left half of the mesentery of the transverse colon is anesthetized in the fashion outlined. A portion of the gastrosplenic ligament just sufficient to allow approach to the

upper leaf of the mesocolon is divided. After this section is thoroughly anesthetized the gastrosplenic ligament on the left side is attacked in the same way. Occasionally one will have to inject separately adhesions between the spleen and the diaphragm. That this method is practicable I have been convinced since it has proved successful in my last ten consecutive splenectomies.

Large intestines. I know of no report in the literature of a complete removal of the large bowels under intra abdominal local anesthesia. I have used the principle of the serpentine injections in administering local anesthesia in two patients in whom complete removal of the large intestines was considered indicated. The technique may be described as follows. After a mid line incision is made, the transverse colon is delivered and its mesentery is injected as already outlined. The fluid is directed widely behind the posterior parietal peritoneum toward the root of the mesentery of the small intestines. This mesentery is then completely anesthetized by means of additional injections. The small intestines are then delivered from the peritoneal cavity, retracted to the left and the cæcum and ascending colon are exposed. The mesenteries of the cæcum and ascending colon are injected in the same systematic way. An incision in the peritoneum is then made near the root of the cæcum and the removal of the bowel is commenced. This removal of the bowel is performed gradually in steps so that repair of the defect in the parietal peritoneum immediately follows upon the division of the mesentery in the given region. Before the splenic flexure is approached the small intestines are turned to the right and the descending colon is anesthetized in the usual manner.

In both patients a complete removal of the large intestines was done. Both stood the operation well and left the operating table with a pulse of 70 to 72. The postoperative course was free from complication with one exception—a transient physiological diarrhoea. Both patients were previously operated upon repeatedly for a diffuse ulcerative colitis. Attempts at short-circuiting did not affect the patients' condition and they remained bedridden until complete colectomy was done. At present the patients are in perfect health. I am emphasizing the fact that the small intestines remain without the peritoneal cavity during the entire removal of the colon.

Pelvic organs. My method of producing local anesthesia by means of large serpentine anastomosing infiltrations is perfectly applicable in gynecology. Here anesthesia is begun by the formation of extensive infiltration along the an-

Fig 5

terior aspect of the sacrum. This infiltration is of no blocking importance in the sense of Braun's parasacral anæsthesia, when one has to seek each individual sacral foramen. This infiltration is caused merely for future anastomosis with the infiltrations made along the promontory and the innominate pelvic line. To produce presacral infiltration the injection is begun in the midline about 1 inch posterior to the anus. Immediately after the needle is inserted the fluid is slowly injected the needle being gradually moved toward the anterior aspect of the sacrum. The solution easily finds a line of cleavage through which it spreads in front of the sacrum. I inject here about 300 cubic centimeters of the novocain preparation. The anæsthesia of the abdominal wall of the parietal peritoneum and in case of adhesions of a small portion of the adjoining intestinal mesentery, is done in the manner outlined. Occasionally the round and broad ligaments may need supplementary injection.

SUMMARY AND CONCLUSIONS

It is apparent that my method of producing local anæsthesia consists in a blocking of the nerve plexus the blocking being begun in the periphery

Fig 6

and being gradually extended toward the centers. Of course during the operation the anæsthetic may spread toward the ganglions but it never suddenly encroaches upon them. This fact contributes much to the physiological safety of the method. The method has all the advantages of splanchnic anæsthesia without any of its disadvantages. It is not aggressive, it is technically easy, it can be used in the upper abdomen through any abdominal incision and even in the obese patient is practicable. It requires no general anæsthesia and it is not followed by a fall in the blood pressure. However this method differs from direct intra abdominal anæsthesia in which the anæsthesia is carried along separate spheres of action or along the mesenteric vessels, methods which reflect and depend upon the intuition and experience of the individual surgeon, but which lack exact systematic performance.

This method of local anæsthesia based upon the use of large amounts of solution of novocain for the production of serpentine anastomosing infiltrations along anatomical layers leads to an immediate blocking of all the nerves coming in

direct contact with the solution. One is not forced to postpone the incision, awaiting the "diffusion" of the solution to the nerve trunks.

Because of the weakness of the solution of novocain, because of the gradual injection during the entire surgical operation, and especially because of the immediate incision and spontaneous removal of the injected fluid, no danger of intoxication is seen in this method of inducing local anæsthesia. The systematic injection of the solution layer by layer, contributes greatly to the ease of orientation in the anatomical structure of

the organs handled, as, for example the dissection of the gall bladder from the surrounding structures, the freeing of the adherent appendix, etc.

The co-operation of the patient is, of course a prerequisite in this method of anæsthesia and therefore the technique is contra indicated in children and in semiconscious patients. Other contra indications are suppurative conditions of the abdomen. In all other instances this method of inducing local anæsthesia has proved practicable and reliable during the years of its employment in my clinic.

THE OPERATIVE TREATMENT OF UNUNITED FRACTURE OF THE NECK OF THE FEMUR

ROYAL WHITMAN M.D. F.A.C.S. NEW YORK

I HAVE read with interest and pleasure Dr Albee's paper¹ on the treatment of ununited fracture of the neck of the femur, particularly because of his unqualified endorsement of the abduction method and because it is evident that he no longer favors the immediate open operation, still employed on various pretexts by certain surgeons. I agree with him that in cases of ununited fracture in which the fragments retain a fairly normal contour, the autogenous bone graft operation, of which he is the leading exponent, offers the best assurance of union.

There remains then for discussion only the third and at the present time much more important class in which, because of destruction of bone the restoration of an approximately normal relation is impracticable. In the treatment of this group leaving out of consideration the palliative bifurcation operation of Lorenz there are practically speaking but two alternatives—the reconstruction operation and the procedure employed by Dr Albee.

The reconstruction operation was first performed in 1916 but was not described until 3 years later.² Its design was to provide a secure support in locomotion and to restore as far as possible normal muscular control. An improvised neck was constructed by utilizing the bearing sur-

face obtained by removing the trochanter at its base, and leverage was restored by transplanting it with its attached muscles to the outer side of the femur at such tension as would assure security of the joint (Figs 1 and 2).

In this paper the various procedures then at command were compared from the functional standpoint, including that of Dr Albee which had been described in 1919 in his 'Orthopedic and Reconstruction Surgery.' From these diagrams it will appear that the trochanter was separated only sufficiently to permit the introduction of the upper extremity of the femur to the acetabulum (Fig 4).

Its development to a physiological bone lever did not appear until 6 years later³ and a further modification is presented in his last paper (Figs 5, 6, 7, and 8).

It may be noted that the figure of 1919 presents no indication of a design to increase leverage and shows a narrow and irregular articulating extremity while that of 1929 is smooth and bulbous. It would seem that the functional results of the

Fig. 1. Left. The condition in ununited fracture of the neck of the femur in which the neck has entirely disappeared.

Fig. 2. The new bearing surface provided by removing the trochanter and transplanting it lower down on the shaft. (Figs 1 and 2 from *Surg. Gynec. & Obst.* 1921: June.)

Fig. 3. A final result of the reconstruction operation.

Fig 4 Old ununited fracture of the neck of the femur with erosion of most of head and neck and with marked osteoporosis of the remaining shell of the head. The trochanter is separated with osteotome as shown by dotted lines in figure at left and is forced outward with the overlying soft structures below as a hinge. The removal of the head then allows the neck to be displaced into the acetabulum (Albee *Orthopedic and Reconstruction Surgery* 1919)

Fig. 5 Albee's method of treating ununited fractures of the neck of the femur by removing head of femur and producing greenstick fracture the trochanter being swung outward on the periosteal hinge. The remains of the neck of the femur and upper end of the great trochanter are to articulate with the acetabulum; the inverted portion of the capsular ligament contributing to the formation of the new articulation (Albee *J Am M Ass* 1923). As contrasted with the original this illustrates the evolution of the physiological lever.

Fig 6

Fig 7

Fig 8

Fig 6 Schematic drawing of author's reconstruction operation with removal of femoral head. dotted line indicates bone's action of upper end of femur by broad osteotome

Fig 7 Displacement of upper end of bone muscle lever outward by abduction of hip which automatically thrusts the new femoral head into the acetabulum at the

same time holding the bone muscle lever in of lique relation to the shaft. The angle is then filled with cancellous bone material from greater trochanter as indicated.

Fig 8 Drawing from X-ray film showing consolidation of union of bone muscle lever with main portion of femur. angle being filled in at 1. Albee *Surg Gynec & Obst* 1929

operation as performed in 1929 must differ materially from those obtained in the earlier cases, but no distinction is made in the table of statistics.

Dr Albee states that "his operation is the simplest yet devised" yet it entails stripping the muscles from the ilium over a large area and splitting off a wide section of bone from the femur. This is then forced outward leaving a triangular space approximately 4 by 3 inches to be filled by prospective bone formation.

The reconstruction operation by contrast has not been changed in any essential since its introduction. It has the advantage of simplicity of design, directness of approach and definiteness of execution. There is no division of muscles, the anatomical adjustments are completed at the time of operation and are therefore independent of the nutritive processes on which Dr Albee counts to assure the stability of the lever.

A final point at issue is that of nomenclature since Dr Albee claims the same name for his operation.

It seems to me that the reconstruction operation justifies its title not merely by priority but by design and accomplishment, while in both particulars Dr Albee's operation presents a complete divergence from the natural construction. I suggest, therefore, in order to avoid confusion, that it be designated by one of its subsidiary titles, preferably the 'physiological bone lever operation' which will indicate the essential distinction between the alternative procedures.

Fig 9 Result after bone muscle lever has united in place illustrating the wide distance between the great trochanter and the side of the pelvis in proximity to the rim of the acetabulum thus allowing for generous abduction (Albee 1925). This illustration shows the actual condition far more clearly than the somewhat fanciful diagrams, particularly the shape and area of the bearing surface. Furthermore, that the displaced trochanter is relatively elevated lessening the distance between the origin and attachment of the abductor muscles and therefore their leverage. Contrast with Fig 3.

THE USE OF IODIZED OIL (LIPIODOL AND IODIPIN) IN THE DIAGNOSIS OF JOINT LESIONS

PHILIP H. KREUSCHER M.D. F.A.C.S. AND H. KELIKIAN M.D., CHICAGO

THE value of iodized oil in the diagnostic visualization of bronchiectatic cavities and spinal canals is well recognized. It has occurred to us that because it is non-toxic, non-irritating and shows a splendid shadow on the X-ray film, iodized oil should be suitable for a similar purpose in major joints. With this in mind, we have used it in several of the major joints especially the knee and hip joints. Valuable information is obtained concerning the conformation of the joint cavity, its capacity, the communication with bursae and with other diseased processes in the joint or communicating with it. Such pathological changes as hypertrophy of the synovial membrane, destruction or adhesions of the synovial capsule, erosions of the articular cartilage, and cavitations into adjacent bones may be well demonstrated by the use of iodized oil injections followed by immediate and subsequent roentgenographs.

It is interesting to note that in the various types of arthritis in which one would expect the joint cavities to be large and contain a large quantity of oil, they will contain only a small

portion because of the partial obliteration of the synovial pouch. The more nearly normal the joint the more evenly is the oil distributed. Patchy distribution indicates pathology. In one of our hypertrophic cases 100 cubic centimeters was injected into the knee joint without producing undue distention or excessive pain (Fig. 9, Case 5).

The technique of the injection of the knee joint is very much the same as for injection of any other material. A point is selected on the outer side of the knee about 1 inch above the external lateral aspect of the patella. Through a small puncture opening in the skin the needle is inserted under the patella into the joint cavity. Any fluid which may be in the joint is completely aspirated with an aspirating syringe. The warm iodized oil is then injected until the capsule is completely distended. Whenever possible the injection should be made without general anesthesia. A roentgenogram is taken immediately after the injection. The films thus taken anteroposteriorly and laterally show the oil in the various recesses of the free joint cavity. After manipu-

Fig 6 Film immediately after injection showing large popliteal compartment of the synovial sac and tongue like projections of the oil into small cavity in tuberosity of the tibia (Case 4)

Fig 7 Partially filled cavitations in the tibia (Case 4)

Fig 8 Two weeks after injection The oil has escaped from the diseased synovial sac along the tendon sheath of the quadriceps hamstrings and gastrocnemius This is the probable route of exit of infection from the joint into the surrounding tissues giving the peri articular swelling and infiltration seen in many acute and subacute cases (Case 4)

ulation of the joint another film may be made to show the passage of oil into other portions of the synovial pouch and occasionally into bursae (Fig 4)

It was found in one of our cases that the iodized oil had penetrated the synovial capsule and had passed into the tendon sheath of the quadriceps extensor (Fig 8) We believe that the oil finds its way out through the synovial capsule because of synovial erosions It has occurred to us that this is probably the route of extension of infection from the joint and that we may, in this way, explain the tendon sheath thickening and peri articular induration which is seen in so many cases of acute or subacute arthritis

For the injection of the hip joint a point is selected one inch below the tip of the greater trochanter and just anterior to it The needle is introduced and follows along the neck of the femur until a definite obstruction is reached This is the head of the femur The needle is slightly withdrawn, pointed sharply anteriorly and directly into the joint cavity

We have injected the knee joint in 7 cases and

the hip joint in 3 Roentgenograms of some of these are shown

In Case 5 a very faint shadow of the popliteal bursa is visualized The oil had not penetrated the bursa sufficiently to outline it This is undoubtedly due to the fact that synovial fluid so filled the bursa that the oil could not immediately pass into it In those cases in which the bursa is at no time visualized, we have reason to believe that the bursal sac is either entirely obliterated or does not communicate with the free joint cavity

Five days after injection a synovectomy was done in this case The synovia was greatly thickened and studded with papillary formations and villous growths Much of the iodized oil was free in the joint We were much interested to know to what extent the oil had invaded this thickened synovial membrane as this might have a definite bearing on the therapeutic value of the injections in infected joints The report by the pathologist Dr Hueper reads as follows 'In sections with Sudan III stained fat droplets are seen adherent to the surface and in the intercellular spaces of

Fig 9

Fig 10

Fig 9 Extensive synovial hypertrophy Joint injected with 100 cubic centimeters iodized oil Showing the enormous distention of the suprapatellar pouch divided into two separate compartments (Case 5 M S)

Fig 10 Lateral view showing distention of synovial pouch and a faint outline of a very large popliteal bursa (Case 5) At operation the bursa was found greatly enlarged with thickened walls and full of a straw colored fluid

the loose connective tissue and between the fibrils of the strong fibrous tissue Fat droplets were also found in the lymphatics of the deeper layers"

Through a small opening in the popliteal space the popliteal bursa was exposed and completely removed The walls were greatly thickened and infiltrated The lumen was small and completely filled with the same type of fluid which had been aspirated from the joint cavity, but very few oil globules were seen This bears out our contention

Fig 11

the same as that which had been aspirated from the joint Oil could not enter into the bursa because of presence of this fluid

Fig 11 (Case 6) Synovial tuberculosis of the hip joint Note partial filling of hip joint and the reflux of iodized oil into a portion of the tuberculous subtrochanteric bursa the major part of which had been removed by operation

that the presence of the fluid would not permit the oil to find its way into the bursa

Clinically, beneficial effects have been derived from these injections of antiseptic oil into the joints in the majority of our cases Freedom of action of the joint and relief of pain have been reported by the patients

The results from this preliminary clinical investigation have been so gratifying that we feel fully justified in continuing these injections both for the purpose of diagnosis and therapy

THE OPERATIVE TREATMENT OF EMBOLISM OF THE LUNGS¹

PROF DR A W MEYER BERLIN GERMANY

From the City Hospital of Berlin Charlottenburg—Krankenhaus We tend

IN Germany, the treatment of embolism of the lungs has interested physicians ever since the days of our surgical genius, Trendelenburg. But since Kirschner's first and only success (in 1924) the treatment has resulted only in failure. Quite recently a number of patients have been saved and it is of these that I wish to write.

Embolism of the lungs is a sort of Damoclean sword, which, unfortunately, threatens every patient who must lie in bed inactive for shorter or longer periods of time. It is not fully realized that such sudden emboli of the lungs occur not only after operation by a surgeon or a gynecologist, but that death from embolism of the lungs is just as frequent in the clinics for internal diseases if one may be permitted to use the word frequent at all in speaking of embolism of the lungs. It was only since we began to study this strange and so often fatal sickness (thrombosis and embolism) that this fact became plain.

In the municipal hospital, Charlottenburg Westend we wished to perform on a dead body an operation for embolism of the lungs, and while in one whole month, the surgical service, which has 500 beds, did not lose one patient from embolism the medical service, which has the same number of beds, lost 7 patients. This should be of interest to all physicians, as well as operating surgeons.

Since we have no sure means of avoiding a thrombosis and embolism, we are unfortunately certain to be confronted again and again with the severest cases of embolism and faced with the decisive question: Shall we wait or not? Will the embolism be overcome? Is it one, anyhow? Shall we undertake the operation for embolism of the lungs? The severest symptoms of embolism can of course abate of themselves and several times I have waited for hours by the bedside of a patient suffering from an embolus, everything prepared and ready and fortunately did not need to operate. It is said that it is very difficult to know when to operate and when not. One who has closely studied patients with this sickness, and who has watched the effects of treatment, devoting himself wholeheartedly to the work, giving of his time and patience—such a man finds it easy to decide when to operate. The patient simply begins to die! And when the man of real experience sees that the patient is dying, he knows that it is

right and proper to operate for embolism of the lungs. It is difficult to characterize the indications for an operation for embolism of the lungs any better—it is not a thing that can be described.

The decision to operate must be made as quick as lightning in the sudden cases, but more time may be used in the chronic, spasmodic cases of embolism. Once operation is decided upon I would advise the following procedure.

In 1908, Trendelenburg proposed that lung emboli be removed from the pulmonary artery. The steps of his procedure are: A T shaped incision of the skin above the left rim of the sternum and the second rib, resection of the second rib whereby the pleura is at once laid bare, section through the cartilage of third rib, and incision of the pericardium. After the pericardium is laid open a sound is passed around the great vessels (aorta and pulmonary artery) which are confluent and arise from the base of the heart. The Trendelenburg sound, which has a bayonet closure, must be connected with a rubber tube. The tube must be drawn through and around the vessels, which can now be drawn forward and strangled. According to the experiences of Trendelenburg, the period of strangulation may be 45 seconds but not more. The pulmonary artery is incised the emboli are extracted from both large branches—a clip is applied on the side of the pulmonary artery, whereby the slit in the artery is squeezed together and it becomes possible to place the sutures above the clip. With this original Trendelenburg method of operation, Kirschner in 1924 saved the life of a patient, a woman of 38 years and was thus the first to demonstrate that this bold and splendid procedure could be used successfully on human beings and might succeed in saving lives.

Up to this time that is to say from 1908 to 1924 all attempts had been in vain. No patient had lived longer than 5½ days. When they did not die on the operating table, as was almost always the case they died during the next few days as a result of subsequent loss of blood, infection of the pleura and the pericardium or as the result of a pneumothorax. Since the Kirschner case, I know of numerous other attempts to operate, for example by Sauerbruch but all were unsuccessful. I, myself performed the operation on bodies on the dissecting table, and later tried to save a

the loose connective tissue and between the fibrils of the strong fibrous tissue. Fat droplets were also found in the lymphatics of the deeper layers.

Through a small opening in the popliteal space the popliteal bursa was exposed and completely removed. The walls were greatly thickened and infiltrated. The lumen was small and completely filled with the same type of fluid which had been aspirated from the joint cavity, but very few oil globules were seen. This bears out our contention

that the presence of the fluid would not permit the oil to find its way into the bursa.

Clinically, beneficial effects have been derived from these injections of antiseptic oil into the joints in the majority of our cases. Freedom of motion of the joint and relief of pain have been reported by the patients.

The results from this preliminary clinical investigation have been so gratifying that we feel fully justified in continuing these injections both for the purpose of diagnosis and therapy.

THE OPERATIVE TREATMENT OF EMBOLISM OF THE LUNGS¹

PROF. DR. A. W. MEYER, BERLIN, GERMANY

From the City Hospital of Berlin Charlottenburg—Krankenhaus Westend

In Germany, the treatment of embolism of the lungs has interested physicians ever since the days of our surgical genius Trendelenburg. But since Kirschner's first and only success (in 1904) the treatment has resulted only in failure. Quite recently, a number of patients have been saved and it is of these that I wish to write.

Embolicism of the lungs is a sort of Damoclean sword, which, unfortunately, threatens every patient who must lie in bed inactive for shorter or longer periods of time. It is not fully realized that such sudden emboli of the lungs occur not only after operation by a surgeon or a gynecologist, but that death from embolism of the lungs is just as frequent in the clinics for internal diseases, if one may be permitted to use the word frequent at all in speaking of embolism of the lungs. It was only since we began to study this strange and so often fatal sickness (thrombosis and embolism) that this fact became plain.

In the municipal hospital Charlottenburg Westend we wished to perform on a dead body, an operation for embolism of the lungs, and while in one whole month, the surgical service which has 500 beds did not lose one patient from embolism the medical service which has the same number of beds lost 7 patients. This should be of interest to all physicians, as well as operating surgeons.

Since we have no sure means of avoiding a thrombosis and embolism, we are unfortunately certain to be confronted again and again with the severest cases of embolism and faced with the decisive question: Shall we wait or not? Will the embolism be overcome? Is it one anyhow? Shall we undertake the operation for embolism of the lungs? The severest symptoms of embolism can of course abate of themselves and several times I have waited for hours by the bedside of a patient suffering from an embolus, everything prepared and ready, and fortunately did not need to operate. It is said that it is very difficult to know when to operate and when not. One who has closely studied patients with this sickness and who has watched the effects of treatment devoting himself wholeheartedly to the work, giving of his time and patience—such a man finds it easy to decide when to operate. The patient simply begins to die! And when the man of real experience sees that the patient is dying, he knows that it is

right and proper to operate for embolism of the lungs. It is difficult to characterize the indications for an operation for embolism of the lungs any better; it is not a thing that can be described.

The decision to operate must be made as quick as lightning in the sudden cases, but more time may be used in the chronic, spasmodic cases of embolism. Once operation is decided upon I would advise the following procedure:

In 1908, Trendelenburg proposed that lung emboli be removed from the pulmonary artery. The steps of his procedure are: A T shaped incision of the skin above the left rim of the sternum and the second rib, resection of the second rib, whereby the pleura is at once laid bare, section through the cartilage of third rib, and incision of the pericardium. After the pericardium is laid open a sound is passed around the great vessels (aorta and pulmonary artery) which are confluent and arise from the base of the heart. The Trendelenburg sound, which has a bayonet closure must be connected with a rubber tube. The tube must be drawn through and around the vessels, which can now be drawn forward and strangled. According to the experiences of Trendelenburg, the period of strangulation may be 45 seconds but not more. The pulmonary artery is incised, the emboli are extracted from both large branches, a clip is applied on the side of the pulmonary artery, whereby the slit in the artery is squeezed together and it becomes possible to place the sutures above the clip. With this original Trendelenburg method of operation, Kirschner in 1924 saved the life of a patient, a woman of 38 years and was thus the first to demonstrate that this bold and splendid procedure could be used successfully on human beings and might succeed in saving lives.

Up to this time, that is to say from 1908 to 1924, all attempts had been in vain. No patient had lived longer than 5½ days. When they did not die on the operating table as was almost always the case they died during the next few days as a result of subsequent loss of blood, infection of the pleura and the pericardium, or as the result of a pneumothorax. Since the Kirschner case I know of numerous other attempts to operate, for example by Sauerbruch, but all were unsuccessful. I myself performed the operation on bodies on the dissecting table, and later tried to save a

¹Lecture presented before the Mayo Clinic, Rochester, Minnesota, New York Post Graduate Medical School and Mount Sinai Hospital, New York.

Figs 1 and 2 Original Trendelenburg clip and sound and author's modifications of each. The upper figures in each picture are the author's modifications.

patient who was dying of embolism of the lungs. This first, unsuccessful operation showed me that (1) the opening of the pleura implies the infliction of a stupendous shock upon the already injured heart, (2) the Trendelenburg sound and clip must be improved as will be shown and (3) the strangulation period of 45 seconds caused by the introduction of the rubber tube around the great vessels puts too much strain upon the already laboring and dilated heart (a sound heart may be able to withstand this period) and that this period of strangulation evidently induces a paralysis of the respiratory centers which becomes irreparable.

I began dissection experiments in order to find out if the pulmonary artery could not be reached

through an extrapleural route. I soon discovered that this could be accomplished in spite of the fact that Trendelenburg stated that he had discovered from his exhaustive studies, that it was impossible to avoid the laying open of the pleura. Kirschner also said that in spite of the extreme danger of infection and the formation of empyema one must of necessity open up the left pleural cavity, however unpleasant the one-sided open pneumothorax might be in the case of a patient fighting hard for his life.

I constructed a pulmonary artery clip with weaker and narrower branches so as to restrict the side stream of blood as little as possible (Fig 1). I had the Trendelenburg sound made of a smaller size as the original model caused great inconvenience when it was inserted (Fig 2). I also covered the pulmonary artery clip with gauze in stead of rubber. With these simple improvements I was able to save the next two victims of embolism upon whom I operated.

In the first patient (34 years of age) 6 days after a gynecological operation there were signs one morning of a severe embolism of the lungs—sudden decline, cyanosis, pallor, labored breathing, pulse barely discernible. The Trendelenburg operation was contemplated but was not considered to be necessary as yet. At 2 o'clock the physicians on duty were summoned with the cry 'The sick woman is dying! Her daughter who was with her rushed to meet us with the cry 'Help! help! my mother is dying! No pulse beat could be felt and the patient breathed with the utmost difficulty. She was chalk white and no longer reacted. Operation was started within 2 or 3 minutes. A T-shaped incision was made from the second to the third rib, extensive resection of these ribs was done and the pericardium was cleared from the pleura and the mammary artery. The pleura was as thin as a spider's web so that the lung could be seen moving beneath it. A slit was made in the pericardium and the Trendelenburg sound was introduced. The pericardial fat was scraped from the pulmonary artery which lay still broad and with

Fig 7 Excision of rib

Fig 8 The forefinger of the right hand gently pushes under the insertion of the fourth rib

out pulsation. The pulmonary artery was incised and the sound was thrust rapidly three times into the right branch. No more emboli could be found on the third insertion. The heart then beat much more feebly and the breathing became more labored. At this tragic moment the operator had a happy inspiration and squeezed the slit in the pulmonary artery between the thumb and forefinger. This made it possible for the blood to circulate more freely because the rubber tube could now be released. At once there was improvement in the heart beat and in respiration. A few seconds later as the heart action had greatly improved slight tension was placed on the tube and triple

investigation of the left branch again resulted in the removal of large emboli. The pulmonary artery clip was fixed on the side. The heart began to flutter and respiration ceased. Gentle massage of the heart with the fingers

Fig 9 Modified Trendelenburg sound introduced and rubber tube being passed around pulmonary artery

Fig 10 Trendelenburg rubber tube in place

FIG. 11 Trendelenburg forceps are almost horizontal

induced a few faint beats but respiration remained totally inhibited. The sick woman lay like a corpse entirely without reaction. At the moment when the operator was about to order artificial respiration my first assistant Dr. Djalo zivski suggested giving carbon dioxide according to Henderson's method and just as experiments had shown us the patient drew a deep breath. A heart beat followed then another and the heart once more beat regularly. We could now row up the vessel. The pulmonary artery clip was removed. Blood escaped at one point so the clip was put back and another suture was made. This overcame all bleeding. The pericardium muscle and skin were sutured. When we started to suture the skin the sick woman had revived sufficiently to cry out in pain and consciousness returned. Her color was perfectly satisfactory when she was taken back to bed. After a number of anxious days she made a complete recovery. Figure 3 is a picture of the specimen and Figure 4 of the patient.

The successful outcome in this case was followed a few weeks later by another successful result after a modified Trendelenburg operation.

FIG. 13 Vertical exploration for embolus

FIG. 12 Incision in artery grasped between thumb and forefinger to close it

One day when I was in the midst of an operation on a woman 60 years of age dying of an embolism was wheeled into the operating room. She had been operated upon 24 days previously for gangrenous appendicitis and embolism of the lungs had suddenly set in. In a few minutes I was able to do an embolectomy and even though it seemed that we might be too late we saved the patient (Figs. 5 and 6). The woman lived only 4 weeks after the operation making the best possible progress. She was about to leave her bed. I was unfortunately absent when a new embolism caused her death. Postmortem dissection showed that the embolism had come from the other leg. The sutures on the pulmonary artery were perfectly healed. No thrombosis had arisen from them so that one might say that the method was successful in this case also.

TECHNIQUE

The steps of the procedure may be given as follows

Since one is operating upon the dying the operation is almost bloodless. The second and third rib must be laid bare with swift, large strokes of the scalpel. These ribs must be freed from perosteum and pleura quickly but very cautiously (Fig. 7). The operator now gently pushes away the mammary artery and the pleura. The forefinger of the right hand is inserted to enter by way of the lower medial angle partly under the breast bone and the operator's hand gently feels its way under the insertion of the fourth rib (Fig. 8). The pericardium shining white and partly covered with fat is plainly in view. Incision with the knife is followed by a flood of pericardial fluid. The pericardial cavity is laid open by introducing cautiously and energetically both forefingers which are spread out. Thus the pleura is pushed still farther out of place, and the pericardial cavity can be opened to a surprising extent.

The next step is the insertion of my modified Trendelenburg sound and the placing of the rubber tube around the artery (Fig. 9). On the cadaver one may be in doubt as to which is aorta and which is pulmonary artery. In the living or rather the dying body there can be no doubt—the aorta lies hidden and the pulmonary artery, swollen and pulseless is at once visible. The Trendelenburg rubber tube (Fig. 10) is useful as we shall presently see, not so much in strangling the vessels as in bringing the large vessels out of the depths which may be considerable in the case of fat patients so that they can be better observed. The pulmonary artery is incised, the tube being held lower. A quantity of blackish blood rushes

out. Emboli which may come from the heart, are also flooded out. Greater tension is now applied to the rubber tube. Forceps are placed in the right pulmonary branch, and the Trendelenburg embolus forceps is now almost horizontal. If the right branch is found to be free of emboli a triple investigation suffices, then the incision in the pulmonary artery is grasped with the thumb and forefinger of the left hand and is pressed together. The tube at once becomes absolutely relaxed. The blood is allowed to flow through the pulmonary artery for a few seconds when, for the first time the tube is fairly energetically tightened and an almost vertical, triple penetration is made into the left branch (Fig. 13). The heart is then relieved by means of renewed digital compression of the slit in the pulmonary artery with the tube quite relaxed. Now for the second time the tube is forcefully tightened. The left hand grasps the cranial end of the slit vessel with a pincers covered with gauze and holds it aloft (Fig. 14), the right hand attaches the arterial clip on the side, the tube is released. Any tightening of the tube naturally renders the work of the heart more laborious and thus injures it. The assistant must be cautioned regarding this, and must be ready instantly to obey the command 'relax,' 'more relaxed,' 'somewhat tighter,' as the case may be.

I have given you an exact description of the manipulation of the rubber tube, because I believe that the respiratory center is very sensitive and should be shut off as little as possible from the arterial blood supply. It has recently been contended that strangulations can be endured as long as 60 seconds. I consider all lengthy strangulations to be dangerous for the nerve centers and those operators who trustfully make use of them will

Fig. 17 Instrument case Instruments are arranged in the order of their use

certainly be disappointed. The digital compression of the slit in the artery and at the same time the keeping of the tube as slack as possible—it is really only necessary to tighten it forcefully as the artery clip is attached—are certainly the least dangerous methods of procedure. In my third successful case, strangulation was reduced to a minimum and respiration though feeble did not cease for a moment.

The following case shows how sensitive the respiratory center may be. A woman who had a fracture of the leg was brought into the operating room looking like a corpse, she did not breathe and the heart had ceased to beat. Since I am an optimist, I attempted to extract the embolus precisely according to my modification, whereupon the heart which as stated was quite still began to beat slowly to the astonishment of us all, and then to beat so quickly and violently that the artery clip on the side had to be held to prevent its being hurled away from the heart. We thought that we might save the woman but the respiratory centers reacted neither to carbon dioxide, Lobelin or any other measures and after artificial respiration had been practiced for an hour the heart flagged and collapsed and nothing could be done.

This experience shows how sensitive the respiratory center is and therefore how important it is to have the strangulation of the vessels as short as possible. When respiration has become regular and the heart beat stronger and more rapid then suture of the vessel can be undertaken deliberately (Fig. 15).

In such instance the heart pulsates sturdily, respiration is good, the face of the sick person which was previously of a deathly white becomes rosy, the muscle vessels begin to bleed, they are ligated, and the pericardium muscle and skin are sutured and so the seemingly magic transformation of a patient from death to life in the course of a few minutes is accomplished.

Figs. 18 and 19 Photographs of clots removed and of patient showing scar

The successful outcome in these 2 cases led us to give further attention to technique of this operation. We constructed an instrument case which contained all the necessary instruments for the operation (Fig. 17). When this case is unrolled everything is in readiness to proceed. The nurse in attendance hands out one instrument after another just as they lie in the case.

The next patient with embolism of the lungs came to us a year later. This case was especially interesting because it demonstrated the value of patience and perseverance. To sit many hours at a time by a patient's bedside is by no means pleasant but it is sometimes well repaid by the results. It shows us that when an embolus is once on the move one has a right to demand of an operating surgeon today that he should have a practiced hand and should be prepared to wait patiently and possibly to perform an operation after a delay of many hours. On four occasions we have waited hour by hour—once in the Charlottenburg Maternity Hospital. This patient developed a severe embolism about 8 days after childbirth. The obstetrician urgently desired an embolectomy, for according to their experience which was undoubtedly extensive they had never seen a patient recover after such a severe case of embolism in child bed. In my opinion however the patient was not a dying woman and this proved to be true for she made a good recovery without operation. If one does not keep watch by the bed of such a patient however it may happen that the fatal jerk upward may happen just when he is absent or that the over

Fig. 20. The rasp is introduced close to the sternum at the cartilaginous portion of the second and third ribs

burdened heart may suddenly collapse while the surgeon is away.

The third case in which I did a modified embolus operation with success was that of a patient who was operated upon for a ruptured ovarian tumor. The wound healed splendidly. Ten days later at 6 o'clock in the morning, signs of a very severe embolism manifested themselves. The sick woman continued to recover under continual watching until at about 6 o'clock in the afternoon a renewed severe clotting ensued. Still I was not at all inclined to do an embolectomy. However I continued to keep watch by the sick woman's bed until 12:15 that night when the heart beats became fainter and fainter, the breathing more and more dyspnoeic and consciousness evidently began to vanish. The patient's last words were "I think I'm going to die." Her pulse could scarcely be felt. Respiration most arduous and superficial and she looked like a dying woman. We did the typical operation as already described. The wounds healed without any further incident (Figs. 18 and 19).

As I have already said, up to now only Kirschner has been successful with the original Trendelenburg method (resection of the second rib trans pleural procedure) and I believe that he was successful only because his patient was young and her sound young heart was able to withstand the enormous burden laid upon it by the pneumothorax.

It gives me great joy to say that two surgeons in Sweden, who had heard my lecture and had seen my demonstration at the Surgeons' Congress in 1926 and who had previously not been successful when they used the original Trendelenburg method have now had splendid results when they followed my method precisely. These two

Fig. 21. Pushing away fat with handle of scalpel and pleura with forefinger of left hand

Swedish surgeons have each had two successful cases. These with my 3 cases make 7 cases reported in which operation has been successful.

Unfortunately, I experienced a great disappointment a few months ago. A very large man of 50 years of age contracted an embolism of the lungs after a simple appendectomy. The extrapleural clearing and the opening of the pericardium were accomplished according to our usual technique, but on account of the unusual depth in which the organs lay as the patient was very fat, I had the misfortune to injure the heart in introducing the Trendelenburg sound. This had previously happened to others among whom might be mentioned Trendelenburg himself and Sauerbruch. This accident caused me to make many further experiments on the dissecting table, and I can now present the steps of an operation which is so abbreviated and simplified that it can be carried out without difficulty by any surgeon or gynecologist even by those who are not familiar with the technique of resection of the ribs. Previously, subperiosteal resection of the ribs with a pleura often as thin as a spider's web, was a task especially in a moribund patient, extremely trying. The operation must be carried out with meticulous care and yet with great rapidity. With my technique however, one can resect the ribs in a few seconds and the steps of the operation are simple and the pleura is not opened or injured. This technique has not previously been described. The sternum must be exposed more than usual. It is not resected extra pleurally as usual at the bony portion of the ribs. The raspatory however, is introduced quite close to the sternum at the cartilaginous portion of the second and third rib (Fig. 20). This takes only a few seconds. Fat lies

Fig 22 Incision into pericardium

beneath, loose, and can readily be pushed aside. Here the Doyen raspatory is brought into play. It is inserted medial to the internal mammary artery and when pushed further in a lateral direction we resect the ribs extrapleurally as far as necessary and without danger to the pleura, because in this layer, the pleura is surprisingly easy to remove. Even in the case of the most aged subjects, the operation is done with undreamed of rapidity and certainty. With a large bone forceps three nips, about $\frac{1}{2}$ a centimeter broad, are made in the sternum at the level of the second and third rib. The fat and pleura under the sternum have previously been set aside with the raspatory. The reversed handle of the scalpel is used to push away the fat of the epicardium and the pleura on the right side, and the left forefinger is used to push away the pleura on the left (Fig 21). Immediately the pericardium comes into view it is brought up between two rigidly bent pincers and an incision is made and then widened digitally, as I have already described (Fig 22). The two forefingers slowly but very forcefully widen the pericardial slit the left proceeding cranially as far as the first rib the right as far as the fourth rib (Fig 23). The space now is very large. The right auricle is plainly visible and it is at once apparent how easily and quickly the small model of the Trendelenburg sound can be introduced (Fig 24).

Fig 23 The incision is slowly but forcefully widened with the two forefingers

Fig 24 Right auricle exposed

Injury is no longer possible. We have not as yet had a chance to operate on a dying patient with this method but I am convinced that this further improvement means considerable simplification of the operation—something which doubtless will make the operation popular. From inquiries and replies from many surgeons it would seem that the bad results from operation are due to the fact, that even by extrapleural procedure overhasty operators tore the pleura. With my modification this can not happen.

I am convinced that since no means has yet been discovered of obviating postoperative thrombosis and embolism the Trendelenburg operation will be more and more used and that it will be practiced by other operators just as is any other operation. The operation is not so difficult as it would perhaps appear. I therefore hope that my suggestions will induce others to try my technique and that they will be successful in relieving patients suffering with this fatal malady.

PROLAPSE OF THE INTESTINE THROUGH A PREFORMED OPENING IN THE GREAT OMENTUM

KARL H. MARTZLOFF, M.D., F.A.C.S., PORTLAND, OREGON

From the Department of Surgery, University of Oregon

THE finding at operation of one or more apertures in an otherwise unremarkable omentum majus is not a rarity. Such unsuspected slits are generally found at the termination of an abdominal operation. They may, of course, be due to injury incidental to the operation at hand, but again, in some instances, they are noted before operative interference and when found, are repaired, and prove of no further significance.

That a slit or slits of this sort may form the starting point for some intra abdominal catastrophe, such as the ensnaring of a segment of intestine appears reasonable. The occurrence of such an event, however, from a review of the literature, appears extremely rare, and it is difficult to say anything concerning its actual incidence. Makins, in a study of 400 cases of intestinal obstruction, reported one instance (0.25 per cent) wherein an opening in the omentum was the cause of an obstruction. No description is given of this case.

We are concerned, in this discussion, only with openings in the omentum that are apparently preformed and not obviously the result of inflammatory adhesions. This, therefore, excludes those instances in which adhesions between the margin or other portions of the omentum to each other as well as to contiguous structures result in constricting bands or what at times appear to be abnormal apertures.

Concerning the etiology of omental openings there is probably more speculation than actual information. From the appearance of one of these slits it is probably impossible to determine whether the abnormal opening is of recent or remote formation. It would appear rather arbitrary to consider such openings congenital unless they are formed in the early period of life, in fact, Prutz believes that the most common cause of omental openings is the gradual atrophy of the connective tissue.

From a review of the available literature the following personal observation forms we believe the sixteenth case record of its kind.

E. A. L., a white woman aged 24 years was first seen October 29, 1927. The family history was altogether irrelevant. The past history was entirely negative except for the following notations: For several years the patient had had more or less abdominal gas with a sense of epigastric fullness immediately after meals. Belching gave relief and

there was no history of pain or constipation. One year ago she had bladder trouble which lasted 3 days. This was not treated by a physician and was not associated with abdominal symptoms.

The menstrual history was irrelevant. The patient had been married 8 months.

The present illness began 9 days previously at which time the patient began to have chilly sensations. Two days later she experienced acute epigastric discomfort with nausea and vomiting. This discomfort became generalized to the entire abdomen but was most noticeable in the right iliac quadrant. The discomfort was constant dull and aching with exacerbations which were not colicky like and did not radiate. There was no further nausea or vomiting but the chills persisted as did the abdominal discomfort and for 2 or 3 days there was urinary frequency and burning.

Physical examination. The temperature was 99 degrees F, pulse 64, respiration 14. The entire examination was irrelevant except for the abdominal findings. The abdomen was symmetrical and moved freely with respiration. At first there was such marked cutaneous hyperesthesia in the right iliac quadrant that it was almost impossible to touch the patient who was very apprehensive. However when the examination was finally satisfactorily performed there was elicited generalized abdominal discomfort on palpation and percussion but no rigidity or muscle spasm. There was also some discomfort to pressure in either costovertebral angle. No viscera were felt; the flanks were tympanitic and the area of hepatic flatness was normal. The pelvic examination was irrelevant.

A provisional diagnosis of pyelitis was made with appendixitis as a possibility.

In the hospital the patient's temperature was never above 98.6 degrees F. The white blood count on two occasions totaled 9,800 and 7,000 with 70 per cent and 60 per cent polymorphonuclear neutrophilic leucocytes respectively. The blood Wassermann reaction was negative. A urine specimen obtained by urethral catheterization contained numerous leucocytes and gram positive cocci. A cystoscopic examination with bilateral ureteral catheterization was irrelevant except for a very moderate hyperemia of the bladder mucosa. While microscopic preparations and cultures of the urine from either kidney showed just a few leucocytes and gram positive cocci in stained smears of the dried sediment. The cultures showed a staphylococcus.

The abdominal symptoms persisted and in spite of the evidence of a pyelitis it was obvious that the pyelitis was not producing either fever or leucocytosis and therefore was not the cause of the abdominal symptoms.

Operation was performed November 3, 1927. An appendix normal both macroscopically and histologically was removed. A complete exploration was also irrelevant until at its termination the reflected omentum was turned down for interposition between the parietal and visceral peritoneum. It was then seen that a loop of intestine lay upon the anterior aspect of the omentum. Closer inspection revealed two openings in the omentum in about the midline the smaller one superior to the larger as shown in Figure 1.

The smaller opening was oval, measured probably 1.5 to 2 centimeters in its greatest dimension and was situated about 2 to 3 centimeters inferior to the transverse colon.

CASES FROM THE LITERATURE

A. thor Name Case	Date	Age of patient	Sex	Portion of intestine involved	Symptoms	Outcome	R marks
No author Name 1	1840	49	F	Small	Typical of ob- struction	Death on sec- ond day No per- fora	Patient had cancer of uterus. Autopsy some small intestine had per- forated through the omentum and become strangled— almost gangrenous
Curran J W 2	1869	22	F	Small	Typical of ob- struction	Death on 16th day No opera- tion	Child previously well. Frightened by dis- charge and whole rungs felt a little pain in belly. Autopsy Good sized rectum in one of the umbilicus with good sized knot of gangrenous intestine protruding through. Perforated
Pierre A 3	187		M	?	Typical of ob- struction	Operation Recovery	Loop of intestine had passed through an aperture 3.5 cm in extent of abdominal traumatic recent ori- gin situated close to the free border of the great omentum. No perforation. Nothing in description to show its traumatic origin
C. Lyle and Lawson 4	1872	47	M	Small (1 um) 40 inches long	Typical of intes- tinal obstruction	Operation Death Cause of obstruction not found at per- fora	Autopsy 40 ches small intestine bluish black had passed through an aperture 3.5 ches in circum- ference in right lower abdominal omentum. Omentum free. No adhesions
Lind 5	1882			Small			Author mentions a case of venous thrombosis of intestinal obstruction due to loop of intestine passing through the aperture of peritoneum
B. R. McKee 6	1886	27	M	Apparently small gut Length not given	Typical of intes- tinal obstruction Fecal contents No abdominal sign	Operation Recovery	Patient had had previous similar attacks. Omentum full of holes. Resected. Intestine incised and easily released. No previous operation
Cattell H W 7	1896	56	M	Small to 12 feet	Typical of ob- struction	Death. Findings at autopsy	Intestine in situ. Bloody fluid in peritoneal cavity. Omental opening not localized in descrip- tion
Guinard A 8	1898	24	M	Small	Typical of ob- struction	Operation Recovery	Tuberculous peritonitis. Omentum appeared as sieve. No hernias in these free border of which was incarcerated. No previous operation
Gorsk 9	1898	82	F	Transverse and descending colon	Typical of intes- tinal obstruction	Operation Aspiration large intestine recovery	Opening 4 cm in diameter at edge of omentum. Edge of rectum 2.5 cm in thickness and falmost car- laginous consistency. Considerable case one of 11 peritonitis. The defect of inflammatory origin less than a simple tear in the omentum
Barking A S 10	1898		M	Small	Strangulated in guinea hernia	Operation Recovery	Omentum and intestine in hernia sac. Strangulation due to testis passing through the hernia. The me- tastasis necessary to cut out the intestine
Lesanti A 11	1899		M	Small	Typical of ob- struction. Tu- mor felt to left of umbilicus Diagnosis Intussusception	Operation resection of 5 in small intes- tine. Murphy button a to- mos complicated re- covery	Patient had syphilis. Is peritonitis by loop of small bowel compressed by opening in great intestine. Bowel gangrenous. Considerable intestinal defect in right because of small nodules and areas of ulceration with grayish yellow bases about defect.
Goodman Chas 12	1906	63	M	Small 8 inches long	Typical of ob- struction	Operation Recovery	Intestine strangulated due to volvulus. In arcer tied 1 omental pedicle one inch from free border. Re- sected by cutting out tumor. No previous operation
Taylor Wm J 13	1907			Small			Author reports 35 cases of intestinal obstruction. One of these a case of intestine passing through a perineal the great mentum which was evidently recent fracture. No other description given
D. H. J. K. 14	1908	43	M	Small 6 feet long	Acute upper ab- dominal pain 5 minutes post cibum. Slight distention with tender- ness and general rigidity. No fever. Diagnosis Perforated gastric ulcer	Operation Recovery	Large amount of blood stained fluid peritoneal cavity. Intestine prolapsed through the navel. great omentum at the free border. Lightly dilated, dark purplish not gangrenous. No adhe- sions
Makins G H 15	1900						No description. Mentally a reference to nature of intestinal obstruction due to an opening in the mentum
Martin G H 16	1909	24	F	Ileum	Intestinal perforation No diagnosis	Exploratory operation Recovery	See text

The large defect also oval measured probably 5 to 6 centimeters and was situated about 2 centimeters inferior to the smaller one. A loop of small intestine (ileum I believe) protruded through the larger defect and lay upon the omentum to the right of the midline. The loop measured about 15 to 20 centimeters in its total length, was slightly distended and of a purplish pink hue. Its mesenteric vessels were questionably dilated though the subserosal capillaries were visibly enlarged. Reduction was easily accomplished and the intestine showed plainly the two points where the omental constriction had been effected.

The margin of the two omental apertures showed no evidence of hemorrhage or fibrin deposition. They were smooth and covered with a pale gray glistening and translucent serosa—evidently preformed defects of undetermined age.

The defects were repaired. The patient had an uneventful recovery and is well at the present time. There have been however occasional recurrences of the bladder symptoms.

This case differs from the others encountered in a review of the literature in that here the outstanding symptoms of intestinal obstruction were absent. It also illustrates the ease with which a symptom producing anatomical abnormality may be overlooked in an otherwise obscure case unless the exploration is performed systematically and where possible under direct vision.

In the accompanying table are arranged in chronological order the reported cases of intestinal prolapse through a preformed omental opening. From this table have been omitted as previously noted, instances in which omental adhesions were the source of intestinal ensnarement. Particular mention may be made of the case reported by Brown which Prutz apparently accepts as coming within the group of cases we are considering. From Brown's description the omental slit was evidently due to an adhesion on the posterior aspect of the omentum. The intestine in his case had passed through an aperture that was posterior to the omentum. In other words there was no trans-omental defect and we have therefore not included this case in our tabulation. The cases of Atkins, Fowler and McWhorter also do not come within the scope of this paper. There may be some doubt as to the propriety of including the case reported by Gorski. This was one of an opening 4 centimeters in diameter at the edge of the omentum through which almost the entire transverse and descending colon had passed. The edge of the ring was about 2 centimeters in diameter and Gorski expressed the belief that the defect was inflammatory in nature rather than a simple tear in the great omentum. This is a most unusual case and probably belongs to the group we are studying.

It also appears that in his monograph Prutz accepts the case reported by Moiler. In this in-

Fig. 1. Drawing showing location of openings in the omentum.

stance the omental opening was caused by the fusion of two pieces of omentum. The findings were made at autopsy which occurred 23 days after a previous abdominal operation and we are excluding this case from our tabulation.

From a comparison of the case reported by Cayley and Lawson from the Middlesex Hospital in 1877 with that of Coupland in 1879 we believe the two reports concern the same patient. In each description the omental defect is localized in the same situation in identical words, the amount of small intestine that passed through the omental aperture was 40 inches in each description and in both observations the site of the distal strangulation was 4 inches from the ileo caecal valve. We therefore have considered this a duplicated case report and have given priority to Cayley and Lawson.

A case reported by Kirchner also deserves mention. Here the jejunum had passed through the omentum but in his careful description Kirchner explains that the constricting bands were pro-

duced by adhesions of the margin of the omentum to the pelvic organs. This case has, therefore been excluded from our tabulation.

The tabulation is self explanatory. The number of reported cases is so small that one doubts the permissibility of any conclusions utilizing percentage figures. The following summary may serve to crystallize the few generalizations that may be drawn from this study.

SUMMARY AND CONCLUSION

1 Prolapse of the intestine through a preformed omental defect not due to adhesions is an exceedingly rare occurrence. In so far as we have been able to determine from the literature this case report represents the sixteenth instance.

2 It may occur at almost any age and there is not sufficient information available to indicate its predilection for any particular age period.

3 No definite predisposing factor has been determined.

4 The small intestine is the portion generally involved.

5 The symptoms of this condition are as one would naturally anticipate, typical of intestinal obstruction. In the case here reported the foregoing generalization is not applicable.

6 The outcome following timely operative intervention has been uniformly good.

MEDIAN COLOSTOMY

LOUIS J. HIRSCHMAN M.D., F.A.C.S., DETROIT

SINCE colostomy was first employed for the purpose of providing an artificial anus, the left inguinal region has been almost invariably selected for its location. The sigmoid colon has been employed for this purpose more often than any other portion of the large bowel.

An abdominal opening over the point where the largest portion of this bowel is most often found, was the most natural one to be made. Inasmuch as an artificial anus functions best when the feces which pass through it are normal in consistency, shape, and quantity, as a general rule, the lower in the colon it can be located, the better it is.

The rectus muscle being thick and strong not only has made a good support for the bowel, but has exercised, at least to a slight degree, some sphincteric function.

It is gratifying to find so many patients who have been subjected to a colostomy in possession of so marked a degree of fecal continence as to be able to attend to their regular duties. In a large number of cases however, the fecal discharge from a left inguinal colostomy has irritated the surrounding skin so that much discomfort has been suffered by the patient.

In people of slight build or those who have been emaciated as a result of their disease, the anterior superior spine of the ilium, being quite prominent becomes eroded, ulcerated, and is made very sensitive. On account of this discomfort, dressings, bands, belts, trusses or colostomy apparatus could not be worn without increasing the patient's distress. This in many instances has created a problem the solution of which has been attended with considerable difficulty.

Patients forced to go through life with a colostomy and who must wear some sort of a bag or other retaining device are usually quite sensitive about their condition. Usually bulging or protrusion on the left side caused by colostomy pads, cups, or bags, causes such a distortion of the patient's contour as to be decidedly noticeable and embarrassing. This is particularly so in people who have become emaciated through illness. In women especially, the difficulty in arranging the clothing so as to disguise their infirmity has presented serious difficulties.

In performing a left inguinal colostomy, the surgeon is limited in most cases to the employment of the sigmoid colon for the colostomy.

The gastrocolic omentum does not allow of sufficient laxity of the transverse colon without undue strain on the stomach, to be brought down and successfully used in this region.

Before performing a colostomy obviously a complete exploration of the abdominal cavity is necessary for both positive and negative diagnostic reasons. An incision either at or near the median line must be employed to make a thorough, complete, and successful intra abdominal surgical examination.

If one elects to perform a left inguinal colostomy after such an examination, a second incision and opening into the cavity must perforce be performed. If, as is often the case, a colostomy is performed preliminary to a subsequent abdominal or abdominoperitoneal extirpation of a malignant growth of the rectum or sigmoid colon, it is quite important that the colostomy be placed not only as high up in the bowel as possible, but also that it be located as high up on the abdominal surface as possible.

By employing the descending or the transverse colon in some cases one is able to resect a larger portion of the colon above the growth and thus secure a greater margin of safety. By placing the colostomy well above the site of the wound which would be necessary for a subsequent resection a clean area is provided for the abdominal operation.

For some years we have been locating our colostomies in the median line, just above the umbilicus, and our patients have been able to wear colostomy bags with much greater ease than when the colostomy was located in the inguinal region.

One unsatisfactory feature in this location has been the soiling of the umbilicus by fecal discharge and the difficulty in cleansing this area. For this reason during the past 3 years we have been excising the umbilicus and using this site for the location of the colostomies.

The technique as first advocated by Angelo Sorel has been employed with slight modification in certain cases. By employing a natural opening into the abdominal cavity which the umbilicus provides we take advantage of the semicircular arrangement of the rectus fibers at this point as well as of the increased strength of the fascial tissue which lessens the tendency to possible later herniation.

Fig 1 left Line of incision
Fig 2 Freeing the umbilicus

Fig 3 left Area punctured for insertion of rubber tubing
Fig 4 Sectional view

The technique of operation as personally employed is as follows:

If local anaesthesia is used a one half per cent solution of novocain in Ringer's solution is chosen. A subcutaneous injection is made from two punctures located at both poles of the proposed incision. This is very rarely longer than 3 inches and is made in the median line curving outward on both sides around the umbilicus above and below, and then again joining above. The fascia is punctured and the muscle infiltrated (Fig 1) on either side down to the peritoneum. Care must be taken not to puncture the peritoneum for fear of injuring the bowel. The umbilicus is grasped with an Allis forceps and freed right down to the peritoneum with scissors and by blunt dissection. Through a peritoneal incision just below the umbilicus an examination (Fig 2) is made in order to be sure that omental adhesions or protruding intestines are not present. With the removal of the umbilicus a sufficient opening into the peritoneal cavity is thus presented so that a complete ocular examination can be made.

By extending the incision downward and continuing the injection of the anaesthetic solution and using great gentleness we can locate the neoplasm. Mesenteric traction must be avoided to prevent unnecessary pain. The liver, gall bladder and spleen can be palpated through a similar extension of the upper half of the incision. With rubber tipped forceps a portion of the descending or transverse colon is brought out of the wound. A non vascular area of mesentery (Fig 3) is punctured with haemostatic forceps

and a piece of $\frac{1}{4}$ inch thick walled rubber tubing brought through this mesenteric opening to act as a support for the colon for the first few days. If the transverse colon is used sufficient omentum is tied off in sections so as to give a clean loop of bowel for the colostomy (Fig 4). The fascia and peritoneum are trimmed back on either side so as to allow the rectus muscle fibers to bulge into the wound. The peritoneum is closed above and below the bowel by plain catgut sutures and the muscle and fascia approximated by number two interrupted chromic catgut sutures. No attempt is made for the purpose of bringing the peritoneum up to the skin as recommended by some authors.

Much better muscular control is obtained by the adhesion of muscular fibers directly to the intestine. The skin is closed by clips and stearate of zinc powder or sterile vaseline applied freely over the protruding bowel.

Much more satisfactory anaesthesia for this operation is that obtained by the subdural injection of novocain. Spinal anaesthesia produces such a wonderful degree of intestinal quiescence that having once employed it in any type of abdominal surgery the surgeon is prone to use it always. The utter flaccidity of the abdominal wall as well as its contents renders intra abdominal examination of all of the viscera a matter of great ease. Any operation and especially on the colon is facilitated by a complete absence of intestinal movements which is so characteristic in etherized patients. The intestines are contracted and lie on the posterior wall of the abdominal cavity as they do in the cadaver.

Fig 5

Fig 6

The operative technique under spinal anaesthesia is the same as when local anaesthesia is performed. There being no protrusion of the intestines it is not necessary to use gauze or other substances as packs or coffer-dams therefore no unwelcome intestinal adhesions are produced.

For several years, a very simple and satisfactory method of opening the colostomy loop has been personally employed. Noting the repugnance of the patients to the odor of their own burning flesh the cautery has never been employed for the purpose of opening the colostomy. Incision is attended by unnecessary haemorrhage and is also disturbing psychologically even though it is painlessly performed.

Usually the opening of a colostomy means a second trip of the patient to the surgery or operating room which is also often unnecessarily disturbing. For this and other reasons opening the colostomy by means of pressure necrosis has been personally employed with very satisfactory results (Fig 7).

After the operation described has been completed and before the dressing is applied the exposed loop of colon is seized with two pairs of haemostatic forceps grasping the longitudinal muscular band about 3 inches apart. Traction is used to raise this portion up while a long curved

Figs. 7 and 8 Colostomy is opened by means of pressure necrosis. This method gives very satisfactory results.

Fig 9 Colostomy completed

hysterectomy clamp is placed along the bowel just below the ends of the traction forceps. The clamping of this forceps puts pressure on a spindle shaped area which becomes the opening of the colostomy when the clamp is removed after 48 hours.

In this way a painless bloodless colostomy opening is produced without the patient being aware of it. The opening is satisfactory and is produced while the patient is in his own bed and it does not require any special preparation, instruments, or 'fuss and feathers'.

The skin surface surrounding the colostomy is kept protected with a large quantity of stearate of zinc powder not only during the healing process but afterward. The patient is encouraged to sit up in bed just as soon as the abdominal incision is sufficiently healed to allow the removal of clips or stitches. He is then urged to attempt to have a movement from the colostomy at regular stated periods usually morning and evening.

If no movement is secured, the colon is flushed through the colostomy, with a few ounces of saline or soda bicarbonate solution. By hold-

Fig 10 Photograph of patient showing colostomy and belt with removal bag

ing a crescent basin under the colostomy with one hand while with the other, he irrigates with a bulb syringe the patient is able to take care of himself nicely without assistance.

A colostomy belt with a removable bag is used, which is very light in weight and which is inexpensive. This has been found much more satisfactory than the more expensive and complicated types of apparatus. The patient is encouraged to walk as soon as he is able and to get out of doors and resume his normal routine of life.

I fully believe that a median colostomy is more strongly supported by surrounding tissues, than is one located in the inguinal region. On account of this fact, the convalescence is more rapid and the patient is able to resume his activities in a much shorter period of time which is a good thing from a psychological standpoint as well as a physiological point of view.

IMPLANTATION MALIGNANCY OF THE ABDOMINAL WALL

HAROLD DVORAK, M.D., MINNEAPOLIS MINNESOTA

From the Department of Surgery and the Cancer Institute of the University of Minnesota

THE fear of local recurrence of malignant tumors prompts the surgeon to excise the initial lesion as widely as he dares. Invasion of the abdominal wall by extension from intra-abdominal malignancy is not so unusual and is an occasional sequel to advanced tumors of the large bowel. Implantation of neoplastic tissue into the abdominal wall during excision of an intra-abdominal neoplasm without its recurrence within the abdomen is, however, a very unusual occurrence. A careful review of the literature has borne out this impression. The rarity of this occurrence justifies the report of the following case.

Mrs. M. W. 69 years of age, white female housewife was admitted to the University Hospital in May 1923 complaining of a tumor of the anterior abdominal wall.

The patient was a healthy individual throughout her youth, suffering only a few of the common illnesses of childhood. Her menses appeared at the age of 13 years and were regular and normal in every respect. She was married at 23. She was never pregnant. Her menses continued normal until she reached her middle thirties when they appeared every 2 to 3 weeks. Pain and profuse vaginal bleeding was noticed then on the first day of each menstrual period. This caused her to seek medical advice and treatment.

In 1907 at the age of 48 years she had erysipelas of the face for several weeks. In the winter of 1907-1908 she visited her physician because of menorrhagia and was told that this was due to change of life. In April 1908 a curettage was performed and a small fibromyoma of the uterus was removed. Following this she developed increases in leukorrhea. In June 1908 the appendix, right ovary and right tube were removed. In November 1908 the uterus and left tube along with a cyst and two tumors of the uterus were removed. These latter were found to be large fibroids. The abdominal wound became infected and healing was somewhat slow. Dr. Ray Knight, who assisted at these operations and who saw the patient from time to time, has kindly given us the information relative to her operations. Dr. F. R. Woodward, who performed the original operations at the old Asbury Hospital, Minneapolis, is deceased and the hospital records of that time are not available.

The patient continued apparently healthy until 1921 when she first noticed a lump about the size of a walnut in her left lower abdominal quadrant. At first it grew slowly and then more rapidly until May 1923 by which time it had developed to the size of a small football. Shortly thereafter she was admitted to the University Hospital. At this time she was suffering from sharp burning pains at the site of the tumor mass occurring four to five times a day but not radiating in any direction. Her best weight had been 180 pounds but she had lost 17 pounds during the 6 months previous to her admission here. She also complained of some weakness. The family history revealed that only one relative, a great aunt, had died of some form of cancer.

The physical examination showed on palpation and inspection a hard diffuse mass about the size and shape of a small football extending in a slightly oblique direction from a point 5 centimeters below and 9 centimeters to the left of the umbilicus to a point on the pubic crest 3 centimeters to the right of the midline. This mass was slightly tender on pressure and appeared embedded in the musculature of the abdominal wall because it could be moved about freely with the abdominal wall and also because the skin could be easily lifted away from the mass. Three centimeters to the right of the midline and extending upward from the pubis to a point half way between the latter and the umbilicus was a scar from the operations of 1908. Beneath this scar the abdominal wall appeared rather thin and to it the right edge of the tumor was fixed. It was felt that this tumor was probably a desmoid of the rectus sheath and excision was recommended. No adenopathy could be demonstrated.

The tumor, including a large part of the left rectus muscle and its anterior sheath, was removed on July 27, 1923, by Dr. A. L. Cameron. On microscopic examination the tumor was found to be an adenocarcinoma, its structure closely resembling alveolar glands lined by columnar epithelial cells. Convalescence was satisfactory and she was discharged apparently well. During 1924 she received superficial X-ray treatments for her abdominal wall condition as prophylaxis against recurrence.

However, the patient was readmitted to the University Hospital on June 26, 1925, because of recurrence of the tumor and abdominal pain. There was found over the site of the previous operation a large postoperative incisional hernia. In the abdominal wall about 2 centimeters to the left and slightly below the umbilicus a round hard tender mass about the size of the patient's fist was palpable. Over the pubic region was found a hard nodular irregular mass roughly 8 by 5 by 5 centimeters in size, adherent to the pubis and tender on palpation, first noticed in September 1924. The adnexa were negative. The pelvic floor was normal. The rectal examination was negative. The patient complained of numbness and pain in the left lower extremity which radiated from the sole of the foot to the thigh. She had lost 20 pounds in weight since the fall of 1924 and had become progressively weaker. On July 12, 1925, 900 milligram hours of radium in needles were inserted into the suprapubic mass.

On October 29, 1925, the patient was readmitted for the fourth time. The suprapubic mass was smaller, she felt better and she said that she did her own housework. The mass near the umbilicus, however, was somewhat larger. The following day she was given 35 milligrams of radium for 10 hours into the suprapubic mass, a total of 350 milligram hours and advised to return later for superficial X-ray treatments of the umbilical mass. She was very co-operative and appeared regularly at the out-patient clinic at intervals of about 4 weeks. Each time she received approximately 40 per cent of a skin erythema dose to the mass near the umbilicus. Treatment was continued until the summer of 1926 when she said she felt good. The abdominal wall tumor had become smaller. The new Cancer Institute at the University of Minnesota, having now been fully established as a unit of the University Hospitals, deep X-ray therapy was begun. Between August,

Fig. 1 Photomicrograph of ovarian cystadenocarcinoma removed at time of necropsy from the abdominal wall of our patient

Fig. 2 Same as Figure 1 under higher magnification
X450

1926 and March 1927 she received three series of deep X-ray therapy

On June 7 1927 she was readmitted for the fifth time. There were many small nodules which could be felt on palpation shipping around beneath the skin of the lower abdomen. She felt quite well except for a dull pain in the back which was now more or less constant. Her appetite was good she had no pain in the abdominal masses and felt fairly strong. On June 13 1927 X-ray examination revealed metastases involving the fourth and fifth lumbar vertebrae which accounted for the pain in the back.

Further deep X-ray therapy was recommended. This was instituted and by August 1927 the abdominal wall tumor near the umbilicus could scarcely be palpated and she again felt much better. Altogether she received between June 23 1927 and December 1927 three series of deep X-ray treatments receiving each time a 110 per cent skin erythema dose to the central part of the pelvis and spine. In January 1928 the scar tissue surmounting the postoperative incisional hernia and tumor area began to break down. By April 1928 following nearly a week of obstinate constipation an intestinal fistula developed opening onto the abdominal surface.

The patient was admitted to the Minneapolis General Hospital in August 1928 with a history of mental confusion for 2 days and constipation for 4 days preceding admission. She complained of shooting pains about the pelvis radiating to the umbilicus. The clinical impression was generalized carcinomatosis. A history note of October 1928 mentioned the persistence of a large hard abdominal mass on the left side. There was considerable emaciation at that time. Death occurred on November 26 1928.

The postmortem examination revealed a pear shaped abdominal defect 10 centimeters by 8 centimeters immediately above the symphysis pubis. In the abdominal defect were two fistulous openings one connecting with the ileum at a point 50 centimeters from the ileocecal junction the other with the midportion of the transverse colon. The intestines in the upper part of the abdomen were bound down by adhesions. The peritoneal surfaces were free of metastases. The pleural and pericardial cavities were free of metastases. No lymph node involvement could be demonstrated. However metastases were found in the

fourth and fifth lumbar vertebrae. The bones of the pelvis appeared normal. The organs of the head and neck were not examined.

Below and to the left of the umbilicus was a fleshy tumorous mass 5 centimeters by 2 centimeters in the left rectus muscle region. Microscopically the tumor was found to be composed of many atypically and poorly formed alveolar structures lined by tall columnar cells and supported by a thin stroma. In many of these alveoli the lining cells had proliferated to the extent of forming fine dendritic processes projecting into the lumen occasionally forming the point of separation of one partly formed alveolus from another. The picture as a whole was that of a papillary cystadenocarcinoma very likely of ovarian origin. The following anatomical diagnoses were made: (1) emaciation and cachexia (2) hypostatic bronchopneumonia (3) implantation carcinoma in the abdominal wall with metastases to the spine (4) intestinal fistula.

It is believed that the origin of the neoplasm in the scar of this case can be attributed to implantation of a portion of the supposedly benign ovarian cyst into the abdominal wall incision at the time of operation in 1908.

In contrast to implantation in the abdominal wall extraperitoneally a much commoner condition is the well known intraperitoneal dissemination from a benign ovarian cyst with implantation upon the peritoneal surface. This process was probably first recorded in Baker Brown's celebrated case which was described by Beigel in 1860.

Wagner (1864) probably described the first case of benign ovarian tumor reproducing its structure

in the abdominal wall proper. A former prostitute, who over a period of 13 years was tapped 42 times because of ascites, had developed three subcutaneous cystic tumors below and to the left of the left breast, in the right axillary fossa, and in the left flank region. These tumors were secondary to the very large intra abdominal benign papillary serous cyst arising from the left ovary. The histological structure of all was identical, as proved at necropsy.

Baumgarten (1884) mentioned the extirpation of a benign papillary serous ovarian cyst. At necropsy sometime later, secondary tumors all histologically benign and identical with the primary ovarian cyst, were found to have occurred not only on the inside of the peritoneum, but also in the abdominal wall extraperitoneally.

Olshausen (1899) described the instance of a woman aged 46 years who had had a left oophorectomy performed in 1878. In 1895 she was operated on by him for an abdominal wall tumor of the right side just above the navel. Histologically, the latter was a benign papillary ovarian cystadenoma. The author believed this to have arisen undoubtedly by inoculation of the abdominal wall during the operation done 17 years previously.

In the same paper this author mentioned another case of a woman of 53 years, who in 1889 was operated upon for the removal of an intraligamentary cystic ovarian tumor, the size of a man's head. On section the tumor was found to have a papillary structure. In 1895 she was operated upon for recurrence in the right ovary and also for a fist sized abdominal wall tumor which proved to be carcinoma. The author believed that these latter were entirely secondary to the first tumor of 6 years previously.

In 1902 Olshausen again reported another similar case of a woman who in 1881 at the age of 29 years had been operated upon for bilateral tumors of the ovary (bilateral ovariectomy). These were of the papillary cystic type. For the past half year she had noticed a tumor on the right side of the abdominal wall which progressively increased in size. It was removed and diagnosed grossly as unquestionable carcinoma. A histological diagnosis not having been ready at the time of the report. This the author believed arose by inoculation at the time of the previous operation because the abdominal wall tumor was found to arise from the scar of the previous laparotomy.

This last case demonstrates three interesting facts found together which had occurred separately in previous cases namely a long interval of time elapsing between the removal of the pri-

mary benign ovarian tumor and the appearance of the secondary in the abdominal wall, origin of secondary in the scar of the previous laparotomy wound finally malignancy of the secondary tumor.

Schnuettgen (quoted by Tauber) up to 1918 found only 8 published cases of benign ovarian tumor metastasis to the abdominal wall. To these he added a case.

Bland Sutton (1922) removed the uterus and bilateral apparently benign, papillary ovarian cysts of a woman. Six years later a rapidly growing tumor of the sternum on the right side at the level of the second intercostal space was noticed. It was removed but promptly recurred and eroded away the whole manubrium. This secondary tumor was microscopically exactly like the primary cyst. The patient died. At necropsy, strangely, no recurrence appeared in the abdomen.

Tauber (1927) reported a woman whose abdomen began to swell and fill up with fluid in 1910. She was finally explored. Fluid was removed. It was not known whether a tumor had been found. Her ascitic condition recurred and she was reoperated upon in 1921 when bilateral papillary ovarian cysts were removed together with three smaller ones found on the peritoneum of the anterior abdominal wall below the umbilicus. No trace of malignancy could be found. In 1926 the patient returned with another recurring cystic mass around the umbilicus and entirely within the abdominal wall. This was removed. Histologically the tumor was found to be a malignant ovarian cyst.

Lang mentioned a pseudomucinous cyst which was removed from the left ovary of a 30 year old woman. Two months later a tumor developed in the scar of the previous laparotomy wound which proved to be an adenocarcinoma.

The cases described were all of the pseudomucinous or papillary cystadenomatous type. However a similar course of events has been reported occurring in another type of tumor. Jaquet in 1899, described an ovarian dermoid which was removed from a woman in 1874. Seventeen years later, 1891, an abdominal wall tumor 15 centimeters in diameter appeared, which proved to be cancerous.

These cases 10 in number including our own were all that could be found in the literature in which primary ovarian cysts supposed to be benign at the time of their removal, were later followed by a benign or malignant reproduction of their general structural type in the abdominal wall (in the thoracic wall in Bland Sutton's case). Of these 10 new growths, 6 were observed to be

malignant and 4 benign. The secondary growths were first noticed 21 years after discovery of the primary growth in 1 case, 17 years in 2 cases, 13 years in our case, at least 10 years in 1, 7 years in 1, 6 years in 1, 2 months in 1, and 2 were of undetermined duration. Of the 6 malignant tumors, one appeared 21 years after discovery of the primary lesion, one 17 years, our case 13 years, one 7 years, one 6 years, and one 2 months.

In all the cases the primary ovarian cysts were considered benign when extirpated. Cases have also been reported in which the primary was obviously malignant when extirpated and simultaneously presented secondary malignant metastases to the abdominal wall specifically to the umbilicus. Cullen (1916) collected 9 such cases.

Mayfield (1926) summarized a study of 100 cases of papillary cystadenoma of the ovary and found that these cysts vary both pathologically and clinically in their degree of malignancy. He found that some small cysts were very malignant, and some large ones benign. Benign and malignant areas coexisted. Such variations in degree of malignancy may account for the great variations in time interval between removal of primary and appearance of secondary abdominal wall growths found in the 10 cases in this series. Papillary ovarian cysts especially when bilateral, always arouse a suspicion of malignancy, and though no malignant area may have been found microscopically, the feeling frequently obtains that it may have been missed. Bell (1924) says:

'Recurrence and metastases of ovarian papillary cystadenomata is frequent even from tumors which appear anatomically benign. All papillary tumors are potentially malignant. For these reasons it is believed that the most likely explanation in the case reported here is that the ovarian cyst removed 20 years prior to the patient's death was malignant from the beginning even though that fact was not observed or demonstrated at the time.'

In locating the primary source of implantation tumors of the abdominal wall lesions of the gastro intestinal tract and uterus must be considered as well as of the ovaries. The mere fact that ovarian cysts had previously been removed must not be misleading. Polano (1905) collected from the literature reports of 7 cases of malignant abdominal wall tumors arising in laparotomy scars after previous removal of apparently benign ovarian tumors. He added one similar case. Necropsy in the latter revealed the presence of carcinoma of the stomach which he believed was very likely the primary growth. Of the 7 cases collected from the literature, on only one, that of Plan-

nenstiel, was necropsy performed. No intra abdominal cancer was found here. Nevertheless, Polano considered the abdominal wall lesion in this case primary and not subsequent to the ovarian cyst. Because of the findings in Polano's case and because no necropsy was done on the other 6 cases, the suspicion always remained that the abdominal wall carcinomata in these 6 might easily have been secondarily implanted not from ovarian cysts but from carcinomata of some other abdominal organ which was missed at the time of the first operation or developed subsequently.

Brewer (1921) cites the case of a woman, who in 1911 had her uterus, tubes, and left ovary removed because of fibroids of the uterus. In 1910 she developed a tumor of the abdominal wall. Removal proved it to be a pure fibromyoma. The author explained its origin to implantation at the time of the previous operation because microscopically it resembled in all details the original uterine fibromyoma.

Adenomyomata described as endometriomata appear to have been rather frequently observed in the abdominal wall and umbilicus in recent years. Cullen (1910) described a case of an adenomyoma of the rectus muscle occurring in a woman who 5½ years previously had been operated upon through an abdominal wall incision to repair a ruptured uterus.

Also Mahle and MacCarty (1920) mention 2 cases occurring in old laparotomy scars and also two cases arising without apparent cause, in the umbilicus.

Lochrane (1923) mentions a case of adenomyoma implanted in the abdominal wall which appeared 4 years after ventrosuspension of the uterus. The tumor was always painful around the menstrual periods. This tumor contained typical uterine glands and smooth muscle. Previous to this (1916) Cullen had already collected 13 adenomyomata of the umbilicus, 4 of which were somewhat doubtful. Ewing (1919) also described cases of adenomyoma of the groin.

Lemon and Mahle (1925) reported 9 ectopic adenomyomata invading the abdominal wall after operation.

Nicholson (1926) reported a case of endometriosis occurring in an old laparotomy scar following a salpingectomy and mentioned 15 such cases reported in the literature following ventrosuspension of the uterus. Not in one case was an anatomical continuity established between the uterus and tumor thus showing that the latter must have arisen by implantation.

Lefevre and Montpellier (1927) described a case and mentioned more than 30 cases now on

record of an endometriosis of the umbilicus Pratt (1927) discussed 42 cases now on record of implanted endometriosis occurring in old laparotomy scars following previous operations, the most frequent type of which was ventrosuspension of the uterus. He added 4 cases.

Sampson (1928) found only 1 case of endometriosis of the abdominal wall following ventrofixation of the uterus with tubal sterilization.

Jacobson (1926) working on rabbits showed that peritoneal implantation of endometrial tissue at a distance from the uterus was most successful during oestrus. From this it might be contended *a priori* that operations on the uterus in the human during or around menstruation are particularly subject to endometrial implantation.

Sampson (1923) offered circumstantial evidence in favor of malignant changes in endometrial tissue in the ovary as the source of certain ovarian cancers.

The literature examined revealed one or two cases of direct extension of a primary uterine adenocarcinoma into the anterior abdominal wall but no implantations following operative removal of uterine carcinoma. Thus, it is seen that fibromyomata, more commonly adenomyomata (endometrioma) arising as primary uterine tumors may be implanted into the abdominal wall at the time of their removal. Such, however, was not the situation in our case.

For purposes of orientation I have included below a brief discussion of abdominal wall tumors as a whole. These divide themselves into two divisions: the abdominal wall in general and the umbilicus in particular.

Malignant tumors of the abdominal wall constitute only a very small proportion of malignant neoplasms. Gurliis (quoted in Zweifel Payr) found among 16,637 cases of malignant tumors in general only 27 malignant tumors of the abdominal wall: 14 sarcomata and 13 carcinomata.

At the University Hospital of the University of Minnesota of 28,013 patients admitted between the years 1910 and 1923, only 9 cases of abdominal wall tumors were found. Of these, 7 were primary: fibroma 1, angioma 1, lipoma 2, hemangioma 1, leiomyoma 1, sarcoma 1, two were secondary—both carcinomata by direct extension and not by implantation.

SARCOMA OF ABDOMINAL WALL

Of malignant tumors in the abdominal wall in general, both sarcoma and carcinoma are found. Sarcomata arise from the skin as well as from the fascia and muscle sheaths of the abdominal wall, they may originate malignantly *per se*, or benignly

from a fibroma or naevus, particularly a pigmented naevus, which subsequently undergoes malignant degeneration. The different histological types found are fibrosarcoma, fibromyoma, angiosarcoma, and, according to another classification, spindle, round, and giant cell sarcoma. The spindle cell sarcoma appears to be the most frequent of this group. Von Klot (1921) collected some 408 cases of abdominal wall connective tissue tumors of which he found 268 to be fibromata.

BENIGN TUMORS OF ABDOMINAL WALL

Of the truly benign types found here are fibroma, lipoma, angioma, myxoma, fibromyoma, adenomyoma, endometrioma. To these must be added rarer forms like atheroma, teratoma, and dermoid and echinococcus cysts. In this benign group, as von Klot's figures have already shown, the fibroma is not only the most frequent, but also the most important. This holds for abdominal wall tumors in general. Mueller (1838) first applied the name, desmoid tumor, to this group. According to Balfour (1916) they occur in women in the ratio of 7 to 1. The average age is 34 years. They are usually found in the anterior or lateral abdominal wall and in 43 per cent of the cases are associated with the rectus muscle, or its sheath, usually the posterior sheath. They are frequent after repeated pregnancies. They are usually of small size but may equal the size of an adult's head, are usually smooth unless very large, and are ovoid, the long axis in the direction of the muscle fibers. The cut surface shows a wavy white glistening surface of fibers intimately interwoven. Microscopically, they vary from a solid fibrous connective tissue overgrowth to a very cellular actively growing fibrosarcoma. The blood supply is poor as in other fibromata so that necrosis may occur. The etiology is obscure, or may be due to traumatic overstretching and rupture of the rectus muscle sheaths during pregnancy. Prognosis is good. Balfour reported 7 cases of which 2 occurred in previous operative scars.

With respect to the origin of desmoid tumors, Danforth mentioned work done by Loeb in which the latter incised the uteri of pregnant guinea pigs. Shortly thereafter, he got nodular growths in the uterine scar. These could be elicited only in uteri which were pregnant. Such tumors can be considered analogous to desmoids caused by traumatic stretching of the abdominal wall in pregnancy.

CARCINOMA OF ABDOMINAL WALL

Carcinoma of the abdominal wall is either primary or secondary. Outside of the umbilical

region, primary carcinoma of the abdominal wall is rare. Secondary carcinoma of the abdominal wall is more common and a primary lesion should always be sought, especially in the gastro-intestinal tract, liver, and female genitalia. The secondary lesions develop by direct extension, by metastasis, or by implantation at the time of previous operation. Such implantations have occurred not only in the scars of previous laparotomies, but according to Williams (1893), also at the site of puncture wounds after frequent tapping of ascites from an ovarian cyst.

DIFFERENTIAL DIAGNOSIS

Besides true neoplasms there must also be considered the inflammatory tumors of foreign body reactions, hematoma, rupture of the rectus muscle resulting in bulging of the ruptured ends, and the infectious granulomata of tuberculosis, syphilis and actinomycosis.

Abdominal wall tumors must be differentiated from intraperitoneal and retroperitoneal tumors. This may be done by having the patient lie on his back and having him raise his trunk to the sitting position without aid, thus contracting the abdominal wall muscles. If the tumor disappears completely from sight and becomes impalpable, it lies behind the abdominal wall. If it disappears only to sight but remains palpable and at the same time immovable, it is in the abdominal wall. If it is not at all influenced but remains visible and palpable, it lies either intracutaneously or subcutaneously. Abdominal wall tumors projecting into the abdominal cavity and tumors of intra-abdominal organs projecting outward become easily confused with one another.

Regarding the differentiation of intraperitoneal tumors from retroperitoneal tumors Bevan (1924) emphasized the usefulness of inflating the large bowel with air and then percussing the abdomen over the site of the tumor area. If tympany is found, the colon overlies the tumor and the latter is retroperitoneal, if dullness is found the tumor overlies the colon and the former is intraperitoneal. Use of the X-ray is always indicated.

TUMORS OF UMBILICUS PROPER

Regarding malignant tumors of the umbilicus proper, the sarcoma is considered the most frequent among connective tissue tumors. On the whole it is rare. More frequent is carcinoma of the umbilicus, which is both primary and secondary. Primary carcinoma is of the squamous and columnar type. The squamous type can arise from remnants of the epithelium of the urachus, or ductus omphalomesentericus.

Secondary carcinoma of the umbilicus may arise from any of the abdominal organs. Head (1926) reported an interesting case of primary carcinoma of the caecum with metastases to the umbilicus.

Umbilical cancer, if primary, is usually of the squamous type, if secondary, it is of the columnar cell type and in that case an indication of an internal primary lesion. The histological structure may frequently indicate its exact location.

Of benign tumors there must be mentioned fibroma, fibrolipoma, angioma, myxoma, adenoma, infectious granuloma and inflammation of the abdominal organs.

SUMMARY

During the excision of an intraperitoneal malignant tumor, implantation into the abdominal wall may occur. Such an implantation may survive and at a more or less remote date begin to grow and present itself as a neoplasm of the abdominal wall. Such an occurrence is reported in this paper. Fifteen years after the patient's first operation a tumor was removed from the abdominal wall which proved to be an adenocarcinoma on microscopic section. Following X-ray and radium treatment, the patient survived for more than 5 years. At necropsy metastases were seen in the spine (fourth and fifth lumbar vertebrae), but no source for the abdominal wall tumor masses was found. Only a few such instances are mentioned in the literature. After a careful search only 9 besides the 1 reported above were found. Most of the tumors originate from ovarian cysts. They are likely to be mistaken for dermoid tumors, as was the case in the instance reported here, unless the possibility of implantation is borne in mind. The subject of tumors of the abdominal wall in general is briefly discussed.

LAWSON TAIT

THE untimely death of Lawson Tait, of Birmingham, England, 30 years ago, cut short one of the most notable medical careers of the last century. That he was a genius no one can doubt who will make himself familiar with his contributions to gynecological and abdominal surgery. Though by no means the first to undertake serious operations within the abdominal cavity, he certainly did more to render abdominal section a safe and practical procedure than any other man and is fairly entitled to the honor claimed for him by Dr. William J. Mayo of being 'the father of modern abdominal surgery.'

Tait began his career as a laparotomist at a time when the operation of ovariectomy had been practically abandoned in England. Of the last 30 ovariectomies performed in Edinburgh, where Tait had received his medical training, not a single one had survived. The operation was actually forbidden in some of the leading London hospitals. Syme the leading Scotch surgeon, one of Tait's teachers to the end of his life refused to perform the operation. Tait nevertheless had the courage to

undertake it soon after he began practice in a provincial town at the age of 23, and before he was 26 he had done the operation 5 times. At his death in 1899 at the age of 54 years he had performed several thousand abdominal sections and with a degree of success unrivaled by any other surgeon.

I happened to arrive in Birmingham the morning of Mr. Tait's death from uræmic coma. I had had the privilege of spending a few months with him as a pupil assistant just 10 years before. On alighting from the train I directed the cabman to drive me to The Crescent, Tait's home and private hospital. Instead of doing so the cabman handed me the morning paper, which was in mourning and bore in large black letters across the page the announcement of Mr. Tait's death. With in a few hours the whole city was in mourning for, next to Mr. Chamberlain, Mr. Tait was unquestionably its most distinguished citizen. His fame had brought to him suffering men and women from the ends of the earth. He had many patients from the United States and Canada and from South Africa and Australia. One patient, an American, the wife of a missionary doctor suffering greatly with an enormous ovarian tumor came from the remote interior of Burmah, having been carried several hundred miles on the shoulders of men to reach the nearest railroad station.

My first meeting with Mr. Tait was in his little office at The Crescent. He sat alone behind a small flat topped desk with a flexible speaking tube close at hand through which he dictated to his secretary in another room. As he sat in his chair he gave one the impression of being a man of gigantic proportions. His

shoulders were very broad, his chest thick, and his large head—he wore a number 8 hat—was covered with a thick mass of dark hair which was inclined to curl. His neck was short. His strong facial features and his abundance of wavy hair gave him an almost leonine aspect. When he stood, however, the impression of greatness diminished somewhat as he was scarcely of medium height.

In manner Mr Tait was kindly and courteous but rather short and abrupt. He had the air of a man preoccupied with intense thought. His speech was rapid and incisive. His sentences terse and pointed. He had an unusually large vocabulary and his choice of words was always the best possible. His ordinary speaking voice was pleasant, almost musical. When aroused and vexed, which often happened, he would roar like a mad bull. Tait was one of the most tender hearted men I ever met. He was gentle and delicate in his manner of dealing with patients and scrupulously careful to observe all the proprieties.

Tait had many crotchets and allowed prejudices to warp his judgment and blind his mental vision. He had a particular dislike for

LAWSON TAIT (1845-1899)

Emmett, one of the finest and sweetest of men. I could never discover any reason for this except that he disagreed with him respecting the nature of the pelvic inflammations to which Emmett had applied the term cellulitis. Tait believed the chief seat of these troubles to be the fallopian tubes, which subsequently turned out to be the truth. He carried his opposition to Emmett so far as to denounce everything he taught as error. In one case which I had previously

studied at the dispensary and in which he was preparing to repair, after his rapid fashion, a torn perineum, there was also a badly torn uterine cervix. I asked, "But, Mr Tait, are you not going to repair the cervix before closing the perineum?" "Oh no," he said "I never pay any attention to Emmett's little crack."

During the several months I was with him he never once repaired a torn cervix although cases of this sort came daily under observation. I doubt if he had any other reason, than his prejudice against Dr Emmett, for thus ignoring lesions of the cervix.

Having some years before when in Vienna

(1883) become acquainted with Billroth's pylorotomy and Woelfler's gastro enterostomy, I one day inquired of Tait why he did not perform these operations. He at once replied, "Pylorotomy is useless because it is never done except for cancer and the cancer always returns. I never do useless operations." The operation of gastro enterostomy he condemned in equally strong terms, declaring that it always resulted in "continuous fæcal regurgitation." His attitude toward these operations illustrates one of the weak points in his character. When a prejudice was once established in his mind it was impossible to uproot it and it so blinded him that he was apparently incapable of treating the subject with intellectual fairness.

In a controversy Tait was a dangerous opponent. He was remarkably skillful in repartee and so dexterous a controversialist that he rarely failed to carry off the honors in discussions at medical meetings even when he was in the wrong. Tait enjoyed nothing better than lampooning an adversary, especially one whom he considered worthy of his mettle. On one occasion his opponent was a well known surgeon who, as his colleagues well knew, had for years been combating the inroads of Father Time by the adroit use of hair dye. In discussing Mr Tait's paper the gentleman suggested that too much weight should not be given to his views because of the fact that he was known to be a man of very strong prejudices, whereupon Mr Tait instantly retorted that he had only one prejudice in the world and that was against a man who dyed his hair. This savage sally quite annihilated his opponent.

Mr Tait's animosity against some of his rivals was so great that it was hardly prudent to mention their names. On the one occasion of which I spoke to him of Spencer Wells he launched upon such a vehement outpouring of

barbed criticisms and acrid animadversions I never ventured to mention his name again.

During operations Mr Tait rarely spoke except to utter now and then a monosyllable or two by way of direction to a nurse or the anesthetist. At other times, however, when riding with him in his carriage, as I had often an opportunity to do, or when riding on the cars, Mr Tait was a genial and interesting conversationalist and had apparently an inexhaustible fund of information on any subject that might be broached. Although he did not finish his university course before beginning his study of medicine, his literary work during the early years of his residence in Birmingham as editorial writer for the *Morning Post* had led him into nearly every field of human interest. He had also been a student of biology under Darwin, whom he almost defied.

Mr Tait frequently attended the theater, which he greatly enjoyed, although he often fell asleep and sometimes snored so loudly as to create considerable disturbance. When not occupied he was in fact liable to fall asleep at any time. In riding up to London I have known him to sleep for almost the entire distance sitting bolt upright in a corner of the compartment and snoring loudly. On one such occasion when the customary fog happened to lift for a few moments, allowing the sun to illuminate his face, I managed to get a good kodak picture of him. Later he allowed me to take another picture as he was in the midst of a surgical operation, his face wearing the intense and rather savage look which it usually had while he was operating. He was very much amused when I presented him with the two pictures mounted on a card labeled "Wide Awake" and "Fast Asleep." This was his first introduction to the Eastman Kodak, then just out, and he became the possessor of one as soon as possible.

Tait was not spectacular in his methods of operating, but in his work he was remarkably quick, neat, accurate, and efficient. His hands were large, his fingers short and thick but remarkably deft. His precise, dextrous, and rapid movements in the performance of an operation was a fascinating spectacle—never a false movement, though he did some extraordinary things. For instance, if in making an incision a spurting artery made a pause necessary for the application of a ligature, he would often catch the handle of his knife between his teeth instead of handing it to an assistant or laying it down. He did everything himself. He rarely allowed the assistant to do anything more than to hold an artery forceps or to support a large tumor while he applied ligatures to the pedicle.

To the writer's knowledge, Tait has seldom been excelled in rapidity and dexterity. Dr "Jimmy" Wood, who was the star operator in Bellevue Hospital when I was a student there in the seventies, used to cut off legs in 30 seconds, and Liston sometimes amputated thighs in 20 seconds. Martin, the famous Berlin gynecologist, did a double salpingectomy in 8 minutes. I saw Tait do the same operation in $7\frac{1}{2}$ minutes. I often noted the time occupied in perineal operations and seldom found it more than 3 minutes, although McKay, who followed me in Tait's service, in his excellent biography makes his time for this operation 5 minutes. On one occasion I held my watch and saw Tait begin and complete an operation for partial laceration of the perineum in just $1\frac{1}{2}$ minutes.

His ordinary method of operating on patients at the Spark Hill Hospital was thus. With his coat off, sleeves rolled up, and wearing a big apron, he stepped to the side of the bed, seized the anesthetized patient, and placed her crosswise on the bed with her hips at the edge, a nurse holding each limb. With a pair of

tissue forceps in one hand and scissors in the other, he dropped upon his knees and with a few quick snips dissected the vaginal flap, made a deep cut on either side, seized a long handled Peaslee needle, and pulled through three or four silkworm gut sutures so placed as to secure good coaptation of the raw surfaces. The whole operation was over in little more time than it takes to describe it.

In operating, Tait always aimed to do as little as possible. His incisions were short, never more than 2 or 2.5 inches unless a larger incision was necessary to remove a growth. His aim was to make the incision just large enough to admit his two large fingers. He said he learned this from Baker Brown. He opened the abdomen a little at one side of the median line and took care to avoid dividing the fibers of the rectus muscle. This practice he learned from A. McKenzie Edwards, one of his teachers at Edinburgh.

He was bitterly opposed to the use of the spray which at that time was in great vogue. I got the impression that his opposition to the spray and to antiseptic methods was chiefly based on his dislike of Lord Lister and Spencer Wells. He even refused to allow an application of antiseptics of any sort to the putrefying hysterectomy stumps which were in those days treated extrapentoneally. As a result, the atmosphere of his wards very often closely resembled that of a slaughterhouse. When one day I asked him to allow me to apply iodoform or carbolic acid to lessen the odor of decaying flesh, he curtly replied, "No," and added "I cannot endure the smell of the stuff. I won't have it around." He did soon after begin the use of dry powdered boracic acid, insisting, however, that he used it only to keep the wound dry and not as an antiseptic.

Although Tait did not believe in antiseptics, he emphasized the necessity for cleanliness. This was perhaps his greatest contribu-

tion to surgery as he was really the father of surgical asepsis. He developed a technique which eliminated many of the perils of abdominal section and so materially reduced the mortality of this operation as to greatly enlarge its scope and enhance its usefulness. Men who followed his leadership in England, notably Greig Smith, Monahan and Mayo Robson, and in this country Joseph Price, Howard Kelly, and the Mayos, reduced the mortality rate to such a degree that the operation lost its terrors and soon came to head the list of major operations as a life saving procedure.

Though he opposed the Lister spray, Tait took the greatest care to keep his hands free from infection. If they became soiled at any time with an infectious fluid he refrained from operating for several days, having learned from experience that soap and water and even the use of the antiseptics then employed would not always insure safety. Rubber gloves were of course not in use in those days. Instruments and ligatures were boiled. Sponges after being soaked over night in a one per cent carbolic acid solution were squeezed put into a muslin bag, and hung up to dry. Only boiled water was used at operations.

At the time I was with him Mr. Tait boasted a record of 116 laparotomies with the same number of successive recoveries. The average mortality of the operation in this country at that time was, I believe, about 20 per cent. He attributed his success in ovariectomy to the adoption of Baker Brown's method of dropping the pedicle into the peritoneal cavity instead of treating it externally with the Spencer Wells clamp and introducing a drainage tube. Tait maintained that peritonitis was not likely to occur if the peritoneal cavity was kept dry.

Another reason for Tait's success was no doubt his radical and courageous departure

from the long established method of dealing with the bowels. As late as 1883, Tait still practiced restriction of bowel activity after ovariectomy, insisting that the bowels should be confined for from 10 days to 2 weeks after operation. A little later, however, he made a radical change in his management of the bowels. Before the operation, the patient was thoroughly purged with saline laxatives and starved for 48 hours. After operation, the bowels instead of being confined were moved by enema on the second morning. Thorough evacuation of the colon on the second morning after operation was a dominant feature of the after care of his patients. Drastic measures were used when necessary to secure an evacuation, and no food was given until after the bowels moved.

Tait would not administer anodynes of any sort so long as there was any hope of saving the patient. The patients sometimes suffered cruelly, but they rarely, if ever, received an anodyne drug of any sort unless they became moribund. He said "I never give any drug unless the patient is going to die."

When asked what should be done in cases of peritonitis following abdominal section, he replied "Nothing at all. The patient who has peritonitis after a surgical operation is certain to die. The time to cure peritonitis is before it begins. If the peritoneal cavity is kept well drained peritonitis will not occur. The important thing is to keep the peritoneal cavity free from stagnant fluids. I am not afraid of germs. They cannot grow without food."

The carbolic acid spray of Lister was conscientiously employed by Spencer Wells and his followers, but Tait achieved better results without the spray than others did with it employing otherwise the same technique. Undoubtedly, the abandonment of the Spencer Wells clamp and the use of the short sterile

ligature and the intraperitoneal treatment of the stump introduced by Baker Brown were the chief factors in reducing the mortality rate from the 23 per cent of Spencer Wells' first one thousand cases to less than 5 per cent in the hands of Tait, Bantock, Thornton, and Keith

Tait's views were strongly supported by the doctrine of intestinal toxæmia which Bouchard had recently brought out. Widal, Roux, and other French investigators had recently shown that in certain conditions, particularly stasis, the pathogenic bacteria always found in the colon may become highly virulent and capable of invading the blood stream and the tissues and producing pleurisy, peritonitis, hepatic abscess, pyelitis, and other grave conditions. Roux had produced peritonitis and abscesses with pure cultures of bacillus coli. Tait maintained that these organisms could not develop without a liquid culture medium, and so he not only introduced a drain in every case, but took care to prevent accumulation of liquid in the abdominal cavity by applying suction to the drainage tube at frequent intervals so as to keep the abdominal cavity as dry as possible.

Tait's departure from the orthodox method of dealing with the bowels before and after

laparotomy was doubtless one of his most important innovations. He led the way, however in numerous departures from established methods and in undertaking new surgical procedures which have enormously increased the scope of abdominal surgery.

Tait claimed that he was the first to perform the operation for removal of the ovaries and tubes for the cure of chronic pelvic inflammation. He was first to operate for the removal of gall stones, first to operate in cases of ruptured tubal pregnancy, and the first to remove the uterine appendages for the relief of bleeding fibroids.

With his great intelligence and broad knowledge, Mr. Tait unfortunately gave no attention to personal hygiene. He was a good deal of a gourmand. He possessed an extraordinarily vigorous stomach which made no protest notwithstanding the enormous quantities of foods and wines as well as stronger liquors which he consumed at dinner. His gross eating habits were doubtless responsible for his premature death at the age of 54 after having previously submitted to an operation for removal of renal calculus.

His last medical paper was entitled "The History of a Sore Kidney," his own

JOHN HARVEY KELLOGG

MOVING PICTURES IN MEDICINE

TO one acquainted with the history of medicine, the rapid development of pedagogic principles in undergraduate teaching has been a source of great interest and pleasure. We have rapidly divorced ourselves from the amphitheater clinic and have brought the student into closer contact with the patient. While graduate teaching has lagged somewhat, yet, even here we are searching diligently for the means of imparting to those detached from medical centers the advances

made in medical science, diagnosis, and treatment. This problem is a difficult one. In both groups the medical profession has eagerly seized upon any method that bids fair to increase the efficiency of teaching.

It was but natural that the moving pictures should be utilized for this purpose. It was also but natural that the early films should be those designed to depict some personal operative procedure produced in an inadequate way by the physician himself. Such pictures have their limitations, but were the logical first step

In the last few years the thinking teacher has realized that the moving picture presents great possibilities in illustrating certain principles of medical science in which it is advisable to combine in a succinct form anatomical structure and function, embryological development, physiological processes, etc. This method of teaching can be utilized to bring to the practitioner of medicine the newer developments of medical science, newer procedures in diagnosis and treatment, the anatomy, physiology, graphic presentations of symptomatology, and principles of treatment. It presents *them in a way that is readily understood and remembered by the busy practitioner*.

This phase of teaching is in its infancy. The addition of the talking voice in certain cases will add to the clarity of the presentation and serve to emphasize certain principles. The moving picture as such offers a great possibility for the dissemination of scientific knowledge, particularly if those producing them keep constantly in mind the principles upon

which such films should be constructed. The essential criteria should always be "Does the film teach sound, fundamental principles?"

At this stage, we should carefully avoid presenting controversial questions. If this be kept in mind and films are prepared to show the advances of medical science and are made available to the medical profession as a whole, it is probable that moving pictures will become one of the most valuable aids in the dissemination of medical knowledge. They can never replace the experience gained from personal contact with disease, nor can they supplant well established methods of teaching medicine, but as an adjunct to the present medical curriculum in schools and postgraduate study on the part of the practitioner, they should prove of inestimable value.

If such a method of medical instruction is to reach the highest level of efficiency, educational ideals and scientific accuracy must be maintained and photographic technique advanced constantly.

MASTER SURGEONS OF AMERICA

JOSEPH PANCOAST

JOSEPH PANCOAST, the son of John and Anne (Abbott) Pancoast, was born near Burlington, New Jersey, November 23, 1805. Nothing is known of his early education. In 1828, he graduated from the medical department of the University of Pennsylvania and immediately began the practice of medicine in Philadelphia, specializing in surgery.

In 1830, the Philadelphia Association for Medical Instruction was formed. This was a quiz organization which consisted at first of Drs. Parrish, Wood, S. G. Morton, John R. Barton, and Franklin Bache. Later Joseph Pancoast was connected with the organization. It was, however, short lived, for at the end of six years it disbanded.

The Philadelphia School of Anatomy was opened by Dr. James Valentine O'Brien Lawrance in 1820. He died in 1823 and the school passed into the hands of the gifted Dr. John D. Godman. In 1826 Godman went to Rutgers College as professor of anatomy and Dr. James Webster assumed charge of the school. Webster accepted in 1830 the chair of anatomy in the Geneva Medical College and in 1831 Joseph Pancoast, the fourth to take charge of this celebrated school, began his brilliant career as an anatomist and surgeon. On October 7, 1835, he was elected physician to the Philadelphia Hospital (Blockley), and soon after physician in chief to the Children's Hospital in the same institution, from 1838 to 1845 he was one of the visiting surgeons to the same hospital. In 1838 he was called to the chair of surgery in the Jefferson Medical College, made vacant by the retirement of Dr. George McClellan, and gave up his charge of the Philadelphia School of Anatomy.

During the seven years he was connected with the school of anatomy he devoted much time to study and writing. In 1831 he translated Lobstein's *De nervi sympathici humani fabrica et morbis*, Paris, 1823. This treatise contains an account of the first case of Addison's disease on record, though it was not recognized as a distinct disease until Addison published, in 1855, his classical work on the diseases of the suprarenal capsules (Henry). Later he edited Manec's *Great Sympathetic Nerve* and his *Cerebrospinal System in Man* and fitly closed his career in the school of anatomy by editing, in 1838, a new edition of Wistar and Horner's *Anatomy*, to

which he added numerous notes, chiefly histological. This he still further re-modeled in 1842 and again in 1846. For years this was the text used by the students at the Jefferson Medical College until it was supplanted by the excellent manual of Erasmus Wilson which eventually gave way to the familiar "Gray." In 1844 he published his *Treatise on Operative Surgery*, which passed through three editions, the third appearing in 1852. He contributed numerous articles to the *American Journal of the Medical Sciences*, *American Medical Intelligence*, *Medical Examiner*, besides publishing many papers on surgical and pathological subjects, introductory lectures, and, in 1836 his well known *Professional Glances Abroad*.

In 1841 Pancoast was transferred from the chair of surgery to that of anatomy which he resigned in 1874, after having filled for 36 years two of the most important chairs in the Jefferson Medical School surgery and anatomy. In 1854 he was elected to the medical staff of the Pennsylvania Hospital and resigned in 1864. He was a member of his state county, and city medical societies, the American Medical Association, Academy of Natural Sciences, College of Physicians of Philadelphia, and of the American Philosophical Society.

Surgery is indebted to Pancoast for a number of new operations. He devised the plow and groove, or plastic suture, by means of which four raw surfaces, the bevelled edges of the flap, and the margins of the groove cut by the side of the nose, to receive the flaps come together. He used this suture in all his rhinoplastic operations with uniform success. He devised a fine needle turned near the point into a hook which he introduced just behind the cornea, through the anterior part of the vitreous humor, between the margin of the dilated iris and the lens. By means of this needle he was able to cut deeply the soft parts of the lens and withdraw along the line of entrance of the needle any hardened nucleus leaving the piece in the outer border of the vitreous humor. The operation was usually followed with little irritation.

For occlusion of the nasal duct in ordinary cases of epiphora he devised a small hollow ivory tube, from which the earthy matter had been removed, which he introduced from in front by a puncture of the lachrymal duct and left it to be slowly dissolved. In bad cases of internal strabismus he found that the tendon of the internal oblique muscle was often encircled by rigid connective tissue and it was only by drawing the tendon out by means of a blunt hook and dividing the tendon that the strabismus could be corrected. In the case of large abscesses lying between the colon and cæcum and in front of the quadratus lumborum muscle, he performed successfully a lumbar operation. By cutting the posterior muscles of the velum palate and dividing any attachment they might have made to the pharynx, he several times restored a voice that had previously been unintelligible.

In empyema he raised a semicircular flap over the ribs, and, puncturing the pleura near the base of the flap, introduced a short catheter down to the inner

end of the puncture and secured it with a string, thus forming a fistulous opening with the movable flap serving as a valve when the catheter was removed. In 1862, he performed, for the first time, division of the trunks of the fifth pair of nerves as they emerge from their foramina, at the base of the skull, as a cure for *tic douloureux*. He devised an abdominal tourniquet, in 1860, which, by compressing the lower end of the aorta, shut off the arterial blood from the lower limbs, thus preventing death from loss of blood in amputations at the hip joint or high up on the thigh. In cases of extroversion of the bladder he turned down cutaneous flaps from the abdomen and groin over the hollow raw surface of the open bladder. This operation was first performed by him in January, 1868.

"During the last fifteen years of his life writing had no charms for him, and when spoken to on the subject he said he thought he had done enough of that kind of work." Dr. Pancoast married in 1829, Rebecca, daughter of Timothy Adams, of Philadelphia. He died March 7, 1882, in the seventy seventh year of his age, "beloved and honored by all who knew him." THE GYNECOLOGY OF MERCATUS

THE beginning of the sixteenth century found Spain rapidly gaining a rather prominent position in the medical world. There were however many reasons why this position should be more of a medical than a surgical one and a glance over the conditions in Spain at this time will explain them. Spain through Columbus' discovery of America had become one of the greatest maritime nations of the world and also one of the richest. Sea service was that of peace and not of war. Her merchantmen sailed between Spain and the Indies which were presumed to be off the coast of Asia bent on missions of trade and commerce and the days of the Armada bringing sea warfare with them did not come until late in the century. Physicians to care for the health of the sailors and treat them if epidemics arose were much more needed than surgeons to care for wounds and because the doctors who followed the sea were being trained for the future duties required of them surgery was largely neglected.

The great new country which was being opened up abounded in a flora that was new to the medical profession and the pharmacists. As the knowledge of physiology and general hygiene was very meager great faith was placed in medicines and the ample supply of new flowers and herbs coming in from the Indies afforded the investigative members of the medical profession material to experiment with in an effort to find new drugs for various diseases. For example the medical department of the University of Alcalá which had been erected by Cardinal Jimenez de Cisneros the head of the Inquisition became greatly interested in this work and its physicians devoted themselves almost wholly to botany until it became one of the foremost schools in Europe along this line. Relations with other European countries were quite friendly. In the latter years of the fifteenth century the Moor had been driven out and so had the Jew, and those wars were over. With the adoption of her own Inquisition under Ferdinand Spain had obtained the right to settle her own religious questions without consultation with Rome and had thus withdrawn from the European political and religious wars which were raging constantly. The Pyrenees made her more or less inaccessible. The rebellion of the Netherlands was accomplished without much fighting and the war with France, which had never been very active

was concluded in 1559. The necessity for army surgeons under these conditions was not very great and the physicians were able to carry on the surgery necessary to peace time.

These factors helped to make surgery as a specialty unnecessary but there was in addition a positive factor which rendered its study and practice more or less dangerous. Surgery being founded upon anatomy ran counter to the ideas of the Church and Spain having founded its own inquisition which was hand in glove with the rulers delegated to the Inquisitors the absolute power over its inhabitants in the matter of heresy, Anatomy was thus almost unknown. In Guadalupe there was a school where dissection was permitted by special privilege from the Pope but for the greater part it was neglected. The great Vesalius who came to Spain as personal physician to King Philip II was said to have been unable to find a single skull in all of Madrid.

Medical men of parts were however fairly numerous. One of the most learned of these physicians was Luis Mercado more commonly known as Ludovicus Mercatus. He was born in Valladolid in 1520 and studied medicine at the University there. Later he became professor of medicine at his Alma Mater and in his old age was made emeritus. He likewise became physician to Philip II and after his death succeeded to the same position with the next King Philip III. He died in 1606 at the age of 86 years. Mercatus wrote a surgery which was published in 1594 and a treatise on dislocations and fractures which appeared after his death in 1625. His most popular work judging from the number of editions—seven—was his gynecology. It was first published in 1570 at Valladolid then at Venice Basle Madrid and Frankfurt and was included in the gynecological collection published in 1583.

The principal interest in this work centers in three chapters the seventeenth chapter of the first book entitled Concerning the Hard and Cancerous Tumors of the Breast and eighteenth and nineteenth chapters of the second book Concerning the Scirrhus Tumor of the Uterus and Concerning Cancer of the Uterus. In these he endeavors to point out the differentiation between benign and malignant tumors of these organs. His knowledge of the subject was considerable and is interesting as it shows a rather advanced point of view for this period.

REVIEWS OF NEW BOOKS

THOSE familiar with Dr Foote's *Minor Surgery*¹ do not need to be told the excellence of the present volume. They will however be interested to know that the clinical sections have been preceded by a concise, complete description of the principles of surgical technique and the operations of minor surgery by Dr Livingston. Dr Foote's lately adopted collaborator and that the senior author himself has preceded the sections on regional surgery with chapters on the general considerations of the different types of pathology—congenital defects and an omphalos, wounds, fractures, inflammations, infectious tumors etc. thus giving himself the opportunity of setting forth in one place the points applicable to the particular lesion wherever it may occur and freeing himself of the necessity of repeating them in each section.

With these additions the book emerges as an excellently arranged complete treatise on the principles and practice of minor surgery. The sequence of sections—technique, bandaging, general consideration of the types of pathology, and finally the regional sections, in which are set forth the details of diagnosis and treatment—could not be improved upon. It insures completeness, avoids repetition and facilitates reference.

For students the book is simple and fundamental, for practitioners and younger surgeons it provides easy reference and maintains the practical point of view. Whatever in bacteriology, pathology or other theory is important in diagnosis or treatment is brought out in its proper place and its proper proportion. Treatment is described in sufficient detail so that it can be followed.

The style of both authors is excellent. One is not pained as he is so often by medical texts by grammatical inaccuracies and awkward diction. It is simple, terse and epigrammatic. The elucidation of principles and the bringing home of points by quotations from the masters adds greatly to its effectiveness.

J R H

THE little book by Professor Naegeli² is an effort to teach an introduction to surgery chiefly by means of pictures. It is based upon the premise which is stated by Professor Garre in the introduction as follows:

General experience and experimental psychology indicate that pictorial illustration is superior to any other didactic method for the purpose of retaining facts in the memory and turning them to practical use.

¹PRINCIPLES AND PRACTICE OF MINOR SURGERY. A TEXTBOOK FOR STUDENTS AND PRACTITIONERS. By Edward Milton Foote, A.M. M.D. and Edward Merkin Livingston, B.Sc., M.D. 6th ed. New York and London: D. Appleton and Company, 1929.

²A GRAMMATIC GUIDE TO ELEMENTARY SURGERY. By Prof. Dr. Th. Naegeli. Translated by J. S. Wm. M.D. M.K.C.P. Introduction by Dr. C. Garre. New York: William Wood and Company, 1929.

The reviewer quite agrees with this general principle but is disposed to criticize the manner in which Professor Naegeli has carried it out. If as the author states the book is to serve as an introduction to surgery, it should limit itself to elementary subjects and should not include reference to gunshot wounds of the intestine, strangulation of the bowel, rupture of the spleen, tuberculosis of the spine, surgery of malignant growths, biliary calculi and so on.

While many of the diagrams are interesting and even striking, the treatment of the subject would seem to be almost too elementary for the medical student or practitioner but more suitable as an informational treatise to the laity. F C

MINOR surgery represents a very extensive and important field yet there is little question but that in our didactic and clinical teaching of the undergraduate too little attention is devoted to the "minor operation." Gastro enterostomy or her motomy intrigue the student or interne more than the treatment of a felon or the removal of a sebaceous cyst yet repeatedly we encounter men who after an excellent interne service are incompetent at such procedures.

The scheme evolved by Christopher in his *Minor Surgery*³ is logical and interesting. It covers the scope of minor surgery after a method that parallels the plan of a well organized text of general surgery. The first seven chapters cover such general topics as wounds, foreign bodies, furuncles, carbuncles, burns and gangrene. The remainder of the text is a regional minor surgery. Beginning with the head, injuries, infections, tumors and deformities are considered. The same general scheme is used to cover neck, trunk, extremities, anus, rectum and genitalia.

There are literally hosts of texts devoted to minor surgery. "Manuals" volumes on "surgical handicraft" etc. A large percentage of these are of little value. Either the author aims at brevity and compactness ruins his book, or he makes the fatal error of including too many procedures that may best be left to the domain of major surgery.

Christopher has given us an excellent book on minor surgery. It is beautifully written, the text is profusely and well illustrated. It should be of particular value to the man in a community remote from hospital centers where he cannot easily obtain advice and consultation on many of the so called 'minor' but important, surgical lesions.

J R. BUCHMINDER

RECENT years have found an ever increasing interest in matters of health. Physicians are anxiously striving to educate the people through

³MINOR SURGERY. By Frederick Christopher, M.D. F.A.C.S. Foreword by Al. B. Kassel, M.D., F.A.C.S. Philadelphia and London: W. B. Saunders Co. 1929.

books, magazines and newspapers while the latter in turn are always searching for material that they can understand. The facts concerning disease are hard to comprehend without some knowledge of the normal action of the human organs and the changes that take place in the organs as a result of disease.

Before reading such books as are written for the public concerning the various diseases one would do well first to become familiar with the ways in which man in the past has recognized and struggled against the diseases that have caused him suffering and contributed to the shortening of his days. With such a background in the history of medicine the nature of disease will become more clear, and the mental response to it more normal.

Medical histories like medical textbooks have been prepared almost exclusively for the use of physicians and others with scientific training. Now we have a book by Dr. Richard H. Hoffmann, called "The Struggle for Health," that has been written in clear simple and understandable language. The book is planned about the lives of the great men who have stood out because of their contributions and discoveries that have cheered and aided men in their struggle toward the goal of health.

Modern times find us making progress in the conquest of disease more rapidly than ever before. Our rapid strides now are in large part made possible by the work that has gone on before. It is a duty as well as a need, for all to acquaint themselves with the battle the great men who have gone before us have waged in the interests of mankind. And I know of a no more pleasant way of acquiring this knowledge than by recourse to the book by Doctor Hoffmann.

H. B.

THE fifth volume* of the Oxford Monographs on *Diagnosis and Treatment* again covers its field in an authoritative helpful manner. General methods of treatment including heliotherapy are accurately and explicitly described in a preliminary section. The X-ray picture of the normal chest is given in detail. The volume contains in addition over 150 skiagrams of pathological conditions of chests. These are large sized and are reproduced with remarkable faithfulness thus making the work a valuable fund of information in regard to roentgen studies of the chest. Because of the author's close contact with the bronchoscopic work of Chevalier Jackson this form of diagnosis and treatment is stressed. Pneumography by lipiodol injection is discussed. One fourth of the work is devoted to pulmonary tuberculosis. The general subject of pulmonary accidents, parasitic diseases, and in-

fections of the lung and pleura is thoroughly covered. This work is a valuable compendium for the practical man.

PAUL STARR

As dogmatic with his opinions as he is prolific in his writings Victor Fauchet and his collaborators have given us an excellent résumé of their experience with the mooted treatment of gastric and duodenal ulcers. "Gastrectomy is in principle the only rational form of treatment for gastric and duodenal ulcers. Only through gastric resection will the patient be cured and protected against relapses or late complications." This is Fauchet's opening statement but he admits that there is much divergence of opinion because as he truly states "We do not yet know what an ulcer is, what is its nature, pathogenesis or its immediate exciting etiology." He finds clinically that chronic colic stasis, appendicitis, cholecystitis, epiploitis, and inflammatory bands usually co-exist with gastric or duodenal ulcers. He also believes that a "genuine ulcer" exists in the presence of hyperchlorhydria and that nothing short of a sufficiently large gastrectomy to remove completely all of the pyloric glands will stop this hyperacidity. Fauchet summarizes his operative indications as follows: In duodenal ulcers (1) with normal or hypo acidity—gastro-enterostomy with invagination or excision of the ulcer (2) with hyperacidity or hemorrhage—duodeno-gastric or simple gastric resection. In gastric ulcers (1) with hyperacidity—gastro-pyloric resection and gastro-enterostomy (2) with normal or hypo acidity—gastro-pyloric resection in order to avoid possible secondary cancer.

The chapter on pre-operative care of the patient is detailed to the point of futility. How removal of tartar from the teeth or painting the gums with tincture of iodine can prevent pulmonary complications is hard to grasp. One cannot but applaud his physiologic statement that any pre-operative purgation should be discouraged. At present 92 per cent of ulcer patients in Fauchet's clinic are operated upon under regional anesthesia (abdominal wall and splanchnics). Simple excision of the ulcer is condemned and Balfour's cauterization is rarely used. The Pean (Billroth No. 1) technique is adopted in 15 per cent and the Polya in 85 per cent of his cases. The chapters devoted to perforating ulcers is excellent. Post-operative complications and their treatment are fully covered. Chapter VII deals with Fauchet's operative statistics at St. Michel's hospital and analyses of 517 gastro-duodenal operations with a total mortality of 8.7 per cent in the past 2 years improved technique and better selection of the type of operation suitable to a given case has reduced the mortality to 6 per cent. The monograph is filled with valuable information and detailed methods of overcoming abnormal anatomical difficulties.

PLANNING FOR THE 1930 CLINICAL CONGRESS IN PHILADELPHIA

THE surgeons of Philadelphia, under the leadership of a strong and representative committee, are developing a highly attractive program of clinics and demonstrations for the entertainment of Fellows of the College and their guests at the twentieth annual Clinical Congress of the American College of Surgeons to be held in that city, October 13-17, 1930. All departments of surgery—general surgery, gynecology, obstetrics, orthopedics, urology, and surgery of the eye, ear, nose, throat and mouth—will be represented in this program.

Clinics and demonstrations will be given at the following hospitals: American Oncologic, American Stomach, Babies, Chestnut Hill, Children's, Children's Homeopathic, Cooper (Camden, N. J.), Evans Dental Institute, Episcopal, Frankford, Germantown Graduate, Hahnemann, Jeanes, Jefferson Jewish, Kensington, Lankenau, Methodist Episcopal, Misericordia, Mt. Sinai, Northeastern, Northwestern General, Orthopedic, Pennsylvania, Philadelphia General, Presbyterian, St. Agnes, St. Christopher's, St. Joseph's, St. Luke's, St. Mary's, Samaritan, Stetson University, U. S. Naval, Wills Eye, Woman's Homeopathic, Woman's Medical College, Woman's Southern Homeopathic. The clinical program will also include demonstrations in the laboratories of the medical schools: Jefferson Medical College, University of Pennsylvania, Temple University, Woman's Medical College.

Operative clinics and demonstrations in the hospitals are scheduled for Monday afternoon at 2 o'clock and for the mornings and afternoons of

each of the following four days. A preliminary clinical program is to be published in the next issue of *SURGERY, GYNECOLOGY AND OBSTETRICS*.

The subcommittee in charge of the section on surgery of the eye, ear, nose and throat will arrange for a series of clinical demonstrations to be held at headquarters each morning, except Monday, in addition to the clinics in those specialties at the hospitals each afternoon.

Programs for a series of evening meetings are being prepared by the Executive Committee of the Congress. At the Presidential Meeting on Monday evening the president elect, Dr. C. Jeff Miller of New Orleans, will be inaugurated and deliver the annual address. Another feature of that meeting will be the annual Murphy oration in surgery. For the scientific meetings on Tuesday, Wednesday and Thursday evenings, eminent surgeons of the United States and Canada with distinguished guests from abroad have been invited to present papers dealing with surgical subjects of present day importance. At the annual convocation of the College on Friday evening, the 1930 class of candidates for fellowship in the College will be received.

The Congress opens at 10 o'clock on Monday morning with the annual hospital conference in the grand ballroom of the Bellevue Stratford Hotel. An interesting program of papers, round table conferences and practical demonstrations dealing with problems related to hospital efficiency is being prepared. The hospital conference, which will continue on Tuesday and Wednesday, is planned to interest surgeons, hospital trustees,

books, magazines and newspapers while the latter in turn are always searching for material that they can understand. The facts concerning disease are hard to comprehend without some knowledge of the normal action of the human organs and the changes that take place in the organs as a result of disease.

Before reading such books as are written for the public concerning the various diseases one would do well first to become familiar with the ways in which man in the past has recognized and struggled against the diseases that have caused him suffering and contributed to the shortening of his days. THE REDISTRIBUTION OF RESPIRATION FOLLOWING PARALYSIS OF THE HEMIADIAPHRAGM

JEROME K. HEAD, M.D., CHICAGO

From the Surgical Research Laboratory of the Research and Educational Hospital of the University of Illinois

INDUCTION of paralysis of the hemidiaphragm has become a standard procedure in the treatment of unilateral pulmonary tuberculosis. It is supposed to, and in many instances does, promote healing by decreasing the size of the pleural cavity and by curtailing the respiratory motion of the homolateral lung. It is a means of inducing local rest and collapse. Most logical and most efficacious in basal lesions, it not infrequently produces improvement or even healing of apical disease. That it should do this is explainable upon the basis that practically all of the expansion of the lung in a vertical direction, even of the apex, is dependent upon the descent of the diaphragm.

The results following the operation are far from uniform. Some cases are cured, some improved, many unimproved, and others are made worse. In any given case it is difficult to say what the result of the operation will be. For these reasons it has seemed worth while to investigate the effect of paralysis of the hemidiaphragm upon the distribution of respiration and to seek some explanation of the variable results.

It is an obvious fact that when one half of the diaphragm is thrown out of action the portion of pulmonary aeration which this formerly accounted for must be made up either by an increased respiratory rate or by a greater expansion of some or all of the remain-

ing thoracic parietes. The tidal respiration must remain constant. Observations upon humans and animals have shown that there is no increase in the rate of respiration. It can be stated, therefore, that paralysis of the hemidiaphragm produces a redistribution of the burden of respiration and that while the movement of certain lung areas may be curtailed that of others is increased. It is of the utmost importance to know the exact nature of this redistribution.

Were there no local mechanical factors which tended to throw a greater proportion of the burden of compensation upon certain lung areas, one could assume that the respiratory center would distribute it equally by causing a greater movement of all of the remaining thoracic parietes. That there are such local factors has, however, long been recognized. In this paper I wish to point out what these are, what is their result, and how variations of pathology can alter and modify them.

HISTORY

Galen observed that contraction of the diaphragm produced an upward movement of the ribs to which it was attached. This conception persisted until Borelli, from experiments on animals and from mechanical considerations, advanced the theory that its contraction tended to constrict the lower thorax and so to depress the lower ribs. In 1833 Duchenne

executives and personnel generally, and an invitation to attend this conference is extended to all persons interested in the hospital field

Other features of importance for which programs are now being prepared include a symposium on cancer and an all day conference on traumatic surgery at which leaders in industry, education and labor together with representatives of insurance companies, surgeons and hospital administrators will participate

General headquarters for the Congress will be established at the Bellevue Stratford Hotel, corner of Broad and Walnut Streets, where the grand ballroom and other large rooms on the second floor, together with additional rooms on the roof have been reserved for the use of the Congress for scientific meetings, conferences, film exhibitions, registration and ticket bureaus, bulletin boards, executive offices, technical exhibition, etc

In recent years a number of fine large hotels have been built in Philadelphia so that there are now ample first-class hotel facilities available for all who will attend

An application for reduced railway fares on account of the meeting in Philadelphia is before the railway traffic associations, and it seems assured that a rate of one and one half the regular first class one way fare will be in effect from all points in the United States and Canada

LIMITED ATTENDANCE

Attendance at the Philadelphia session will be limited to a number that can be comfortably accommodated at the clinics, the limit of attendance being based upon the result of a survey of the amphitheaters, operating rooms, and laboratories in the hospitals and medical schools to determine their capacity for accommodating visitors. Under this plan it will be necessary for those who wish to attend to register in advance

Attendance at all clinics and demonstrations will be controlled by means of special clinic tickets, which plan provides an efficient means for the distribution of the visiting surgeons among the several clinics, and insures against overcrowding as the number of tickets issued for any clinic will be limited to the capacity of the room in which that clinic will be given

A registration fee of \$3.00 is required of each surgeon attending the annual Clinical Congress, such fees providing the funds with which to meet the expenses of the meeting. To each surgeon registering in advance a formal receipt for the registration fee is issued which receipt is to be exchanged for a general admission card upon his registration at headquarters. This card, which is non transferable, must be presented in order to secure clinic tickets and admission to the evening meetings

Fig 1 The upper tracing represents the movements of the left the lower those of the right costal margin. At the point X the right phrenic nerve was severed. There followed immediately an increase in the excursion of the right costal margin a decrease in that of the left. Continuous stimulation of the distal end of the severed right phrenic nerve produced a decreased excursion of the right costal margin. On the left both the inspiratory and expiratory levels were raised. Brief stimulation of the nerve during each inspiration produced a decrease in the excursion on the homolateral side—an increase on that opposite.

its insertion in the central tendon. It is maintained in its dome like shape by the negative intrapleural pressure, the pericardial ligaments, the positive intra abdominal pressure and the support of the abdominal viscera. For a considerable distance above its origin its upper surface coheres to the thoracic wall. Neither its origin nor its insertion are fixed points. Contracting thus around an arc in what direction it exerts its force upon the ribs to which it is attached must depend upon the ratio between the height and the breadth of the arch. The higher the dome the more will the pull be upward, the lower the more medianward. At the beginning of inspiration the upward pull must be at its maximum. As respiration proceeds and the ribs rise and the dome descends the median pull must increase proportionately. Resistance to the descent of the dome is thus an obvious factor in increasing the upward pull. On the other hand the cohesion of the upper surface of the diaphragm to the thoracic wall tends to raise the origin of the ribs and so to increase the tendency to a medianward pull. That the pulling apart of these coherent surfaces exerts a definite pull in this direction is evidenced by the phenomenon known as Lytton's sign, the sinking in of the intercostal spaces as the diaphragm is pulled away from them. Another factor to be

considered is that the direction in which a rib will move under application of a force at a certain point is dependent not upon the direction of application at that point but upon the relation of this direction to the axis of the rib which runs through its two attachments to the vertebra.

One is thus confronted with a number of incommensurable factors. From the theoretical consideration one can say that contraction of the diaphragm may tend either to raise or to depress the ribs to which it is attached that it may act to raise them at the beginning of inspiration to lower them at the end, or that in individuals with narrow thoraces and high diaphragms it may tend to raise them while in those with broad thoraces and flat diaphragms it may tend to lower them.

From observations of thoracic movements in normal individuals Lytton's sign is the only thing that indicates in which direction the force is exerted and this is not conclusive evidence. In most individuals the lower ribs move upward on inspiration but whether this is aided or hindered by contraction of the diaphragm cannot be determined. The inspiratory descent of the lower ribs seen in asthma and other conditions associated with flattening of the diaphragm and increased diaphragmatic action indicates that in these conditions

published the results of numerous experiments on dogs, horses and humans which contradicted the work of Borelli and confirmed the earlier conception of Galen. Duchenne found that in the intact animal stimulation of one phrenic nerve with the galvanic current caused an increased upward movement of the ribs on the stimulated side and that section of the nerve caused a corresponding decrease, but that opening of the abdomen and evisceration produced a reversal of the results. From this he concluded that normally the resistance offered to the descent of the diaphragm by the abdominal viscera, especially the liver, tended to hold up the dome and serve as a fixed point toward which the ribs were lifted as the muscle shortened. Duchenne's experiments were so convincing that for 60 years his conclusions were not disputed. Although Gerhardt maintained that in certain pathological conditions in which the diaphragm was flattened its contraction drew downward the lower ribs it was not until recently (1913) that Hoover seriously questioned the work of Duchenne and presented a mass of clinical and experimental observations in support of the earlier conception of Borelli.

The essence of Hoover's conclusions is that the contracting diaphragm exerts a medianward rather than an upward pull upon the lower ribs and consequently acts as an antagonist of the muscles tending to elevate and spread them. He observed repeatedly in human beings and dogs that paralysis of the hemidiaphragm was followed by an increased upward and outward movement of the lower ribs on the affected side and a widening of the subcostal angle. Stimulation of the nerve caused a narrowing of the lower thorax except in the exceptional instance in the dog where the subcostal angle was very small and the diaphragmatic arch high.

More recently Lemon has stated that neither in dogs nor humans has he been able to observe that section of the phrenic nerve made any change in costal breathing.

In 1926 Roith stated that following paralysis of the hemidiaphragm in the human there was an increased movement of all of the ribs on the affected side. Roith advised section of the upper intercostal nerves to counteract this

in instances in which paralysis of the diaphragm was induced in the treatment of apical pulmonary tuberculosis.

Schnippenkotter, working on the cat, found the intrapleural tension at the base on the affected side the same as on the sound side. At the apex there was a greater excursion on the affected side. He noted also an increased excursion of the ribs on the side on which the diaphragm had been paralyzed and a hypertrophy of the intercostal musculature.

Paralysis of the hemidiaphragm in the human is followed by an increased movement of the ribs on the homolateral side. Observation of 200 patients who have undergone the operation of phrenic exeresis has shown that in the majority there is an increased outward and upward movement of the lower ribs on the affected side and always, unless pulmonary disease has greatly contracted the upper thorax, an increased movement of the upper ribs. Thus costal breathing is increased throughout the affected side. Observation of these cases has also shown that this accentuation of upper costal breathing occurs even when basal adhesions or atelectasis prevent it in the lower thorax, thus indicating that the greater movement of these ribs is independent of that of the lower ones and that it is not merely that they are relieved of the normal resistance of the pull of the diaphragm.

It remains to consider why this occurs. The following mechanical factors can be conceived of as contributing to it: (1) removal of the force of the contracting diaphragm from the ribs to which it is attached; (2) changes in the intrapleural pressure; (3) changes in the intra-abdominal pressure; and (4) increased elasticity of the partially collapsed lung.

The effect of the contracting diaphragm upon the ribs to which it is attached. What direct effect the contraction of the diaphragm has upon the ribs to which it is attached is uncertain. As we have seen it has been maintained that it raised them, that it tended to depress them, and that it made no change in their movement. From a theoretical point of view the problem presents itself as follows: The diaphragm arising from the six lower ribs, the lumbar vertebra and the ensiform cartilage arches upward and medianward to

Fig. 1 The upper tracing represents the movements of the left the lower those of the right costal margin. At the point X the right phrenic nerve was severed. There followed immediately an increase in the excursion of the right costal margin a decrease in that of the left. Continuous stimulation of the distal end of the severed right phrenic nerve produced a decreased excursion of the right costal margin. On the left both the inspiratory and expiratory levels were raised. Brief stimulation of the nerve during each inspiration produced a decrease in the excursion on the homolateral side—an increase on that opposite.

its insertion in the central tendon. It is maintained in its dome like shape by the negative intrapleural pressure, the pericardial ligaments, the positive intra abdominal pressure and the support of the abdominal viscera. For a considerable distance above its origin its upper surface coheres to the thoracic wall. Neither its origin nor its insertion are fixed points. Contracting thus around an arc in what direction it exerts its force upon the ribs to which it is attached must depend upon the ratio between the height and the breadth of the arch. The higher the dome the more will the pull be upward, the lower the more medianward. At the beginning of inspiration the upward pull must be at its maximum. As inspiration proceeds and the ribs rise and the dome descends the median pull must increase proportionately. Resistance to the descent of the dome is thus an obvious factor in increasing the upward pull. On the other hand, the cohesion of the upper surface of the diaphragm to the thoracic wall tends to raise the origin from the ribs and so to increase the tendency to a medianward pull. That the pulling apart of these coherent surfaces exerts a definite pull in this direction is evidenced by the phenomenon known as Lytton's sign—the sinking in of the intercostal spaces as the diaphragm is pulled away from them. Another factor to be

considered is that the direction in which a rib will move under application of a force at a certain point is dependent, not upon the direction of application at that point but upon the relation of this direction to the axis of the rib which runs through its two attachments to the vertebra.

One is thus confronted with a number of incommensurable factors. From the theoretical consideration one can say that contraction of the diaphragm may tend either to raise or to depress the ribs to which it is attached, that it may act to raise them at the beginning of inspiration to lower them at the end or that in individuals with narrow thoraces and high diaphragms it may tend to raise them while in those with broad thoraces and flat diaphragms it may tend to lower them.

From observations of thoracic movements in normal individuals Lytton's sign is the only thing that indicates in which direction the force is exerted and this is not conclusive evidence. In most individuals the lower ribs move upward on inspiration but whether this is aided or hindered by contraction of the diaphragm cannot be determined. The inspiratory descent of the lower ribs seen in asthma and other conditions associated with flattening of the diaphragm and increased diaphragmatic action indicates that in these conditions

Fig. 2 The upper tracing represents the movements of the right costal margin. The lower those of the left. The arrow indicates the point at which the right phrenic nerve was cut. There followed immediately a decrease in the excursion of the right costal margin.

the diaphragm exerts a downward pull upon the ribs and that this pull is sufficient to overcome the force of the muscles tending to raise them.

Hoover has noted also that conditions tending to raise or hold up one half of the diaphragm such as subdiaphragmatic abscess, are associated with an increased upward movement of the lower ribs on the affected side. Adhesions between the diaphragm and the chest wall have an opposite effect, and I have recently seen a case in which this was so marked on the right side that there was a true paradoxical movement of the lower thorax—the right side moving medianward as the left expanded.

These observations allow one to conclude that when the dome of the diaphragm is lowered or the costal origin of the fibers elevated by adhesions its contraction exerts a medianward pull upon the lower ribs sufficient to overcome the force of the muscles tending to raise them. It allows of no conclusion as to the effect of the contraction under normal conditions but tends to substantiate what was suggested by the theoretical consideration, that the medianward pull increases with the depth of respiration as the dome is lowered and the ribs raised. It must be borne in mind that the actual upward movement of the ribs may be in spite of an antagonistic pull of the diaphragm rather than because of an upward one.

ANIMAL EXPERIMENTS

Experiments performed upon dogs have substantiated the findings of Hoover. In animals with broad thoraces and wide subcostal angles, section of the phrenic nerve is followed by an increase in the outward and upward movement of the ribs to which the diaphragm is attached. During stimulation of the distal end of the severed nerve they are drawn downward and medianward (see protocol 1).

In dogs with narrow thoraces and high diaphragmatic arches section of the phrenic nerve is followed by a decrease in the upward and outward movement of the ribs to which the diaphragm is attached. Stimulation of the distal end of the severed nerve produces a brief initial elevation of the ribs and then as the contraction of the diaphragm proceeds a marked downward and medianward movement (see protocol 2).

If adhesions are produced between the diaphragm and the thoracic wall the inspiratory movement of the lower ribs and to a certain extent of the whole hemithorax is markedly reduced. Under these conditions section of the phrenic nerve is followed by a marked increase in the movement of the ribs (see protocol 3).

In the human adhesions between the diaphragm and the chest wall limit markedly the movement of the ribs on the affected side. When such adhesions are present section of

the phrenic nerve is followed by a marked increase in the movement of the ribs, especially of those to which the diaphragm is attached (see protocols 4 and 5)

The effect of paralysis of the hemidiaphragm upon the intra abdominal pressure It seemed conceivable that an inspiratory increase in intra abdominal pressure could force outward the lower ribs if they were unprotected from it by a contracting diaphragm. The tracings shown in protocol 6 demonstrate that following paralysis of the hemidiaphragm the intra abdominal pressure becomes slightly negative on inspiration slightly positive on expiration, the reverse of what obtains under normal conditions. This inspiratory negative intra abdominal pressure is slight not sufficient to break the coherence between the diaphragm and the chest wall and while it certainly restricts the upward and outward movement of the lower ribs is too small to be of much importance.

The rôle of the intrapleural pressure In humans, as has already been noted, paralysis of the hemidiaphragm is followed by an increased upward and outward movement not only of the ribs to which it is attached, but of those of the whole hemithorax. One would conclude that the greater movement of the upper ribs was because of the removal of the drag of those to which the diaphragm is attached were it not that the increased movement of the former occurs even when local mechanical factors prevent a freer excursion of the latter. Some other factor than the removal of the direct antagonism of the diaphragm must be sought to account for this phenomenon. This factor is I believe the effect of the absence of the contracting diaphragm upon the intrapleural pressure.

If a dog's spinal cord be severed in the lower cervical region paralyzing the intercostal musculature and leaving the diaphragm functioning on each inspiration as the diaphragm descends, the ribs are drawn forcibly downward and medianward. They move paradoxically in relation to the diaphragm. This motion is markedly decreased if the pleural cavity is opened widely. This indicates that the paradoxical movement of the ribs is produced by the lowering of the intrapleural pressure

Fig. 3. The upper tracing represents the movements of the left costal margin the lower those of the right. The right phrenic nerve had been severed. Inspiratory stimulation of the distal end of the severed nerve produced a marked increase in the excursion of both costal margins. Continuous stimulation produced a decrease in the excursion of the right costal margin and an elevation of both the inspiratory and expiratory levels on the left.

incident to the descent of the diaphragm. The diaphragm sucks the ribs inward. In normal breathing the decrease in pressure caused by diaphragmatic descent similarly opposes the elevation of the ribs. The muscles raising them are, however, sufficiently strong to overcome this force and their action in turn, by lowering the intrapleural pressure, opposes the descent of the diaphragm. Through the medium of the intrapleural pressure, the diaphragm and the muscles acting to elevate the ribs are therefore direct antagonists. If one is paralyzed the other can act more freely. There is thus a balance between the two sets of muscles and a purely mechanical basis for compensation of the failure of either one.

It has been repeatedly observed that restriction of movement of the ribs on one side of the thorax is followed by increased action of the corresponding hemidiaphragm. It seems reasonable to believe that the explanation offered above accounts for this and also for the increased action of the ribs when the diaphragm is paralyzed.

In this connection one is again confronted with the problem of the effectiveness of the mediastinum as a partition between the two pleural cavities. If pressure changes are transmitted through it from one pleural cavity to the other, paralysis of one half of the diaphragm would affect the movement of the ribs of the opposite hemithorax as much as of those on the same side. In the dog in which the mediastinum is excessively mobile, this

Fig. 4. The upper tracing shows the respiratory excursions of the left hemithorax the lower those of the right which had been restricted by the production of adhesions between the diaphragm and the chest wall. At the point X the right phrenic nerve was cut. This was followed immediately by a marked increase in the excursion of this side of the thorax.

occurs (see protocol 7). In the human the greater movement of the homolateral side presupposes a difference of pressure in the two cavities, a condition favored by fixation of the mediastinum by disease.

EXPERIMENTAL EVIDENCE

In the dog section of one phrenic nerve is followed by an increased excursion of the upper ribs of both hemithoraces. Stimulation of the distal end of the severed nerve produces a marked decrease in the excursion of these ribs (see protocol 7).

In the dog section of one phrenic nerve is followed by a rise in pressure in both pleural cavities (see protocol 8).

In the human it has been feasible to test this only in instances in which the paralysis was induced as an adjunct to artificial pneumothorax, and so only on the affected side. In these cases extraction of the nerve was followed by a rise in intrapleural pressure of about 3 centimeters of water. The range of pressure between inspiration and expiration was decreased by 1 centimeter of water (see protocol 9).

To explain the increased excursion of the upper ribs on the homolateral side in humans

on the basis of this change in intrapleural pressure and the removal of this antagonistic action of the diaphragm one must assume that in the human the mediastinum is a much more effective partition between the two pleural cavities than it is in the dog and that the pressure change is limited to a great extent to the homolateral pleural cavity.

CONCLUSIONS

1. In man paralysis of the hemidiaphragm is followed by an increased respiratory excursion of the ribs of the homolateral hemithorax.

2. The intrapleural pressure on the homolateral side is raised by approximately 3 centimeters of water and the range of excursion is decreased by 1 centimeter of water.

3. In dogs with broad thoraces and low diaphragmatic arches the diaphragm in all phases of respiration is a direct antagonist of the muscles tending to elevate and spread the ribs to which it is attached.

4. In dogs with narrow thoraces and high diaphragmatic arches contraction of the diaphragm first tends to elevate the ribs to which it is attached but as the ribs rise and the dome descends the direction of its pull becomes more transverse and it opposes the action of

Fig 5 The upper tracing represents the movements of the left third rib the lower those of the right. The arrow indicates the point at which the right phrenic nerve was severed. There followed immediately an increase in the excursion of the ribs on both sides.

the muscles tending to elevate and spread the ribs.

5 In dogs paralysis of the hemidiaphragm is followed by an increased respiratory excursion of the upper ribs of both hemithoraces and by a rise in pressure in both pleural cavities.

6 This increased excursion of the upper ribs is explainable upon the basis that normally the contraction of the diaphragm by lowering the intrapleural pressure opposes the inspiratory elevation of the ribs. Paralysis of one half of it allows them to move more freely.

7 That in the dog the change is noted in the ribs of both sides of the thorax while in the human it is limited to those of the homolateral side can be explained upon the basis that in the human the mediastinum is a more effective partition between the pleural cavities than in the dog and tends to limit the pressure changes to the single pleural cavity.

8 In both man and the dog high adhesions between the diaphragm and the chest wall increase the advantage of the diaphragm as an antagonist of the muscles tending to elevate and spread the ribs and limit markedly their excursion and also the descent of the diaphragm.

9 In the presence of such adhesions induction of paralysis of the hemidiaphragm is fol-

Fig 6 Stimulation of the distal end of the severed right phrenic nerve produced a marked decrease in the movement of the third ribs on both sides.

lowed by an especially marked increase in excursion of the ribs on the affected side and in some cases by an increase in the total vital capacity.

10 Normally the intra abdominal pressure is negative on inspiration, positive on expiration. Following induction of paralysis of the hemidiaphragm it becomes positive on inspiration negative on expiration.

CLINICAL DEDUCTIONS

The observations mentioned, indicating as they do that paralysis of the hemidiaphragm is compensated for chiefly by an increased costal respiration on the homolateral side and so by a greater transverse and anteroposterior expansion of the homolateral lung and showing that this redistribution may be changed by various pathological factors, offer an explanation of the variable results following the operation of phrenic exeresis in the treatment of pulmonary tuberculosis and, by doing this suggest new indications and contra indications to the operation and the advisability of employing accessory procedures to govern the distribution of the compensation.

One can summarize these deductions as follows

Fig 7 Inspiratory stimulation of the distal end of the severed right phrenic nerve produced a decrease in the excursion of the third ribs on both sides

1 The operation is likely to be most efficacious in the treatment of basal lesions

2 When used in the presence of apical disease one would expect the best results in instances where fibrosis of the lung prevented an increased excursion of the ribs. In other instances the condition could conceivably be made worse

3 Where there are present adhesions between the diaphragm and the chest wall or basal fluid tending to lower the dome, the operation is followed by a great increase in costal respiration in the homolateral lung and in these cases one would anticipate the least beneficial the most harmful results

4 Whenever the operation of phrenico-exeresis is used in the treatment of unilateral pulmonary tuberculosis some accessory procedure should be carried out which has as its result a limitation of costal breathing on the affected side

5 If a procedure is used aiming to limit costal excursion the diaphragm should be paralyzed concurrently

Protocol 1 The effect of section and stimulation of the phrenic nerve upon the ribs to which the diaphragm is attached. Dog with broad thorax

Male dog of Spaniel type was operated upon under ether anesthesia drop method. Through a small incision low in the cervical region the right phrenic nerve was exposed and a thread run beneath it. The abdomen was then opened and after the normal functioning of both diaphragmatic halves had been verified was closed with silver clips.

The right and left lower costal margins were then exposed through small midaxillary incisions. Thread

Fig 8 The upper tracing represents the pressure in the right pleural cavity the middle that in the left and the lower the intra abdominal pressure. Section of the right phrenic nerve produced an increase in the pressure in both pleural cavities and an increase in the inspiratory negative pressure in the abdomen

were run from the costal margins downward above the dog's body over pulleys and were attached to muscle levers arranged to write one above the other on a revolving smoked drum. Upward movements of the ribs produced upstrokes of the levers and vice versa. The upper lever recorded the movements of the left costal margins the lower those of the right.

A normal tracing was taken (Fig 1). At the point where the right phrenic nerve was cut. This produced an increase in the excursion of the right costal margin—a decrease in that of the left. Continuous stimulation of the distal end of the severed nerve with the galvanic current produced a marked decrease in the excursion of the right costal margin. The excursion of the left costal margin remained the same but both the inspiratory and expiratory limits were elevated.

Brief stimulation of the nerve synchronously with each inspiration produced a decrease in the excursion of the right costal margin.

Following the experiment paralysis of the right hemidiaphragm was verified by opening the abdomen and observing it directly.

Protocol 2 The effect of section and stimulation of the phrenic nerve upon the movement of the ribs to which the diaphragm is attached. Dog with narrow thorax

Male dog of Collie type was operated upon under ether anesthesia.

The same experiment was carried out on this dog—one with a narrow thorax and a high diaphragmatic arch.

Section of the nerve produced a decrease in the excursion of the right costal margin (Fig 2).

Stimulation of the distal end of the severed nerve synchronously with each inspiration produced an increased excursion of the right costal margin.

Continuous stimulation of the nerve produced a brief initial increase in the excursion followed by a marked decrease (Fig 3).

Protocol 3 The effect of section of the phrenic nerve upon the movement of the ribs to which the diaphragm is attached in a dog in which there had been produced high adhesions between the diaphragm and the chest wall

Male police dog weight 10 kilograms was operated upon under ether anesthesia

Through an upper abdominal incision the right dome of the diaphragm was sutured to the chest wall at the level of the fourth rib in the midaxillary line. Three mattress sutures were passed through the diaphragm and the chest wall so that the free ends hung on the outside of the body and that each suture when tied surrounded a rib. The right phrenic nerve was exposed in the neck and the costochondral junction of the two sixth ribs were laid bare for the attachment of the recording apparatus. Threads were fastened to these two points and carried downward above the dog's body and over pulleys and attached to muscle levers in such a manner that an upward movement of the ribs would produce an upward movement of the levers and vice versa. The levers were adjusted to make tracings upon a revolving smoked paper. The upper lever recorded the movements of the left thorax, the lower those of the right. A normal tracing was taken (Fig. 4). This showed a marked limitation of movement of the hemithorax in which the adhesions had been produced. Following section of the right phrenic nerve the movement of the ribs on this side was immediately and greatly increased.

Protocol 4 The effect of section of the phrenic nerve upon the movement of the ribs in a man with adhesions between the left half of the diaphragm and the chest wall

Mr J. L., a single American laborer of 40 years came to the dispensary of the Research and Educational Hospital complaining of the usual symptoms of pulmonary tuberculosis of 2 years duration. A year before he had developed a pleurisy with effusion on the left which had been treated by repeated aspirations. Physical X-ray and sputum examinations confirmed the diagnosis of bilateral pulmonary tuberculosis. The roentgenogram showed high adhesions between the left diaphragm and the thoracic wall. Examination with the fluoroscope showed no descent of the left diaphragm. On physical examination it was found that movement of the ribs throughout the left thorax was markedly restricted and that on inspiration the lower ribs moved downward and inward paradoxically. He complained of inspiratory pain in this region.

On March 2, 1929 the left phrenic nerve was extracted. Observation of the respiratory movements after the operation revealed a marked increase in the movement throughout the affected side. The lower ribs now moved in the normal direction on inspiration and the pain which had been present previous to the operation had disappeared. There was little if any further elevation of the diaphragm.

Protocol 5 The effect of section of the left phrenic nerve upon the movement of the ribs in a man with

Fig. 9 Diagrammatic illustration of the effect of paralysis of the hemidiaphragm upon the intrapleural pressure in man. Before the operation the pressure ranged between 0 on expiration and -3 centimeters of water on inspiration. After the operation the expiratory level was raised to +2 centimeters of water and the inspiratory level to zero.

adhesions between the left half of the diaphragm and the chest wall

Mr J. C., a single American office worker 30 years of age entered the Research and Educational Hospital of the University of Illinois complaining of a draining sinus of the left axillary region. On the basis of clinical and roentgenological examinations a diagnosis of chronic empyema was made. Following a course of pulmonary irrigations he was operated upon and a cavity was found which was bounded below by the diaphragm and extended upward and posteriorly under the scapula. The ribs and intercostal tissues overlying it were resected and the wound packed. Healing progressed satisfactorily save that a small sinus persisted.

Six months later the sinus was still present and examination at this time showed that on inspiration the area of the old wound was drawn forcibly inward and downward that there was a paradoxical movement of the ribs of the entire lower thorax and that the movement of the upper ribs was markedly restricted. It seemed obvious that these phenomena were caused by the pull of the adherent diaphragm and that this continuous intermittent tug was a factor in preventing healing of the sinus. For this reason the left phrenic nerve was extracted. Following the operation the area of the wound was no longer pulled inward on inspiration and the movement of the upper ribs was markedly increased. The discharge from the sinus was decreased by 50 per cent. The vital capacity which before the operation had been 1,600 cubic centimeters was raised to 1,700 cubic centimeters.

In this case high adhesions between the diaphragm and the chest wall produced a para-

doxical movement of the lower thorax. This was reversed by paralyzing the diaphragm with the result that the vital capacity was increased rather than reduced.

Protocol 6 The effect of section of one phrenic nerve upon the intra abdominal pressure.

Terrier type female dog ether anesthesia. The abdomen was opened and a rubber tube the end of which was protected by a wire guard was inserted into it. The wound was then closed tightly about the tube. The opposite end of the tube was connected with a tambour manometer arranged to record upon a revolving smoked drum. The right sixth rib was exposed in the midaxilla and a thread run from it downward over a pulley and connected with a muscle lever arranged to make tracings directly beneath the manometer. Inspiration was indicated by upstrokes of the muscle lever. The right phrenic nerve was exposed in the neck.

A normal tracing was taken. This showed that on inspiration the intra abdominal pressure was positive on expiration negative. The right phrenic nerve was then severed. Following this the intra abdominal pressure became negative on inspiration positive on expiration.

Protocol 7 The effect of paralysis and contraction of the hemidiaphragm upon the movement of the upper ribs.

The dog was prepared in the same manner as was the animal in protocol 1. Threads running to the muscle levers were attached to the exposed third ribs instead of to the costal margins. After a normal tracing had been taken the right phrenic nerve was clamped and there followed an immediate increase in the movement of the ribs of both hemithoraces (Fig 5).

Continuous stimulation of the distal end of the cut nerve with the galvanic current produced a marked decrease in the movement of the ribs (Fig 6).

Stimulation on each inspiration had the same effect (Fig 7).

Protocol 8 The effect of paralysis of the hemidiaphragm upon the intrapleural pressures.

Collie type male dog ether anesthesia by drop method.

Through a small incision low in the cervical region the right phrenic nerve was exposed and a thread was run beneath it. The abdomen was then opened and after the normal functioning of both diaphragmatic halves had been verified was closed with silver clips. The right and left lower costal margins were then exposed through small midaxillary incisions. A trochar was inserted into each pleural cavity. The two thoracic trochars were connected with tambour manometers arranged to make tracings one above the other on a revolving smoked drum. Below these levers two others were placed one for recording section or stimulation of the nerve and the other the time in seconds. After a normal tracing had been taken the right phrenic nerve was clamped and cut.

After section of the nerve the pressure in both pleural cavities rose. Both the inspiratory and expiratory levels were elevated (Fig 8).

What seems to be a very slight rise in the intra pleural pressures is when tested by the water manometer about 3 centimeters of water. That it is so small on this record is due to the relative inelasticity of the tambour manometers at the limits of their motion.

Protocol 9 The effect of paralysis of the hemidiaphragm upon intrapleural pressure in the human.

Mrs. M. C. a married woman 35 years of age had tuberculosis of the right lung for 2 years. A partial collapse of the lung had been obtained by artificial pneumothorax. To supplement this the right phrenic nerve was extracted. Immediately before the operation the pneumothorax needle was inserted into the right pleural cavity and the pressure read from the water manometer. The proximal column of water was -3 on inspiration 0 on expiration. Immediately after the operation it was 0 on inspiration and +2 on expiration. The inspiratory pressure had dropped by 3 centimeters of water and the expiratory by 2 centimeters. The range of pressure change had been decreased by 1 centimeter of water (Fig 9).

ADDENDA

Experiments performed upon rabbits since this article was submitted for publication have shown the following facts:

1. Normal respiration in the rabbit is wholly diaphragmatic.

2. As the diaphragm descends the ribs are drawn downward and medianward.

3. If one phrenic nerve be cut the movement of the ribs is reversed and they rise on inspiration the ribs of the two hemithoraces moving equally.

4. If after one phrenic nerve has been cut the midpoint of the diaphragm is fixed by grasping it with a forceps through the opened abdomen so that it can no longer be drawn toward the sound side the movement of the ribs on the sound side is markedly curtailed on the side on which the diaphragm has been paralyzed markedly increased.

It is probable that fixation of the midpoint of the diaphragm not only prevents the muscle on the sound side from exerting a pull upon the ribs of the opposite side but also that it serves to fix the mediastinum and allow variations of pressure in the two pleural cavities.

CARCINOMA OF THE SMALL BOWEL¹

FRED W. RANKIN, M. A., M. D., F. A. C. S., ROCHESTER, MINNESOTA

Division of Surgery, The Mayo Clinic

AND

CHARLES MAYO, 2D, M. D., ROCHESTER, MINNESOTA

Fellow in Surgery, The Mayo Foundation

ALTHOUGH carcinoma of the small intestine is fortunately relatively infrequent, it is not so rare but it is of more than academic interest. In spite of this the subject is practically neglected in the usual works on surgery. It is with the hope in mind that in presenting a composite word picture of a series of such cases, diagnosis will be somewhat simplified. It is an axiom that neoplasia of the small intestine is diagnosed before operation only on rare occasions.

Tumors of the small bowel may be classified as benign or malignant, the benign group includes adenoma, fibroma, lipoma and myoma, the malignant group, carcinoma and sarcoma. Since this paper is to deal primarily with carcinoma of the small intestine we dismiss with a few words the subject of sarcoma. In 1904 Nothnagel in 4,538 necropsies, reported 243 cases of intestinal sarcoma, in 6 of which the growths were in the ileum and in none of which was the growth in the jejunum. On the other hand Corner and Fairbank, in 1905 reviewed 103 cases of sarcoma of the intestine of which 63 per cent were in the small bowel and the largest number of these in the ileum. Occasionally in the literature one runs across reports of single cases of sarcoma of the small intestine, the majority of which are examples of the small round cell and spindle cell types. Soper has recently reported a case of spindle cell sarcoma. The age incidence in sarcoma is between 30 and 40 years.

Concerning the rarity of carcinoma in the part of the intestine between the pylorus and the ileocecal valve Leichtenstern in a series of 780 carcinomata of the intestinal tract found 16 primary in the ileum. Bunting reported one case of carcinoma of the small intestine in 2,200 necropsies. McKenty reported 2 cases in 2,500 necropsies. Johnson reported the statistics of 41,838 necropsies at

the Vienna General Hospital in which 3,585 cases of carcinoma were revealed, 343 of these were intestinal of which 10 were in the ileum and none was in the jejunum. Hinz found that of 584 cases of carcinoma of the intestinal tract 18 were in the small bowel.

It is easy to see from these reports, that there is wide variation in the frequency with which carcinoma of the small intestine is found. This may possibly be due to the care with which necropsies are made, to the individual factor of the physician being able or unable, to recognize the condition, and to the size and character of the clinic or hospital.

Judd in 1919, reported that, in a number of clinics 3 per cent of the intestinal carcinomata was found in the small intestine. At The Mayo Clinic, the incidence of carcinomata from the cardiac end of the stomach down to and including the rectum is approximately 0.062 per cent. Disregarding the type of carcinoma there must be some explanation of the rarity with which carcinoma is found between the pylorus and the ileocecal valve. As in all matters in which the truth is not known there are many theories to account for the facts the chief among which are based on the following characteristics of the small intestine: (1) the fluid nature of its content, (2) the alkalinity of the intestinal fluid and (3) the absence of abrupt bends. In the colon on the other hand the content is of a different nature and stasis also may play a part in the greater frequency with which carcinoma is found. Without an understanding of the etiology of carcinoma one is wise to avoid attempting to explain the reasons why, in one place the disease is found comparatively frequently and in another infrequently. There is not sufficient evidence to warrant the view that carcinoma of the small intestine develops on the basis of embryonic rests or of morbid changes in Brunner's glands.

Fig. 1. Constricting annular carcinoma of the jejunum.

Great difficulty was met in reviewing the literature. The main problem lay in detecting the cases in which carcinoid tumors were wrongly classified under the title carcinoma. This fault occurred all too frequently and the effort to glean the actual cases of carcinoma was doubled.

MATERIAL

Judd in his paper in carcinoma of the small intestine reported on the cases at The Mayo Clinic up to the year 1919. We carry the report through 1919 to October 1, 1929 (tabulation). Between January 1, 1919 and October 1, 1929 inclusive carcinoma occurred in the small bowel 31 times, as compared with 2,775 times in the large bowel and rectum, and 2,646 times in the stomach. Adding Judd's cases, reported in 1919, there have been 55 cases of carcinoma of the small intestine compared with 4,597 of the large bowel and rectum together, and 4,335 of the stomach.

Only those cases were selected in which from the surgical standpoint, and in a large majority of cases from the pathological standpoint, the carcinoma was primary in the small intestine. Those cases in which carcinoma

was found in the small intestine in combination with carcinoma elsewhere, as in the stomach, large intestine or rectum, were not included. The choice was carefully made in order to fulfill one of the main purposes of this paper, namely, to establish a basis on which diagnosis of primary carcinoma of the small intestine might be made.

AGE AND SEX

The average age of patients with carcinoma of the small intestine for the entire group of 55 was 47.5 years. There was however a wide range of variation, the youngest patient was 32 years of age, and the oldest, 69. Eight patients were less than 40 years of age. Keyser, in 11 cases, found the average age to be 43.9 years. Ewing gave the average age as 46.5 years.

Whereas Lahey in 1914 found the sexes sharing equally in the affliction, we find 37 males and 18 females. This more nearly coincides with the figures of Venot and Parcelier, 70 per cent males and 30 per cent females.

SYMPTOMS OF CARCINOMA OF THE SMALL INTESTINE AS A WHOLE

The individual picture of carcinoma of the small intestine varies but the background remains the same. Variations will be brought about by (1) extent of the local growth, (2) extent and situation of metastasis, (3) individual resistance, and (4) the type and grade of carcinoma (Broders' classification). Since the growth lies in the small bowel the subjective and objective signs and symptoms are chiefly of intestinal origin.

In all cases the chief complaint was "abdominal cramps," "abdominal distress," "stomach trouble," "obstruction," or other terms carrying the same significance. From this point on in cases of this sort accurate diagnosis rests primarily with the physician and here must be stressed the importance of history taking and of the art of analysis.

In duration of symptoms there is wide variation from 2 or 3 months to 5 years or more. The average in our series was about 14 to 15 months. Factors which affect duration of symptoms are the type and grade of the carcinoma, individual resistance, and so forth.

The onset of symptoms may be frank or insidious. When the initiation of the process has been of average or short duration, the onset of the illness is generally frank and is characterized by a sudden attack of abdominal cramps. The picture then presented is that of acute intestinal obstruction, the main features of which are (1) sudden, severe abdominal cramps, most frequently localized in one of the lower quadrants, (2) gas and varying distention, (3) nausea and vomiting, (4) visible and reverse peristalsis, and (5) borborygmus. This first attack is usually of short duration, a matter of hours, and is followed by complete recovery. Weeks or months may pass before another exacerbation of acute intestinal obstruction occurs. This may or may not be more severe than the preceding attack, but with the advancement in the disease the tendency is for greater severity and shorter intervals between recurrences of the obstruction. Each renewal is sudden and follows a meal. Late in the course of the trouble, there are no intervals of freedom from symptoms; patients always have gastric distress, but have spells of feeling much worse.

Food dyscrasia is a varying factor. Commonly one gets a history which simulates, to a degree, duodenal ulcer or disease of the gall bladder and the patient will say, "Nothing agrees with me." Since, in many of these cases, free hydrochloric acid is lacking from the stomach it is not strange that in some cases there is distress from food. Constipation is more frequently complained of than diarrhoea. When there is a history of diarrhoea, it is found to have alternated with constipation and in this simulates carcinoma of the colon. We find as Johnson and Susman found that constipation in carcinoma of the small bowel becomes increasingly obstinate. Occasionally the history of tarry stools and even of repeated hemorrhages from the bowel is obtained. In the majority of cases however, such a history is not given. In spite of this we re-emphasize the importance of repeated tests for occult blood in the stool.

It may be that the first noticeable change in a patient with carcinoma of the small intestine is slowly developing anaemia. The anaemia is progressive and it is not unusual for

Fig. 2. Marked ulceration in constricting annular carcinoma of the jejunum.

the victim to present himself for treatment of "pernicious anaemia." Often it is only with considerable difficulty that a differential diagnosis can be made in a case of advanced secondary anaemia. It does not respond to administration of liver or to other methods of treatment now prescribed. As the anaemia creeps on, malaise keeps apace. Suffice it to say that in the presence of unexplained secondary anaemia, the possibility of a malignant lesion of the small intestine should be kept in mind. The average concentration of haemoglobin in our series of cases was 59.5 per cent, it was 40 per cent or less in 9 cases. Regardless of the concentration of haemoglobin being higher in some cases than one would expect the appearance of the patient is pale and pasty. The average color index was 0.675 in the 12 cases in which it was taken. The average blood pressure was 118 systolic and 70 diastolic. Considering the mean age as 47.5 years, this is somewhat low.

GENERAL EXAMINATION

In giving the results of general examination, we confine ourselves to positive features that are directly relative to carcinoma of the small intestine. We discuss secondary signs, such as those referable to the head, neck, thorax, and genito urinary system, not forgetting that they are important in determining risk and prognosis, and that they may be so numerous and serious as to obscure the primary trouble.

The patient is generally anæmic may be cachectic, and has lost some weight. In our series, the average loss was 28 pounds.

The results of abdominal examination depend of course, on the stage of the disease at which it is made. It is not usual at the clinic to see patients in the stage of acute obstruction but undoubtedly most of them are seen by a physician at such times. Therefore it is well to remember the picture of acute high intestinal obstruction and to consider neoplasm of the small intestine as a possibility in its causation. Because the duration of signs of acute obstruction is short (a matter of hours) and because it usually is relieved, we consider mainly the signs that appear in the intervals and that become more marked as the disease progresses. First, inspection reveals visible and reverse peristalsis. Distention is variable but frequently is seen later in the course of the trouble when the obstruction becomes more chronic. Second palpation discloses tenderness and rigidity usually more marked over a given area which changes with the situation of the growth. If a mass is palpable and often one is it is movable and tender unless the growth has broken its bounds and has become adherent to a fixed object. But as a rule when a mass is palpable and movable 'slips away from the fingers' and is tender and when other signs and symptoms are present carcinoma of the small intestine may well be suspected. Third auscultation is not always necessary in order to locate the growth. Gurgling at the point of obstruction may be audible at some distance. *Borborygmus* is a significant observation.

SPECIAL EXAMINATIONS

In 20 cases analysis of gastric content was done. Of these, in 9 there was no free hydro-

chloric acid, in 4 marked decrease, in 1, hyperacidity (total acidity of 90 and free hydrochloric acid of 70, in terms of cubic centimeters of tenth normal sodium hydroxide), and in the others acidity was average in degree. The situation of the growth seemed to have no connection with these data.

Proctoscopic examination usually gives negative results, although occasionally rectal or anal papillæ or polyps are discovered. The trouble of making the examination is worth while however in order to help rule out disease of the lower part of the bowel.

Roentgenological examination is important from a negative standpoint that is when the patient shows signs and symptoms of some intestinal lesion it is of value in aiding in the elimination from the diagnosis of duodenal ulcer, and of disease of the stomach or colon. An occasional case is diagnosed by roentgenological examination. Crane of The Mayo Clinic some time ago stated that when there was prolonged gastric retention without signs of gastric pyloric or bulbar involvement the suspicion of carcinoma of the duodenum should be aroused.

Portis and Portis in 1913 reported a case diagnosed roentgenologically as a probable case of tumor of the jejunum. The diagnosis was based on the following data: (1) the stomach was negative (2) the duodenum was dilated, (3) the small bowel near the duodenum filled and remained filled giving the appearance of a stomach with an air space above the fluid level (4) the bowel at a point distal to the dilatation was definitely constricted and (5) reverse peristalsis was observed in the dilated portion proximal to the constriction. The surgeon at operation, found an annular growth in the jejunum near the ileum for which resection and lateral anastomosis were done.

Clark reported a case in 1916 in which the lesion was located by roentgenological examination.

Soper, to illustrate the value of roentgenological examination of the small intestine cited 11 cases in one of which there was carcinoma 12.5 centimeters downward from the ligament of Treitz and in one a sarcoma of the spindle cell type 35 centimeters below the

FIG. 3 Application of clamp to one leg of the bowel mesentery ligated

FIG. 4 Both blades of the clamp in place removal of the segment of the bowel with cautery

ligament of Treitz. He stated, in conclusion that intensive study of the course of a barium meal in its passage through the small intestine is necessary in order to establish a diagnosis. We believe that the danger of increasing the obstruction by retention of barium in an already obstructed intestine unless satisfactory means for its removal are available, is a serious handicap to a successful surgical procedure.

PATHOLOGY

In the majority of our series of cases the tumors were reported pathologically, to represent the various grades of adenocarcinoma. It is hoped that at a future date we may report in greater detail the pathological aspects of carcinoma of the small intestine. However the two most common forms are those which develop on degenerating polyps and the ring type which simulates the growth commonly found in the large intestine (Figs. 1 and 2).

Bland Sutton in 1914 stated that carcinoma occurred more commonly in the duodenum than in either the jejunum or ileum. We on the other hand find that of these three the highest incidence is in the jejunum with the frequency of lesions in the duodenum and ileum approximately equal. There seems to be no evidence to lead one to believe that carcinoma in the duodenum develops on the basis of chronic ulcer. Judd likewise drew this conclusion.

Mueller recalled, in 1925 the important consideration of carcinoma of the ampulla of Vater. He believed that probably the most common origin of growths in this region was from the duodenal mucosa at the papilla, and also, that carcinoma of any part of the duodenum may involve the papilla by extension. This we have seen in one case, with the intermittent jaundice he described.

In 21 cases (38 per cent), the carcinomata were found in the jejunum. A surprising number of these was at or a short distance from the ligament of Treitz.

In 14 cases the carcinoma was primary in the ileum. At the ileocecal valve it is sometimes difficult to determine whether the growth has extended into or from the ileum. Carcinomata of the ileocecal coil however, are rare; they have occurred at the clinic only seven times in the last 10 years. Recently, a case of localized tuberculosis of the ileum was observed 75 centimeters from the ileocecal valve and the history in many respects was similar to that in carcinoma of the small intestine. This condition must be remembered as one difficult to distinguish from carcinoma except at operation.

METASTASIS

Metastasis is a common accompaniment of malignancy in the small bowel. Invasion affects, first, the mesenteric lymph nodes and

Fig 5

Fig 6

Fig 7

Fig 5 Anterior layer of sutures
Fig 6 The clamp reversed and the first layer of posterior sutures being applied

Fig 7 Removal of clamps agglutination holds the edges of the bowel together

peritoneum, then the liver, lungs, long bones, and spinal dura, in order. Metastasis takes place, probably, at an early stage of the disease and obviously influences seriously the undesirable outlook in lesions in this situation. In one in every three of our cases, at the time of operation, there was metastasis which either excluded radical surgical measures, or, if the metastasis was present only in the lymph nodes influenced unfavorably the ultimate outcome.

TREATMENT

The treatment of carcinoma of the small bowel when the growth is removable, obviously is resection, with reestablishment of the continuity of the lumen of the bowel. When, because of the attendant obstruction it is not removable or resectable, entero-anastomosis, side tracking the pathological lesion is the procedure of choice. Occasionally one will feel justified in doing resection, with anastomosis in the presence of metastasis since this occasionally may be accomplished in a mobile segment of bowel almost as readily and with as little danger of contamination as a side tracking palliative entero-anastomosis.

In accomplishing resection of a segment of the bowel which is to be rejoined under favorable conditions it has been our practice to employ an aseptic type of anastomosis over a three-bladed clamp, devised by one of us (Rankin) and used satisfactorily in a large series of resections of the large bowel. Path-

ological conditions of the small bowel are so exceedingly rare except for the traumatic lesions that demand resection that opportunity to use this clean method of anastomosis in the small intestine has been relatively infrequent. However we have used it three times in this series establishing an end to end anastomosis in two instances and in one instance lateral anastomosis. The choice between end to end and lateral anastomosis in reestablishment of the continuity of the bowel either large or small is a question and must be settled in each case in accordance with the choice and experience of the individual operator. It is our belief that in most instances and certainly in lesions of the small bowel end to end anastomosis is the method of choice. The advantages of an aseptic type of anastomosis are not satisfactorily established but suffice it to say that, other things being equal, the more cleanly two sections of bowel are joined, the more satisfactory the outcome should be because of the decreased chances of peritoneal contamination. The clamp method of aseptic anastomosis in our hands, has proved simple and satisfactory (Figs. 3 to 10).

In the end to end anastomosis, which is the simplest method of joining the bowel, the steps are relatively few and easily accomplished. They consist of the following: (1) ligation of the vessels supplying blood to the segment to be removed, (2) application of the blades of the clamp, incorporating a loop of small bowel

Fig 8

Fig 9

Fig 8 Second row of sutures being applied on the anterior surface
 Fig 9 Second row of sutures being applied on the posterior surface
 Fig 10 The operation complete with the fingers breaking out the diaphragm between the loops

Fig 10

to either blade and, before application, making sure of the blood supply to either end (3) removal of the affected segment with the cautery after applying another clamp above the Rankin clamp, (4) application of a row of sutures around the entire circumference of the bowel before withdrawal of the clamp (5) withdrawal of the clamp and tying of sutures, (6) application of a second row of sutures around the entire circumference of the bowel (7) closure of the mesenteric defect, and (8) breaking out of a diaphragm by invaginating a finger through the anastomosis. If the suture is placed only through the subperitoneal coats the operation of resection may be accomplished absolutely without contamination. The clamp is strong enough to cause sufficient pressure to control hemorrhage from the end cut into in the bowel and agglutination keeps the end of the bowel closed until the suture is drawn taut thus preventing leakage. We have never seen secondary hemorrhage, stricture or leakage in any of our cases in which resection of the large or small bowel has been accomplished by this method. Its simplicity and satisfactory application, we believe, recommend its continued use.

PROGNOSIS

The prognosis in carcinoma of the small bowel whether the growth is apparently satisfactory for resection or whether the operation

is palliative is unsatisfactory and the length of life even following resection is short. There is no difficulty in deciding once the abdomen is open, whether or not resection is feasible. Any tumor which is removable should be extirpated whether or not lymph nodes are involved because it is almost as simple a procedure to do an end to end anastomosis in the small bowel as it is to do a sidetracking lateral anastomosis which excludes the lesion. Occasionally blind enterostomy is the procedure of choice in a case of acute obstruction in which one does not feel that even exploration is warranted. This may tide the patient over until a more radical step may be taken. The lives of most of our patients have been short even after removal of the growth. No patient in this series has yet lived longer than 3 years. The range of life of those who have lived was from 1 month to 3 years, and the average was less than a year.

Death comes at an early stage in carcinoma of the small bowel when compared with resectable growths of the large bowel and of other portions of the gastro intestinal tract. Perhaps the digestive activity of this portion of the alimentary canal, the abundant lymphatic supply, and the high grade of malignancy of the neoplasms are important factors in the gravity of the prognosis.

Fig. 5

Fig. 6

Fig. 7

Fig. 5 Anterior layer of sutures

Fig. 6 The clamp reversed and the first layer of posterior sutures being applied

Fig. 7 Removal of clamps, agglutination holds the edges of the bowel together

peritoneum, then the liver, lungs, long bones, and spinal dura in order. Metastasis takes place, probably, at an early stage of the disease and obviously influences seriously the undesirable outlook in lesions in this situation. In one in every three of our cases at the time of operation there was metastasis, which either excluded radical surgical measures or, if the metastasis was present only in the lymph nodes, influenced unfavorably the ultimate outcome.

TREATMENT

The treatment of carcinoma of the small bowel when the growth is removable, obviously is resection with reestablishment of the continuity of the lumen of the bowel. When because of the attendant obstruction, it is not removable or resectable, entero anastomosis side tracking the pathological lesion is the procedure of choice. Occasionally one will feel justified in doing resection with anastomosis in the presence of metastasis, since this occasionally may be accomplished in a mobile segment of bowel almost as readily and with as little danger of contamination as a side tracking palliative entero anastomosis.

In accomplishing resection of a segment of the bowel which is to be rejoined, under favorable conditions it has been our practice to employ an aseptic type of anastomosis over a three bladed clamp, devised by one of us (Rankin) and used satisfactorily in a large series of resections of the large bowel. Path-

ological conditions of the small bowel are so exceedingly rare, except for the traumatic lesions that demand resection that opportunity to use this clean method of anastomosis in the small intestine has been relatively infrequent. However, we have used it three times in this series, establishing an end to end anastomosis in two instances and in one instance lateral anastomosis. The choice between end to end and lateral anastomosis in reestablishment of the continuity of the bowel either large or small is a question and must be settled in each case in accordance with the choice and experience of the individual operator. It is our belief that in most instances and certainly in lesions of the small bowel, end to end anastomosis is the method of choice. The advantages of an aseptic type of anastomosis are not satisfactorily established but suffice it to say that other things being equal the more cleanly two sections of bowel are joined the more satisfactory the outcome should be because of the decreased chances of peritoneal contamination. The clamp method of aseptic anastomosis in our hands has proved simple and satisfactory (Figs. 3 to 10).

In the end to end anastomosis, which is the simplest method of joining the bowel, the steps are relatively few and easily accomplished. They consist of the following: (1) ligation of the vessels supplying blood to the segment to be removed, (2) application of a loop of small bowel

7 Roentgenological examination is of particular importance only from a negative standpoint in the present state of knowledge, but it seems likely that future progress along diagnostic lines will make the roentgenological examination much more accurate and definite

8 Resection and end to end anastomosis is the surgical procedure of choice. When this is not possible lateral entero anastomosis should be done to short-circuit the obstruction

9 The prognosis is poor regardless of the surgical procedure

10 Metastasis takes place early

ILLUSTRATIVE CASE

The patient a married woman complained chiefly of *cramps vomiting and anemia* of 2½ years duration. At the onset the abdominal cramps had been mild and intermittent, distributed generally over the abdomen and the patient had paid but little attention to them. She had noted a great deal of borborygmus and bloating. She had been mildly constipated for years, but never had gone more than 2 days without a stool. She had not noticed blood in the stool. In the winter of 1927 and 1928 the trouble had become more noticeable, one severe attack had lasted a few weeks and had been accompanied by vomiting. There had been no blood in the vomitus however. Pain at this time had begun in the right lower quadrant of the abdomen had passed up along the line of the ascending colon and under both costal margins into the thorax.

The patient came to the clinic in September 1928 and was in hospital 2 weeks. All roentgenological examinations gave negative results. She was given a diet high in vitamins and liver. Blood was found in the stool on microscopic examination and evidence of blood was obtained by the guaiac test. In October, 1928, after a period of dieting there was not much objective change she felt better however. In January 1929 cramps persisted to some extent she was given fetal liver powder, roentgenological examinations gave negative results.

The patient returned home in January and a few days after her arrival severe pain appeared in the right lower quadrant of the abdomen the pain radiated along the ascending colon to the margin of the ribs and then to the back. The liver powder seemed to bring on the attacks vomiting and pain ceased with cessation of administration of liver powder. When administration of the powder was resumed, attacks recommenced. She entered a hospital near her home and continuous rolling gurgling and splashing in the abdomen were noted. Following the attack the patient's progress was satisfactory until the attack which caused her to return to the clinic.

Ten days before the patient returned pain had appeared in the upper part of the abdomen. Later the pain had moved downward. Distention with gas pressure against the heart and palpitation vomiting and visible peristalsis appeared. There was very little evidence of cholecytic disease except vomiting. The patient complained of nervousness

a racing heart and tingling in the feet at night. She had had trouble with bloating at night and had a feeling of pressure in the thorax. There was no gross blood in the stool but erythrocytes were found microscopically.

On examination the patient was found to be anæmic. Otherwise the examination was negative except for the abdomen which was distended and tender (graded 2). On stimulation of the abdominal walls visible peristalsis was easily seen more on the left than on the right and below the umbilicus. A definite mass was not felt there was borborygmus graded 3. There had been loss of weight of 16 pounds. The blood pressures in millimeters of mercury were 130 systolic and 60 diastolic. Hemoglobin was estimated at 37 per cent and the color index was 0.6. Analysis of gastric content revealed total acidity of 48 free hydrochloric acid of 32 and combined acids of 37. Two roentgenological examinations of the stomach, colon and thorax and one of the gall bladder gave negative results. The test for occult blood in the stool was positive. Certainly obstruction was present but the situation of the obstruction was unknown. Roentgenological examination of the colon gave negative but not conclusively negative results. The diagnosis was as follows: tumor of the small bowel (50 per cent) volvulus (25 per cent) and malignant condition of the colon (25 per cent).

At operation carcinoma at the duodenojejunal juncture, with partial intestinal obstruction was found. Duodenojejunostomy was done with anastomosis between the third part of the duodenum and a point in the jejunum 15 centimeters below the growth. Evidence of metastasis was not found. The growth was not resected because the mesentery was so thick. Four months later the patient was much improved.

CONCLUSIONS

1 Carcinoma of the small intestine is rare, it represents at The Mayo Clinic, 0.62 per cent of the cases of carcinoma of the gastrointestinal tract.

2 The primary signs and symptoms are directly relative to intermittent obstruction and to secondary anæmia.

3 Duration of symptoms varies with the individual case, but the average is 14 to 15 months.

4 A movable tender mass that "slips away from the fingers" should arouse suspicion.

5 The tendency as noted in the history is for constipation to be a rather constant symptom and for it to become increasingly obstinate, although occasionally it is interspersed with attacks of diarrhoea.

6 Repeated tests for occult blood are important in suspicious cases.

weakness and loss of weight in 3 cases, and vomiting in 2 cases. Many patients mentioned other conditions in addition to their chief complaints.

Thirty seven of the patients had a complaint of such indefinite epigastric distress as fullness after meals, belching of gas, and sour stomach.

Thirty seven patients complained of epigastric pain which varied from a burning, gnawing type of pain to definite, severe epigastric pain. Fifteen of these patients gave a history suggestive of peptic ulcer, with periodic spells of distress characterized by the sequence of pain, food, and ease.

The loss of weight ranged from 5 to 70 pounds in a period varying from 2 weeks to several years. The average loss was 23 pounds in 4 months. Eleven of the patients had not lost weight at the time they came to operation.

Twenty six of the patients had demonstrable epigastric tumors. Four of this group, as mentioned, presented themselves at the clinic with the chief complaint of tumor. Some of the tumors were fixed and some moved on respiration. One was palpable only when the patient was in a standing position. One patient had visible gastric peristalsis.

The tumor was situated in the mid epigastrium in 13 cases, to the left of the epigastrium in 11 cases and to the right of the epigastrium in 2 cases. In a few of these cases it was situated below the umbilicus.

The presence of a palpable tumor does not seem to have any evident relationship to the resectability of the lesion or to the prognosis. In 2 of the cases of palpable tumor, the roentgenographic report was of a normal stomach. Sixteen or more than half of the cases of tumor fell within the operable group. Five of the 12 patients who were living when last heard from, one of whom had lived 9 years, were included in the group with palpable tumor.

Sixteen of the patients gave a history of gastro intestinal hæmorrhages for a period of 1 to 9 months. Black, tarry stools were most frequently noted, although a few of the patients had vomited blood. The hæmorrhages were single or repeated. One patient had a

TABLE 1—COMPARISON OF FREQUENCY OF SARCOMA AND CARCINOMA

Period	Cases		Ratio
	Sarcoma	Carcinoma	
1908-1915	5	1131	1:226
1916-1920	15	973	1:65
1921-1925	21	1185	1:56
1926-1928	6	821	1:137

fatal hæmorrhage following simple exploration for what proved to be inoperable sarcoma of the stomach.

Twenty seven patients (half of the series) complained of occasional or daily vomiting. Few gave a history of a retention type of vomiting, a few induced vomiting for relief of symptoms.

The concentration of hæmoglobin varied from a high figure of 88 per cent to a low figure of 24 per cent. Forty three patients had a value for hæmoglobin above 50 per cent. In the group of 43 patients with a reading for hæmoglobin above 50 per cent, only 7 had a clinical history of gastro intestinal hæmorrhage. Six of the group of 10 patients with a reading below 50 per cent had a clinical history of bleeding. The ratio between those with a reading for hæmoglobin below 50 per cent to those with a reading above 50 per cent was as 1 to 4.

Determination of the gastric acids was made in 42 of the 54 cases. In this group, free hydrochloric acid was absent in 17. In 25 cases the average reading for free hydrochloric acid in terms of cubic centimeters of tenth normal sodium hydroxide, was 37, the highest value for free hydrochloric acid was 66.

If the 25 cases with free hydrochloric acid be divided into three groups, the following values were found: 0 to 30, with an average of 17, in 17 cases; 30 to 50, with an average of 41 in 5 cases; and 50 or more, with an average of 57, in 3 cases.

Five of the group showed considerable retention of gastric content, the maximal retention was 2,000 cubic centimeters and the average for the 4 cases 1,036 cubic centimeters.

Roentgenological studies were made in 45 of the series and the following diagnoses were

SARCOMA OF THE STOMACH¹DONALD C BALFOUR M.D. F.A.C.S. AND JAMES C MCCANN M.D. ROCHESTER MINNESOTA
Fellow in Surgery The Mayo Foundation

RECOGNITION of sarcomatous gastric lesions dates back to 1847, when Bruch reported the first case on record. Ewing estimated that sarcomata constitute about 1 per cent of gastric tumors. Haggard reviewed the subject up to 1920 and found that 244 cases of sarcoma of the stomach had been reported in the literature, in 107 of these the patients came to operation. Masson reviewed the cases which occurred at The Mayo Clinic from 1908 to 1920 inclusive, and found 13 proved cases of sarcoma in 2,067 cases of malignant lesions of the stomach, a ratio of 1 sarcoma to 159 carcinomata of the stomach.

This report is a clinical analysis of 54 cases of sarcoma of the stomach which have been studied at The Mayo Clinic from January, 1908 to July, 1929, inclusive. Diagnosis in all of the cases but one was made as a result of surgical intervention for gastric lesions, in the one exception, a sarcomatous lesion of the stomach was found at necropsy. In 5 cases tissue was not removed at operation, the diagnosis was based on the gross appearance of the inoperable tumor. In 3 instances the pathologist reported the possibility of the tissue being cellular carcinoma. In one instance the stoma of a gastro-enterostomy was involved so that there were 45 cases in which a definite diagnosis of sarcoma of the stomach was made and 9 cases in which the diagnosis was 'probably sarcoma'.

The yearly incidence of sarcoma of the stomach as seen at the clinic has not been at all constant. It has varied from 1 to 6 cases a year. There was a similar fluctuation in the ratio of sarcoma to carcinoma during this period, with an average ratio of 1 case of sarcoma to 111 of carcinoma, in a total group of 4,159 cases of malignant lesions of the stomach (Table I).

The ages of these patients were comparable to those reported from other sources. Finlayson reported the youngest patient as 3½ years of age. Gosset reported the oldest

patient as being 85 years of age. The average age in the cases reported in the literature is about 40 years, whereas the average age of patients with carcinoma of the stomach is 61 years.

In our series, the youngest patient was aged 10 years and the oldest, 67. The average age for the whole group was 43 years. This confirms the opinion of most writers that sarcoma of the stomach occurs earlier in life than does carcinoma of the stomach. The numbers of cases in various age periods were as follows: from 10 to 20 years, 2 cases; from 20 to 30 years, 7 cases; from 30 to 40 years, 7 cases; from 40 to 50 years, 16 cases; from 50 to 60 years, 12 cases; and from 60 to 70 years, 10 cases.

The literature conveys the impression that occurrence of sarcoma of the stomach is equal in both sexes. In our series there were 31 males and 13 females.

In only 4 cases in the series of 54 cases was a history of a malignant lesion in the immediate family elicited. The father of one patient had carcinoma of the stomach, the brother of another patient had carcinoma of the intestine, a third reported that his son had carcinoma of the rectum, a fourth said his mother had carcinoma, the site of which he did not know.

CLINICAL FEATURES

The average duration of the symptoms of which the patients complained was 18 months. Sixteen of the group had had symptoms for from 2 to 9 years. The average for the remaining 38 patients was only 6 months. The average duration of symptoms in cases that proved to be inoperable was 11 months.

The presenting symptoms varied from a localizable gastric disorder to indefinite general abnormal conditions which did not indicate the seat of trouble. The various chief complaints were as follows: dyspepsia in 23 cases, epigastric pain in 19 cases, epigastric tumor in 4 cases, bleeding in 3 cases

weakness and loss of weight in 3 cases, and vomiting in 2 cases. Many patients mentioned other conditions in addition to their chief complaints.

Thirty seven of the patients had a complaint of such indefinite epigastric distress as fullness after meals, belching of gas, and sour stomach.

Thirty seven patients complained of epigastric pain which varied from a burning gnawing type of pain to definite, severe epigastric pain. Fifteen of these patients gave a history suggestive of peptic ulcer, with periodic spells of distress characterized by the sequence of pain, food, and ease.

The loss of weight ranged from 5 to 70 pounds in a period varying from 2 weeks to several years. The average loss was 23 pounds in 4 months. Eleven of the patients had not lost weight at the time they came to operation.

Twenty six of the patients had demonstrable epigastric tumors. Four of this group, as mentioned, presented themselves at the clinic with the chief complaint of tumor. Some of the tumors were fixed, and some moved on respiration. One was palpable only when the patient was in a standing position. One patient had visible gastric peristalsis.

The tumor was situated in the mid epigastrium in 13 cases, to the left of the epigastrium in 11 cases, and to the right of the epigastrium in 2 cases. In a few of these cases it was situated below the umbilicus.

The presence of a palpable tumor does not seem to have any evident relationship to the resectability of the lesion or to the prognosis. In 7 of the cases of palpable tumor, the roentgenographic report was of a normal stomach. Sixteen, or more than half of the cases of tumor fell within the operable group. Five of the 17 patients who were living when last heard from, one of whom had lived 9 years, were included in the group with palpable tumor.

Sixteen of the patients gave a history of gastrointestinal hemorrhages for a period of 1 to 9 months. Black, tarry stools were most frequently noted although a few of the patients had vomited blood. The hemorrhages were single or repeated. One patient had a

RECOGNITION of sarcomatous gastric lesions dates back to 1847, when Bruch reported the first case on record. Ewing estimated that sarcomata constitute about 1 per cent of gastric tumors. Haggard reviewed the subject up to 1920 and found that 244 cases of sarcoma of the stomach had been reported in the literature in 107 of these the patients came to operation. Masson reviewed the cases which occurred at The Mayo Clinic from 1908 to 1920 inclusive, and found 13 proved cases of sarcoma in 2,067 cases of malignant lesions of the stomach, a ratio of 1 sarcoma to 159 carcinomata of the stomach.

This report is a clinical analysis of 54 cases of sarcoma of the stomach which have been studied at The Mayo Clinic from January, 1908 to July, 1929 inclusive. Diagnosis in all of the cases but one was made as a result of surgical intervention for gastric lesions, in the one exception, a sarcomatous lesion of the stomach was found at necropsy. In 5 cases tissue was not removed at operation, the diagnosis was based on the gross appearance of the inoperable tumor. In 3 instances the pathologist reported the possibility of the tissue being cellular carcinoma. In one instance the stoma of a gastro-enterostomy was involved so that there were 45 cases in which a definite diagnosis of sarcoma of the stomach was made and 9 cases in which the diagnosis was 'probably sarcoma'.

The yearly incidence of sarcoma of the stomach as seen at the clinic has not been at all constant. It has varied from 1 to 6 cases a year. There was a similar fluctuation in the ratio of sarcoma to carcinoma during this period, with an average ratio of 1 case of sarcoma to 111 of carcinoma, in a total group of 4,159 cases of malignant lesions of the stomach (Table I).

The ages of these patients were comparable to those reported from other sources. Finlayson reported the youngest patient as 3 $\frac{1}{2}$ years of age. Gosset reported the oldest

patient as being 85 years of age. The average age in the cases reported in the literature is about 40 years, whereas the average age of patients with carcinoma of the stomach is 61 years.

In our series, the youngest patient was aged 10 years, and the oldest, 67. The average age for the whole group was 43 years. This confirms the opinion of most writers that sarcoma of the stomach occurs earlier in life than does carcinoma of the stomach. The numbers of cases in various age periods were as follows: from 10 to 20 years, 2 cases; from 20 to 30 years, 7 cases; from 30 to 40 years, 7 cases; from 40 to 50 years, 16 cases; from 50 to 60 years, 12 cases; and from 60 to 70 years, 10 cases.

The literature conveys the impression that occurrence of sarcoma of the stomach is equal in both sexes. In our series there were 31 males and 13 females.

In only 4 cases in the series of 54 cases was a history of a malignant lesion in the immediate family elicited. The father of one patient had carcinoma of the stomach, the brother of another patient had carcinoma of the intestine, a third reported that his son had carcinoma of the rectum, a fourth said his mother had carcinoma the site of which he did not know.

CLINICAL FEATURES

The average duration of the symptoms of which the patients complained was 18 months. Sixteen of the group had had symptoms for from 2 to 9 years. The average for the remaining 38 patients was only 6 months. The average duration of symptoms in cases that proved to be inoperable was 11 months.

The presenting symptoms varied from a localizable gastric disorder to indefinite, general abnormal conditions which did not indicate the seat of trouble. The various chief complaints were as follows: dyspepsia in 23 cases, epigastric pain in 19 cases, epigastric tumor in 4 cases, bleeding in 3 cases.

the growth proved to be irremovable. In the 11 others, the growth had been successfully removed surgically. Ten patients of these 11 are dead. The 4 others represent a third of the 12 patients who are reported as being alive.

Desjardins said that of the sarcomata of the stomach, those which are most favorable for treatment by roentgen ray are lymphosarcomata and that if they could be diagnosed early enough they might be cured by irradiation alone. The basis for the effectiveness of this treatment is that the lymphocytes are more sensitive to the rays than are any other cells of the body. He has shown that if the body of a rabbit is irradiated for an hour, destruction of lymphocytes can be demonstrated.

The extent of the irradiation depends very much on the clinical aspects of the case and is always an individual problem. If the surgeon reports the lesion as limited to the stomach, then irradiation is limited to that region. If lymphatic involvement is reported, then irradiation is extended to the nodes over the omentum and the perigastric region. The question of whether or not to treat peripheral regions is determined by the presence or absence of palpable nodes in those regions. From 1 to 4 courses of treatment may be given to patients as the first series and these may be repeated later as the indications arise.

Definite results are obtained in the treatment of lymphosarcoma. In cases in which the growth has been removed irradiation apparently controls the extension of the process into lymphatic structures. In the inoperable cases, it has definite palliative value, and if irradiation is intelligently given the condition of the patient may be greatly improved for a considerable time. Many patients report marked improvement in their subjective gastric symptoms as well as in their general condition.

The other types of sarcoma, fibro angio sarcoma and myosarcoma, hold little promise so far as the efficacy of irradiation is concerned. The resistance of these tissues to irradiation is much higher than the sensitivity of the tissues of the upper portion of

the intestinal tract. Irradiation for a period sufficiently prolonged to affect such growths would lead to toxic disturbances in the upper intestinal mechanism such as are observed in mechanical intestinal obstruction.

PATHOLOGY

The difficulties in diagnosis are not entirely clinical. Experienced pathologists occasionally will hesitate to make a positive diagnosis in cases which prove, by the course of the disease and subsequent pathological examinations, to be sarcoma. In the case reported by Freeman, the specimen removed was sent to several pathologists of note who made diagnoses of carcinoma, lymphosarcoma, inflammatory tissue, and chronic granuloma.

The sarcomata of the stomach in the cases included in this series varied from one about 3 centimeters in diameter in a diverticulum of the stomach to a tumor which involved most of the stomach. Frequently the tumors were situated in the antrum, but usually far enough from the pylorus so that obstruction by the tumors was uncommon. One lesion was reported at operation to be obstructing the pylorus. In one instance the tumor extended from the stomach beyond the pylorus, and into the duodenum. The cardia was never involved. The most common situation of the tumors was on the lesser curvature, but the greater curvature and the anterior and posterior walls were also the site of origin of the lesions.

In the inoperable cases, the tumors were reported as being posterior, involving the pancreas, and also as extending into the omentum. In one instance there was a secondary mass in the pelvis. One lesion, also, was associated with multiple small tumors in the colon.

The mucosa was intact in some cases, whereas in others there was a defect, ranging from a small perforation about 1 millimeter in diameter to an extensive area of ulceration. Frequently, those patients with a history of gastro intestinal hæmorrhages had ulceration or perforation.

The record of gross metastasis does not throw much light on the prognosis of these

made malignant lesion in 35 cases, ulcer in 3, extragastric tumor in 2, possible benign tumor in 1 case, and negative in 5 cases

In these 45 cases in which roentgenological study was done, 8 of the lesions were reported as inoperable. Two of the group, however, were found to be resectable at operation

In 3 of 15 cases in which the lesions were found to be inoperable at exploration, roentgenological studies were not made because of the definiteness of the lesion. In 6 of the 12 other cases, the lesions were correctly reported as inoperable after roentgenological examination

In 38 cases, the lesions were operable, and all of these except 2 were reported as operable by the roentgenologist. These 2 were reported as of doubtful operability, in 1 case the patient has now lived for 6 years and 7 months. This shows the advisability of exploration in cases classified as of doubtful operability by the roentgenologist, if the rest of the clinical study justifies exploration

Most of the clinical diagnoses in the 54 cases were of carcinoma of the stomach. Two of the cases were diagnosed before operation as sarcoma and the roentgenologist called one of the growths a lymphosarcoma, which it proved to be at operation. The clinical diagnoses were as follows: carcinoma of stomach in 30 cases, abdominal tumor in 8 cases, ulcer of stomach or duodenum in 5 cases, benign tumor of the stomach in 3 cases, Banti's disease in 2 cases, pyloric obstruction in 2 cases, cystic gall bladder in 1 case, sarcoma in 1 case, and lymphosarcoma in 1 case

TREATMENT

The primary purpose of treatment is removal, and this paper is concerned only with the cases which came to operation. A variety of procedures was carried out as listed herewith: 15 patients in whom the tumors proved to be inoperable were subjected to exploration and none of them is living; 27 underwent the Polya type of resection, 8 of whom are living, 6 underwent sleeve resection and 2 are living, 3 were subjected to excision of tumor and 2 are living; palliative gastro-enterostomy was done for 2 patients neither of whom is living

There are several points connected with the surgical management of these lesions which are important. Seldom, if ever, except in children, is a lesion suspected of being a sarcoma, but in patients in the second or third decade of life a large tumor, known to be in the stomach, should always be suspected of being a sarcoma. Some of these tumors may be so large that surgical intervention appears inadvisable, but even when the roentgenological report suggests that the tumor is inoperable, it is occasionally found to be removable. The reason for this is that certain types of sarcoma are not of an infiltrating type and the line of demarcation of the tumor is definite. Thus the tumor may be so large, and situated so far to the left, as to be mistaken for a splenic or renal tumor and its origin determined only by fluoroscopic examination. Some of the tumors in this series had caused perforation of the stomach and had become fixed to adjacent structures, so that, when the abdomen was opened, the tumors appeared to be irremovable. Nevertheless, in such cases, after separation of the tumor it may be found that the malignant condition has not extended outside of the stomach and removal of the growth can be justifiably undertaken

The methods of resection are essentially the same as those employed for resection of carcinoma. In cases of sarcoma, however, there are more frequent indications for restoring gastro intestinal continuity by antecolic end to side entero anastomosis. More extensive resection can be accomplished in sarcoma than in carcinoma because of the sharper demarcation of the growth in the former

Coley's toxins were administered after operation in 2 of the cases in conjunction with irradiation. Freeman reported a case of lymphosarcoma in which only incomplete removal was possible and in which Coley's toxins and irradiation were used after operation. The patient was alive and well 2 years after operation. Irradiation by roentgen rays alone was used after operation in 14 cases. All of the lesions thus treated were examples of lymphosarcoma with the exception of one case of myosarcoma. In 3 of the 14 cases, simple exploration was carried out,

the cases, a ratio of operability of 66 per cent

Treatment consisted, when possible, of partial gastrectomy followed by administration of Coley's toxins and irradiation by roentgen rays in suitable cases

The tumors varied considerably in size, and several types of sarcoma were reported by the pathologist. Neither the type of tissue nor the presence of metastasis threw much light on prognosis

The immediate operative mortality for the whole group was 11.3 per cent

The postoperative duration of life in the cases in which only exploration was done averaged 4 months. The average duration of life after operation of those patients who underwent resection and have died was 11 months. The average postoperative duration of life for the 12 patients who were living when they were last heard from has been 5 years, 1 has lived for 9 years

cases Of the patients now dead nodes were reported to be uninvolved in 4 whereas in 11, lymphatic involvement was reported Of the patients now living (excluding those of the last 2 years) nodes were reported to be free of involvement in 6, and in 6 there was a report of lymphatic involvement In only 1 case in the series was involvement of the liver evident by the presence of nodules Extension of the lesion into the serosa, as shown by microscopic study, did not throw especial light on the prognosis Two of those patients in whom such extension was found are included in the group of patients who are living

Histological study of removed tissue was made in all but 5 cases In these 5, the diagnosis was made on the definite appearance of the gross lesion In 3 of the 49 cases in which tissue was submitted for diagnosis, the pathologist reported the possibility of the lesion being cellular carcinoma In 1 other case, that of a sarcoma of the stoma of a gastro enterostomy, the jejunum was involved apparently more than the stomach Therefore in this series there are 45 cases in which operation was performed and in which the diagnosis was based on definite histological study of the tissue The following pathological diagnoses were made lymphosarcoma in 32 cases, fibro-sarcoma in 5 cases myosarcoma in 3 cases angiosarcoma perithelial angiosarcoma and spindle cell sarcoma in 1 case each and sarcoma in 6 cases

Of the 12 cases in which the patients were living when last heard from the diagnosis was lymphosarcoma in 7, in the 5 remaining cases it was fibrosarcoma angiosarcoma perithelial angiosarcoma spindle cell sarcoma and sarcoma, respectively The ratio of lymphosarcoma and fibrosarcoma among the patients who are living is about the same as that in the whole series Therefore, a conclusion as to their relative malignancy cannot be drawn

RESULTS

The number of immediate deaths following operation in the whole series of 53 cases was 6 (11.3 per cent) One of these deaths resulted from hæmorrhage following simple exploration

The immediate mortality in the cases subjected to direct surgical procedures on the

stomach was 5 deaths in 38 cases (13.5 per cent) Two of these deaths were due to pneumonia without other complications, and 3 to peritonitis

The group in which simple exploration was done comprised 15 cases The youngest patient was 16 years of age the oldest 6 the average age was 41 The pre-operative duration of symptoms in this group was 11 months The group included most of the cases in which tissue was not taken for diagnosis, as the diagnosis appeared substantially correct by inspection The duration of life after the exploration averaged 4 months The longest duration of life was 11 months One patient lived only 2 days death was due to spontaneous hæmorrhage

Of the 38 patients from whom removal of the growth was accomplished 12 were living when last heard from and 26 were dead The average postoperative duration of life for those who died was 11 months the shortest duration was 3 months and the longest 7 years and 3 months

Of those living when last heard from the average postoperative duration of life has been 5 years The longest duration of life when the patient was last heard from was 9 years

SUMMARY

A clinical analysis of 54 cases of sarcoma of the stomach seen at The Mayo Clinic from January 1908 to July 1919 is offered In all but 1 case the patient came to operation The average age of the patients at the time of diagnosis was 43 years There was a preponderance of males over females in a ratio of 23 to 1 In only 4 instances was a family history of malignant disease elicited

The average duration of symptoms before operation was 18 months The presenting complaints were dyspepsia pain tumor bleeding weakness and vomiting Thirteen patients gave a history of gastrointestinal hæmorrhage Free hydrochloric acid was present in the gastric content of 60 per cent of the patients The majority of lesions were diagnosed as carcinoma of the stomach before operation was performed The tumor could be removed surgically in 36 of the cases it could not be removed in 15 of

III (moderate anæmia) Those patients with erythrocyte counts between 3.0 and 2.6 million form Group IV (severe anæmia) All patients with counts of 2.5 million or less fall in Group V (very severe anæmia)

Chart 1 indicates that in a study of one thousand pregnant women, regardless of the period of gestation, 47.4 or 47.4 per cent showed a moderate to a severe anæmia (below 3.6 million), whereas only 16.1 or 16.1 per cent had an erythrocyte count above 4 million.

The analysis of erythrocyte counts in relation to trimesters of pregnancy is shown in Chart 2. In the first two trimesters only 12.1 patients were available for study. Of this group 30 or 24.7 per cent manifested a moderate to a severe anæmia (below 3.6 million). Of the 722 patients examined in the third trimester, however, 41.0 or 56.7 per cent had a moderate to a severe anæmia, while 34 or 21.7 per cent of the 157 women examined during labor gave erythrocyte counts below 3.6 million. The preponderance of evidence shows anæmia to be most marked during the third trimester.

In Chart 3 hæmoglobin estimations during gestation are depicted. It is to be seen that a distinct hæmoglobinæmia (70 per cent or less) occurred in 58.6 patients or 58.6 per cent, whereas only 12.9 or 12.9 per cent of the women had a hæmoglobin percentage above 80.

Those patients with 70 per cent hæmoglobin or less were grouped according to the number of previous pregnancies. This was done so as to determine if any relationship exists between parity and the hæmoglobin deficiency. This grouping revealed that 28.5 of the patients were primigravidae while 71.5 had previously borne children. Of the 28.5 women pregnant for the first time, 16.4 or 54 per cent had a hæmoglobin estimation of 70 per cent or less, whereas 42.2 or 58 per cent of the multigravidae gave a percentage of 70 or less. Parity seemingly was not related to the low per centages of hæmoglobin.

Over 70 per cent of the patients were between the ages of 20 and 30. The anæmia was just as prevalent in the young women as in the older groups.

In making a microscopic examination of the blood, the usual changes of a secondary anæ-

TABLE I—ONE HUNDRED PATIENTS WITH TWO COUNTS IN PREGNANCY

No. of Patients	Millions of red blood cells per cmm in first two trimesters	Counts at term		
		Unchanged	Decrease 100,000 or more	Increased 200,000 or more
20	4 or over	2	15	3
35	3.9 to 3.6	13	13	9
36	3.5 to 3.1	2	12	20
9	3.0 or less	2	1	6
100		21	41	38

mia were in evidence, such as anisocytosis, polychromatophilia and poikilocytosis. The color index was less than 1.0 in every case.

COURSE OF ANÆMIA DURING PREGNANCY

To ascertain if any improvement occurs in the anæmia with the advance of pregnancy, counts were performed on 100 patients in the first two trimesters and again at term.

Table I reveals that 55 patients gave counts above 3.5 million prior to the seventh month. Of this group 28 or almost 50 per cent showed a decrease of 200,000 or more red cells at term. Of the 45 anæmic patients, only 13 or 28 per cent exhibited a similar decrease, whereas 26 or 58 per cent underwent a definite improvement. Thus, it appears that only those patients with a distinct anæmia in the early months of gestation showed any improvement at term. Patients becoming more anæmic with the advance of pregnancy should be observed carefully for evidences of serious disturbances in the blood forming organs.

ERYTHROCYTE COUNTS IN THE PUERPERIUM

The erythrocyte counts of 200 patients were performed within 48 hours after delivery and again 7 to 10 days postpartum in order to determine the immediate effect of childbirth. It is to be noted from Chart 4 that of the 106 patients with a moderate to severe anæmia, 16 per cent displayed a further reduction in the number of red cells immediately after delivery, whereas 58.4 per cent showed a marked rise. Of the group of 94 patients with normal counts during pregnancy (over 3.5 million), a much larger percentage (73.4 per cent) manifested a reduction shortly after labor.

Chart 5 denotes the marked improvement occurring 7 to 10 days after delivery, 72.6 per

THE "PHYSIOLOGICAL" ANÆMIA OF PREGNANCY

A STUDY OF ONE THOUSAND PATIENTS

P BROOKE BLAND M D, F A C S LEOPOLD GOLDSTEIN M D AND ARTHUR FIRST M D PHILADELPHIA
 From the Department of Obstetrics Jefferson Medical College Hospital Philadelphia

IN an earlier investigation (4) of the blood content in 300 pregnant women made by the writers, it was found that a deficiency in the number of red corpuscles and in the hæmoglobin content is not of unusual occurrence, being present in approximately one half of this class of patients. The present study has been extended to include a much larger number of gravid patients. Herewith is reported in systemized form the results of the blood counts and hæmoglobin estimations in one thousand gravid women in the different trimesters.

During the past 2 years routine hæmatological examinations were made on all gravid women in our antenatal clinic. These examinations consisted of erythrocyte, leucocyte and platelet counts, hæmoglobin estimations together with Wassermann and blood sedimentation tests. The results of the platelet determinations and of the blood sedimentation tests have been analyzed at some length in previous publications (5, 6).

The patients herein studied were of the ordinary clinical type, coming mostly from the tenements of the city and enjoying none of the advantages of luxury and wealth. Not one of these patients, however, had any complicating diseases at the time the count was performed.

The Thoma hæmacytometer supplied with the Leitz counting chamber and the Neubauer ruling was used in the enumeration of the erythrocytes. For the hæmoglobin determinations, the Dare hæmoglobinometer was employed, as it is believed to be sufficiently accurate for our purpose.

In the present study, the normal low limit for the red cells is set at 4.0 million per cubic millimeter, and for hæmoglobin content at 70 percent.

REVIEW OF LITERATURE

Nasse, in 1836 was the first to point out that the erythrocyte count was physiologically reduced during gestation. Besides the

"physiological" anæmia of pregnancy, two other types of anæmia occur occasionally in the gravid state: first, the pernicious type described by Channing in 1842 and, second, the severe hæmolytic anæmia discussed by Rowland, Allan, and others.

Numerous authors (Fouassier, Meyer, Bluenthal, Kuehnelt, and others) have shown that pronounced anæmia occurs frequently in pregnancy. Thompson claims it is most marked in the first and last trimesters of pregnancy. Gram in a study of 59 pregnant women made the average hæmoglobin estimate of between 71 and 79 per cent throughout gestation. Alder noted an average hæmoglobin of 50 per cent in a study of 11 patients. Kerwin and Collins observed a similar hæmoglobin anæmia. Lyon reported that 38 per cent of the women examined in the last trimester had a hæmoglobin content below 70 per cent. Gallo way found an anæmia existing in all three trimesters of pregnancy.

The question whether the anæmia improves with the advance of gestation is still a disputed point. Kuehnelt observed that a distinct improvement took place after the thirtieth week.

The progress of anæmia in the puerperium has been investigated by Fehling, Rucker, Given, Meyer, Dubner, Sieben, and others who contend that there is an even greater degree of anæmia shortly after labor with a subsequent improvement and that within 2 weeks after delivery the count rises higher than during pregnancy.

RESULTS OF ERYTHROCYTE DETERMINATIONS

For the purpose of clarity the patients were divided into five groups according to the severity of anæmia manifested. The patients with counts of 4 million or over comprise Group I (normal count). Those with counts between 3.9 and 3.6 million form Group II (mild anæmia). The patients with counts between 3.5 and 3.1 million comprise Group

Chart 4 Erythrocyte counts 24 to 48 hours after labor in 200 patients

Chart 5 Erythrocyte counts 7 to 10 days postpartum in 200 patients

1 The hypothesis advanced by Audral and others that the anemia is due to chlorosis, is a possible explanation

2 The contention of Kiwisch, Willcocks, and others, that there is a serous hydrops in pregnancy brought about by increased glandular activity, is also tenable. They believed that the relative deficiency was due to a progressive enlargement of the vascular area during gestation and to a large increase in the water of the plasma. This dilution of the blood might manifest itself in a lowered cell count, even though the erythrocytes were not actually reduced in number.

3 The belief that the anemia occurs only in the weak and undernourished gravid women, in those deprived of proper dietetic and medical treatment, is especially supported by Peter, Fehling Meyer, and Schroeder. The statistics published in our previous study, however, revealed that private patients coming from an environment conducive to good health likewise exhibited some anemia in pregnancy though not as severe as in the ward patients. From this observation, it is plausible to suppose that pregnancy itself had brought about the anemia. Furthermore, the marked improvement occurring 2 to 6 months after delivery in most of the ward patients tends to substantiate the anemic influence of pregnancy.

4 The theory of Hofbauer states that a syncytial hemolysin in the ectodermal cells of the chorion caused the maternal blood destruction. With the advance of pregnancy, an

antihemolysin formed in the mother's blood which prevented further blood destruction. If this failed to occur, a progressive anemia would continue during pregnancy. Therefore, it seems one is justified in assuming that there may be a combination of factors directly or indirectly responsible for the anemic condition so frequently encountered.

One of the most interesting facts brought out by the present survey is the return of the maternal blood to its relative normal state within 2 to 6 months after delivery. This certainly denotes that the anemia probably did not exist prior to gestation. One can conceive, however, that a patient who was anemic before and during pregnancy might improve considerably as the result of 12 days' rest in the hospital and careful postnatal management.

Lyon observed a similar anemia in a group of non pregnant women with retroversion, and

Chart 6 Erythrocyte counts 2 to 6 months after delivery in 100 selected cases

Chart 1 Erythrocyte counts in 1000 pregnant women (all trimesters)

cent of the 106 patients anæmic during pregnancy manifested a pronounced tendency to recover

It is our belief that the loss of blood during labor is primarily responsible for the diminution of red cells after labor. The multiplication of red corpuscles during the puerperium is probably due to the increased activity of the blood forming organs, nature's stimulation of hæmopoiesis to compensate for the primary blood loss in labor.

PROGRESS OF ANÆMIA TWO TO SIX MONTHS AFTER DELIVERY

One hundred selected patients with an anemia during pregnancy had another count taken 2 to 6 months after delivery. A comparison of these counts shows that many patients had made remarkable recoveries. Especially is this to be observed in the red cell tabulation (Chart 6) in which it is noted that of 60 patients with a count below 3.6 million

Chart 2 Percentages of counts below 3.6 million per cmm in different trimesters

during gestation, only 4 failed to rise above this level. However, 2 of these 4 patients showed an improvement of over 200,000, the other 2 on examination one year after delivery, had made no improvement. Although no patient in the selected group had a normal count in pregnancy, 61 of them gave counts of 4 million or over, 2 to 6 months after child birth. On final analysis it was found that an increase in the red cell count above 200,000 occurred in 92 patients.

Chart 7 shows that 43 patients (43 per cent) had a relatively normal hæmoglobin estimation (over 80 per cent) within 6 months after delivery, although none of these patients had over 80 per cent hæmoglobin during gestation. Only 18 patients with hæmoglobin below 70 per cent failed to rise above this level. However, of these 18 patients, 13 had actually gained over 10 per cent hæmoglobin, though the final estimation was still 70 per cent or lower.

Finally, it may be stated that 93 per cent of the group of 100 selected patients showed an improvement of at least 10 per cent in the hæmoglobin content.

DISCUSSION

In a previously published investigation (4) many factors were studied in order to disclose their possible relation to this blood deficiency. Foci of infection in the teeth, tonsils and urinary tract were believed to exert very little influence on the severity of the anemia. Syphilis and toxæmia were seemingly not prominent etiological factors. The specific cause of the secondary anemia therefore remains unknown.

Numerous theories have been advanced in explanation.

THE RELATION OF HEPATITIS TO CHRONIC CHOLECYSTITIS

HARRY KOSTER M.D., F.A.C.S. M. A. GOLDZIEHER M.D. W. S. COLLENS M.D. BROOKLYN NEW YORK

From the Surgical and Pathological Services of the Crown Heights Hospital

MANY patients who have been subjected to cholecystectomy for chronic gall bladder disease are not entirely cured of the symptoms which brought them to operation. The residual symptoms cannot be explained completely on the basis of a neurotic constitution, concomitant cardiovascular lesions, or senescence. Clinically it is true that the longer the duration of the disease before operative treatment is instituted, the less the likelihood of cholecystectomy relieving all the symptoms. This is not surprising when it is recalled that (1) anatomical investigations have demonstrated the association of permanent dilatation of the intrahepatic biliary passages with cholecystitis, (2) chronic inflammation of the gall bladder with repeated acute exacerbations may have produced an interference with the normal function of the sphincter of Oddi allowing reflux of bile into the pancreatic ducts leading to a chronic pancreatitis, (3) dense adhesions to, or perforations into, the stomach or duodenum from the gall bladder may interfere permanently with gastric and duodenal motility and thus leave permanent sequelae to the primary lesion. That there may be other reasons for the persistence of symptoms seems likely.

Because of the topographically and functionally close relationship between the liver

and the gall bladder, it was decided to reinvestigate histologically the livers of patients suffering from gall bladder disease.

A series of 27 cases was examined in the following way. Sections of the liver from both the right lobe and the left lobe were taken. In no instance was a section taken at a distance of less than 8 centimeters from the margin of the gall bladder bed. In some of these cases an injection of 5 cubic centimeters of 1 per cent trypan blue solution or 5 cubic centimeters of Higgin's India ink into the left gastro-epiploic vein was made prior to the excision. The sections were wedged-shaped and weighed almost 1 gram. The incisions extended at least one centimeter into the liver substance. They were fixed immediately in formaldehyde embedded in paraffin and were examined after they were stained with the usual methods.

HISTOLOGICAL DESCRIPTION

In 25 of the 27 cases, definite liver changes were found, although in Cases 7, 10, and 15 only one of the two specimens removed from different parts of the liver showed such lesions. In all these cases, there was definite histological evidence of chronic inflammatory change in the gall bladder.

There were only 2 cases in which no changes could be found in the liver. One of these (Case

Chart 7 Hemoglobin estimations 2 to 6 months after delivery in 100 selected patients

he, therefore, maintained that the anaemia of pregnancy represented a pre existing anaemia. The patients, however, who did not manifest any improvement in our series were probably anaemic before the advent of pregnancy. Thorough examination of these women may reveal other causative factors.

SUMMARY AND CONCLUSIONS

1 Of the one thousand patients examined in various periods of gestation, 47.4 per cent gave evidence of an anaemia, with red cell counts of 3.5 million or less.

2 A distinct haemoglobinemia of 70 per cent or less occurred in 58.6 per cent of the gravidæ.

3 Only 24.7 per cent of the patients examined in the first two trimesters showed a moderate to a severe anaemia in contrast to 56.7 per cent of the patients examined in the third trimester. Although the latter group constitutes a much larger number of patients we feel that the anaemia is as a rule more marked with the advance of pregnancy. Of a group of 35 patients with a definite anaemia in the early months of gestation, 26 showed improvement at term.

4 Of 106 patients with a moderate to a severe anaemia, however, 58.4 per cent began to show improvement within 1 to 2 days after childbirth. Of 94 patients with a mild anaemia or a normal count during pregnancy, 73.4 per cent showed the effect of labor by a further

reduction of the red cell count within 24 to 48 hours.

5 A marked improvement ensued within 7 to 10 days after labor, occurring in approximately 72.6 per cent of the 106 patients anaemic during pregnancy.

6 The most interesting feature disclosed by this study was the remarkable recovery developing within 2 to 6 months after delivery. A distinct improvement in the red cell count took place in 92 per cent of the 100 patients examined. In 95 per cent there was also a marked improvement in the haemoglobinemia.

NOTE: The Dare hemoglobinometer employed in this study was tested and standardized at frequent intervals by Dr. Baxter L. Crawford, pathologist to the Jefferson Medical College Hospital.

Fig. 1 Section from liver Periportal infiltration Multiple small intrahepatic nodules Low power

from the bile 2 minutes after injection into the portal vein

Recent work has also shown that bacteria circulating in the blood stream are ingested first by the Kuepfer cells and many of these bacteria survive the process of phagocytosis and remain viable in the body of the cell for days and weeks. An elimination of these bacteria occurs after any kind of stimulation of the Kuepfer cells when they appear in the bile.

Such observation would point to another very probable source of infection of the gall bladder. That is, through the bile ducts through which the infected liver bile reaches the gall bladder and begins the infection of the latter. The fact that Graham succeeded in demonstrating the same bacterium in cultures from both the liver tissue and from the bile in the gall bladder would be in perfect harmony with such a process. Experimental evidence also points in this direction. It has been shown by Wilkie that cholecystitis can be produced in rabbits by intravenous injection of streptococci. If, however ligation of the cystic duct precedes the injection of streptococci, no cholecystitis can be observed. It is also of great importance in these experiments that no liver changes occur in the cases in which ligation of the cystic duct seems to prevent the development of cholecystitis. On the other hand, in cases in which cholecystitis does develop the liver changes observed are quite similar to those described by Graham and by us. Wilkie also showed that liver changes

Fig. 2 Section from liver Small bile duct and vein surrounded by a coat of round cells including a few polymorphonuclear leucocytes

could be prevented in cases in which cholecystitis was produced experimentally by the intravenous injection of streptococci if the gall bladder had previously been dissected free from its bed so that it hung from its vascular and biliary pedicle and was prevented from readhering to the liver bed by the interposition of omentum.

Graham tries to overcome this apparent incongruity by suggesting the lymphatic path for the spreading of the infection from the liver to the gall bladder. This view has also been supported by Judd.

Graham states that hepatitis begins and is most marked in the periportal tissue. The infection is apparently brought to the liver by the portal vein and more rarely perhaps by the hepatic artery. Pericholangitis then occurs and because of the intimate anastomosis between the lymphatics of the intrahepatic and extrahepatic biliary systems, a direct extension takes place into the wall of the gall bladder. It is perhaps a vicious cycle between the gall bladder and liver whereby each may infect the other. Still, the majority of the cases of cholecystitis, according to him, represents a lymphatic spread from the liver. The minority includes some hematogenous cases, some contact infections from bacteria carried down in the bile and a few cases which may have originated from an ascending infection of the common duct.

17) showed anatomically distinct lipoid infiltration of the gall bladder mucosa (strawberry gall bladder) but no other changes indicating even a moderate degree or a healing stage of cholecystitis. The other case (24) was operated on with the diagnosis of cholecystitis but a peptic ulcer of the pylorus was found and the gall bladder proper did not show inflammatory changes, histologically.

On examining the slides with low power magnification it was easy to ascertain that there were numerous foci of cell infiltration. These foci were observed mainly in the connective tissue about the larger intrabepatic branches of the portal vein. Such infiltration spread eccentrically from one side of the vessel wall toward the periphery and only occasionally surrounded the whole lumen. The infiltration was usually more of a diffuse character and tended to spread over the ramifications of the periportal stroma. Closer examination revealed that the areas most heavily infiltrated were those in which small bile ducts could be seen. Wide lymph vessels were also often observed in some of these areas.

Besides these conspicuous perivascular infiltrations quite a few nodules were scattered throughout the liver tissue which appeared on low power examination as primary intrahepatic foci. Invariably however a bile duct was visible in the center and it was demonstrable that the aggregation of cells took place in the connective tissue which surrounded this bile duct. Smaller branches of the portal vein and lymph vessels could also be seen.

The cells found in both perivascular infiltrations and the scattered nodules were of various types including lymphocytes, a few plasma cells, histocytes, fibroblasts, polynuclear leucocytes and occasionally eosinophiles. The presence of histocytes could be established clearly in those cases which prior to the excision had received an injection of India ink or trypan blue. Storage of the dyes by some of these cells revealed their true nature and determined them as cells of the active mesenchymal type. Polynuclear leucocytes were not found in every case. They were most numerous in Case 2 in which the inflammatory condition of the gall bladder was also of a more subacute type.

Examination of the liver tissue outside of the nodules and perivascular infiltrations showed certain changes of varying intensity. They consisted of the presence of a larger number of Kupffer cells than usual and of the presence of fairly numerous cells in the lumen of the intertrabecular liver capillaries. These cells included polynuclear leucocytes, lymphocytes, and particularly large mononuclear cells, most of which belonged obviously to the group of monocytes. These intracapillary changes were not met with in every case and their intensity was unequal in its distribution over a single slide.

We can summarize these changes as follows. There is an interstitial hepatitis of varying intensity which is localized essentially in the periportal connective tissue. The inflammation is of a chronic character and seems to center about the larger branches of the portal system.

The presence of inflammatory changes in the liver in cases of gall bladder disease has been stressed by Graham (5) in a series of papers in which he tried to show that such changes are practically constantly associated with cholecystitis. Experimental work done by the same author led him to the belief that there was a casual connection between liver and gall bladder changes. Graham (6) recognized two ways of infection. One is the direct hematogenous route whereby bacteria reach the gall bladder wall through the circulation and bacterial emboli in the gall bladder capillaries are responsible for the onset of inflammation. The other way is that of lymphatic spread from the liver through the outer coats and finally to the mucosa of the gall bladder. Graham believes that the latter is the more common and almost regular way in which infectious cholecystitis is brought about.

It has been proved beyond any reasonable doubt that bacteria which circulate in the blood either in case of septicemia or after experimental injection into the blood are rapidly excreted from the liver and pass into the bile as in the process of normal secretion. This has been shown experimentally for typhoid bacilli (Doerr and Chiarolanza), bacillus prodigiosus (Fuetterer), and staphylococcus (Biedl and Kraus). Fuetterer was able to recover bacteria

titis and concomitant liver changes. Wilkie's experiments, in which the gall bladder was separated from the liver by the interposition of omentum and in which cholecystitis was produced by the intravenous injection of streptococci but no liver changes developed subsequently, are further substantiation of our objection to Graham's interpretation. Graham himself in a later paper seems to realize the fallacy of his early statements and admits the possibility of liver infection secondary to gall bladder disease. He maintains, however, the conception of a vicious cycle according to which the infection would also spread from the liver to the gall bladder.

If Graham's point of view were correct we should find severe inflammatory changes of the gall bladder in all cases of severe hepatitis. This is not borne out by actual clinical and postmortem experience.

Our histological findings corroborate those of Graham, but the arguments presented induce us to take a contrary view of the pathogenesis of the hepatic lesion. We maintain that the gall bladder lesion is prior to the development of inflammatory changes in the liver. The mechanism of the production of gall bladder infection still remains a question. It is most probable that gall bladder infection is brought about by bacteria laden bile. It seems also logical to assume that in most or perhaps in all, cases the bile contamination results from bacteria which have passed through the capillary filter of the liver without the production of noteworthy local changes. The infection once developed in the gall bladder spreads to the liver through some of the lymphatics of the gall bladder which drain into the liver. The products of such gall bladder infections bacterial or otherwise once in the liver are carried through the larger lymphatics to the periportal tissue and are responsible for the changes described in this paper.

This conception of secondary involvement of the liver in primary gall bladder disease can be reconciled to the clinical observation that patients with long standing gall bladder disease are less frequently and completely relieved of their symptoms by cholecystectomy than are those in whom the disease has been of shorter duration. It also suggests another reason for the plea for earlier surgical treatment in gall bladder disease.

SUMMARY AND CONCLUSIONS

- 1 Changes in the liver coincident to cholecystitis are described
- 2 These lesions are interpreted as chronic hepatitis predominating in the periportal tissue
- 3 The relationship of the liver lesion to chronic gall bladder disease is discussed
- 4 Evidence is presented to demonstrate that the liver changes are secondary to gall bladder inflammation

We desire to express our thanks to the members of the Staff of the Crown Heights Hospital whose co-operation made it possible to secure the clinical material for study.

Fig 3 Section from liver Intrahepatic nodules surrounding small bile ducts Small lymph vessel in the center

Fig 4 Section from liver Small nodule eccentrically adjoining a bile duct Storage of fine India ink granules in the histocytes

Our histological findings confirm those of Graham. This is of considerable importance since in our cases the sections were taken at so great a distance from the gall bladder bed that it would be impossible to ascribe the changes to the spreading of the inflammation by direct extension. Similar lesions were found in sections taken from the left lobe of the liver on the other side of the falciform ligament, through which some of the lymphatics of the liver drain.

This seems to establish the constant association of interstitial hepatitis with cholecystitis. The explanation of the pathogenesis of the liver lesion as described by Graham does not seem warranted. Description of the lymphatics of the gall bladder and of the liver and the consideration of the functional value of both organs would make it difficult to accept lymphatic drainage from the liver to the gall bladder. That the drainage normally goes the other way seems more likely from the work of Rous and McMaster showing the absorption of water from the gall bladder in the process of concentrating bile. Harer, Hargis and Van Meter introduced a hypertonic solution of potassium sulphocyanide into the gall bladder lumen and then collected lymph from the subserous lymphatics by cannalization with capillary tubes. The lymph so obtained gave a Prussian blue reaction with ferric chloride.

Primary hepatic inflammation by hematogenous infection does not localize in the peri-

portal connective tissue and is at variance with the picture which we have described. Bacteria circulating in the blood in case of septicæmia or after experimental injection are taken up by the phagocytic cell of the liver sinuses. The reaction to the presence of bacteria in these sinuses is manifested by exudation and proliferation at those points with extension into the adjacent liver tissue. The periportal tissue may participate in this process later on, but the changes here if they do occur do not appear as the outstanding features of the inflammatory reaction. This type of lesion presents a great contrast to the histological picture obtained in an ascending biliary infection in which the lesion is predominantly periportal.

The two arguments presented would indicate that exception must be taken to two basic contentions in Graham's paper. His theory assumes primary infection of the liver and spreading of the inflammatory process to the gall bladder through the lymphatics. These concepts are not tenable in view of the anatomical, physiological and pathological evidence just presented. Further support of our position against that of Graham is furnished by the experimental work of Wilkie, who demonstrated the significance of descending contact infection in the pathogenesis of cholecys-

We have observed 23 cases of this localized type of chronic ulcerative colitis, in 15 of which the patients were first seen in 1928 and in the first half of 1929. In only 1 case had the diagnosis been made before the patient came to the clinic. This led us to report this series of cases. There seems to be little doubt that other similar cases have passed through our hands unrecognized. In the 23 cases, surgical exploration was carried out in 11 and the suspected disease was confirmed. The condition most frequently confused with, or suspected in, these cases was tuberculosis. Surgical intervention seemed wise in several cases to determine whether or not tuberculosis was present and in 3 further verification was obtained by necropsy.

The clinical story in most of these cases aroused suspicion, but in none was it entirely diagnostic. The salient features included in intermittent attacks of diarrhoea, or of frequent rectal discharges, usually mixed with mucus and streaked with blood. At times a severe haemorrhage was the first indication of trouble. Pain was a prominent feature in all but one case, usually it was cramp like and was felt along the line of, or in some portion of, the colon. At times it came in attacks lasting a few days, with twinges of pain off and on and then there was complete freedom for a few days, resembling in some instances the colic like pain of cholecystic disease.

The diarrhoea or frequency of rectal discharges was rarely as great as in the usual severe case of chronic ulcerative colitis, but it was more frequently associated with grueling cramps. Fever of low grade was usual and loss of weight was rather striking; one patient lost 50 pounds in 4 months.

Data obtained by roentgenograms of the colon, after barium enema, are given in the tabulation.

SUMMARY OF HISTORIES OF ELEVEN ILLUSTRATIVE CASES

CASE 1. A merchant, aged 50 years, came to the clinic August 25, 1928, with a history of occasional rectal bleeding of 4 or 5 years' duration. The blood had been mixed with the stools and the stools had been streaked with blood. The day before admission he had suffered a severe rectal haemorrhage with collapse which had subsided with rest and sedatives.

Fig. 1. Case 1. Spastic deformity involving the transverse colon.

so that by August 29 we felt safe in making roentgenological examination of the colon after injection of barium. The roentgenoscopic examination disclosed the entire transverse colon involved in an extensive spastic deformity with considerable irregularity of the contours of the lumen. Proximal to the hepatic flexure and distal to the splenic flexure the colon was normal (Fig. 1). Proctoscopic examination did not give evidence of chronic ulcerative colitis.

CASE 2. A plumber aged 48 years, came to the clinic August 5, 1929 with a history of having had diarrhoea since 1904. Meanwhile he had felt run down. He had been having a slight elevation of temperature, frequent night sweats and weakness. The diarrhoea had consisted of about eight rectal discharges every 24 hours. A diagnosis of pulmonary tuberculosis had been made, although no abnormalities had been noted in the thorax and he had been confined in a sanitarium for tuberculosis for 4 months. Examinations of sputum and stool had failed to reveal acid fast bacilli. During his care in sanitarium his fever had subsided and his general condition had improved, but the condition of the bowel had remained the same. In addition to the continued diarrhoea there had been attacks of bleeding, distress in the epigastrium and at times pain in the region of the umbilicus which sometimes had required hypodermic injections and which sometimes had been relieved by vomiting. Proctoscopic examination August 9 disclosed a normal

THE designation "chronic ulcerative colitis" suggests to clinicians of any considerable gastro-intestinal practice a serious infectious disease. That the name is inadequate is generally agreed. "Colitis" is a loose term which in the minds of many includes intestinal conditions, both organic and functional without the necessary presence of inflammation of the colon. This should not be so. "Chronic ulcerative" might easily be taken to refer to other than one type of inflammation. The German term "colitis gravis" connotes its seriousness. It does not convey the idea of its suppurative nature. The two words "ulcerative" and "colitis" seem well chosen. In addition there should be a modifying term to designate etiology. "Bacterial" may not be specific enough but will serve to distinguish the condition from the parasitic, tuberculous, chemical or toxic ulcerations of the colon.

The clinical signs and symptoms of chronic bacterial ulcerative colitis include a history of frequent rectal discharges of blood, pus, and mucus, mixed with feces of variable consistency, depending in a large measure on the extent to which the colon is involved. The ulceration usually begins in the rectum and spreads upward eventually to involve the entire colon. It may, however, affect any part of the colon and occasionally several parts of the colon. Early in the course of the disease or at a time when the rectum and rectosigmoid portion of the colon only are affected the stools may be scybulous and surrounded by or mixed with blood, also there will be frequent passages of shreds of bloody pus and mucus, with great desire to strain, and occasionally with gripping pain and tenesmus. When all or most of the colon is involved the stools are liquid or mushy and mixed with mucus, blood, and pus. Gruelling cramps are not uncommon. Distress from gas, gripping

and various sensations along the course of the colon are often experienced. A peculiar gray pallor is common, and varying degrees of anemia exist. In the severer cases a morbid body odor prevails. An anxious, rather hopeless facial expression is not uncommon. The patient's lack of control of the bowel, with the feeling that he must remain near a lavatory, may account for some of this. Much weight may be lost.

A septic type of fever occurs in the severe fulminating cases, although slight elevation of temperature is common in chronic cases. Mild leucocytosis, with polymorphonuclear leucocytes predominating is the rule. Depleting chronic invalidism occurs rather early in the disease. There is a form of this disease hitherto not well understood, namely cases in which the mucosa in the view of the proctoscope and sigmoidoscope, is normal.

The literature is lacking in descriptions of an ulcerative condition of the colon of the type of chronic ulcerative colitis in the absence of proctoscopic evidence. At The Mayo Clinic, in recent years cases have come to our attention in which there was no proctoscopic evidence of chronic ulcerative colitis yet the patients presented themselves with symptoms similar to those described in the preceding paragraphs and they were found to have extensive involvement of other parts of the colon.

Previously we have stressed the great importance of the barium enema in the diagnosis of chronic ulcerative colitis. In the group of cases here described the roentgenogram is the sole method of gaining a clue to the diagnosis other than clinical assumption.

In some instances surgical exploration has become necessary to confirm the diagnosis or else because of obstruction or other complication operation has afforded opportunity to establish the diagnosis.

We have observed 23 cases of this localized type of chronic ulcerative colitis, in 15 of which the patients were first seen in 1928 and in the first half of 1929. In only 1 case had the diagnosis been made before the patient came to the clinic. This led us to report this series of cases. There seems to be little doubt that other similar cases have passed through our hands unrecognized. In the 23 cases surgical exploration was carried out in 11 and the suspected disease was confirmed. The condition most frequently confused with, or suspected in, these cases was tuberculosis. Surgical intervention seemed wise in several cases to determine whether or not tuberculosis was present, and in 3 further verification was obtained by necropsy.

The clinical story in most of these cases aroused suspicion, but in none was it entirely diagnostic. The salient features included in intermittent attacks of diarrhoea, or of frequent rectal discharges usually mixed with much pus and streaked with blood. At times a severe haemorrhage was the first indication of trouble. Pain was a prominent feature in all but one case, usually it was cramp like and was felt along the line of, or in some portion of the colon. At times it came in attacks lasting a few days, with twinges of pain off and on, and then there was complete freedom for a few days, resembling in some instances the colic like pain of cholecystic disease.

The diarrhoea or frequency of rectal discharges was rarely as great as in the usual severe case of chronic ulcerative colitis, but it was more frequently associated with grueling cramps. Fever of low grade was usual and loss of weight was rather striking, one patient lost 50 pounds in 4 months.

Data obtained by roentgenograms of the colon, after barium enema, are given in the tabulation.

SUMMARY OF HISTORIES OF ELEVEN ILLUSTRATIVE CASES

CASE 1. A merchant aged 50 years came to the clinic August 25, 1928 with a history of occasional rectal bleeding of 4 or 5 years duration. The blood had been mixed with the stools and the stools had been streaked with blood. The day before admission he had suffered a severe rectal haemorrhage with collapse which had subsided with rest and sedatives.

Fig. 1. Case 1. Spastic deformity involving the transverse colon.

so that by August 29 we felt safe in making roentgenological examination of the colon after injection of barium. The roentgenoscopic examination disclosed the entire transverse colon involved in an extensive spastic deformity with considerable irregularity of the contours of the lumen. Proximal to the hepatic flexure and distal to the splenic flexure the colon was normal (Fig. 1). Proctoscopic examination did not give evidence of chronic ulcerative colitis.

CASE 2. A plumber, aged 48 years came to the clinic August 5, 1929 with a history of having had diarrhoea since 1924. Meanwhile he had felt run down. He had been having a slight elevation of temperature, frequent night sweats and weakness. The diarrhoea had consisted of about eight rectal discharges every 24 hours. A diagnosis of pulmonary tuberculosis had been made although no abnormalities had been noted in the thorax, and he had been confined in a sanitarium for tuberculosis for 4 months. Examinations of sputum and stool had failed to reveal acid fast bacilli. During his care in sanitarium his fever had subsided and his general condition had improved but the condition of the bowel had remained the same. In addition to the continued diarrhoea there had been attacks of bleeding distress in the epigastrium and at times pain in the region of the umbilicus which sometimes had required hypodermic injections and which sometimes had been relieved by vomiting. Proctoscopic examination August 9 disclosed a normal

THE designation "chronic ulcerative colitis" suggests to clinicians of any considerable gastro intestinal practice, a serious infectious disease. That the name is inadequate is generally agreed. "Colitis" is a loose term which in the minds of many includes intestinal conditions, both organic and functional, without the necessary presence of inflammation of the colon. This should not be so. "Chronic ulcerative" might easily be taken to refer to other than one type of inflammation. The German term "colitis gravis" connotes its seriousness. It does not convey the idea of its suppurative nature. The two words "ulcerative" and "colitis" seem well chosen. In addition there should be a modifying term to designate etiology. "Bacterial" may not be specific enough but will serve to distinguish the condition from the parasitic, tuberculous, chemical, or toxic ulcerations of the colon.

The clinical signs and symptoms of chronic bacterial ulcerative colitis include a history of frequent rectal discharges of blood, pus and mucus, mixed with feces of variable consistency, depending in a large measure on the extent to which the colon is involved. The ulceration usually begins in the rectum and spreads upward, eventually to involve the entire colon. It may, however, affect any part of the colon, and occasionally several parts of the colon. Early in the course of the disease or at a time when the rectum and rectosigmoid portion of the colon only are affected the stools may be scybalous and surrounded by or mixed with blood, also there will be frequent passages of shreds of bloody pus and mucus, with great desire to strain and occasionally with gripping pain and tenesmus. When all or most of the colon is involved the stools are liquid or mushy and mixed with mucus, blood, and pus. Gruelling cramps are not uncommon. Distress from gas, gripping,

and various sensations along the course of the colon are often experienced. A peculiar gray pallor is common, and varying degrees of anemia exist. In the severer cases a morbid body odor prevails. An anxious, rather hopeless facial expression is not uncommon. The patient's lack of control of the bowel with the feeling that he must remain near a lavatory, may account for some of this. Much weight may be lost.

A septic type of fever occurs in the severe fulminating cases, although slight elevation of temperature is common in chronic cases. Mild leucocytosis, with polymorphonuclear leucocytes predominating is the rule. Depleting chronic invalidism occurs rather early in the disease. There is a form of this disease hitherto not well understood, namely cases in which the mucosa in the view of the proctoscope and sigmoidoscope, is normal.

The literature is lacking in descriptions of an ulcerative condition of the colon of the type of chronic ulcerative colitis, in the absence of proctoscopic evidence. At The Mayo Clinic, in recent years, cases have come to our attention in which there was no proctoscopic evidence of chronic ulcerative colitis yet the patients presented themselves with symptoms similar to those described in the preceding paragraphs and they were found to have extensive involvement of other parts of the colon.

Previously we have stressed the great importance of the barium enema in the diagnosis of chronic ulcerative colitis. In the group of cases here described the roentgenogram is the sole method of gaining a clue to the diagnosis other than clinical assumption.

In some instances surgical exploration has become necessary to confirm the diagnosis or else because of obstruction or other complication operation has afforded opportunity to establish the diagnosis.

Fig 3 Case 3 The localized narrowing just distal to the site of ileocolostomy resembles the constriction in Figure 2

tory of having had loose stools for $2\frac{1}{2}$ years a condition which had become progressively worse until in 24 hours he had been passing between 25 and 30 watery stools mixed with mucus and blood. On admission he was having between 8 and 12 such discharges. Exploration September 24, 1934 gave evidence of chronic ulcerative colitis of the transverse colon for which a permanent ileostomy opening of the modified Brown type was done. Considerable improvement in the patient's general condition followed. March 18, 1925 plastic repair of a mal-functioning ileostomy opening was made and a postoperative ventral hernia was repaired. Death occurred 9 days later from generalized peritonitis.

CASE 6 A married woman aged 26 years who came to the clinic June 16, 1938 had begun to have trouble with her bowels following a severe attack of influenza 3 years previously. At no time since had she had more than 5 or less than 3 loose stools in 24 hours. There had been very little mucus and blood had not been observed; however the patient used an outside toilet and mucus or blood might not have been observed. Proctoscopic examination showed normal rectal and sigmoidal mucosa and roentgenologic examination disclosed extensive narrowing and loss of haustra of the hepatic flexure and entire transverse colon. In Figure 5 besides abrupt narrowing and destruction of normal contour inadequate filling due to the marked hyperirritability is

Fig 4 Case 3 There is marked improvement in the deformity. The roentgenogram was made 4 weeks after that shown in Figure 3

shown. Figure 6 shows a large portion of the small intestine filled with opaque medium, but the uppermost transverse segment is the transverse colon after the condition has improved. The roentgenogram was made 5 weeks after that shown in Figure 5. Concentration of the medium and apparent widening of the involved segment are shown.

CASE 7 A married woman aged 35 years came to the clinic in August, 1925 with a history of gnawing epigastric pain of 4 years duration. The pain had come on in attacks lasting 3 or 4 weeks at a time with free intervals of 6 to 8 weeks. Food or soda had not given relief. Nausea and vomiting occasionally had been associated with the pain. For this reason appendectomy and abdominal exploration had been done in October, 1924 at which time disease of the stomach had not been found. There had been no history of diarrhea but there had been intermittent loose stools with alternate periods of constipation. Roentgenograms of the thorax, gall bladder and stomach gave negative results at this time. Roentgenologic examination October 3, 1935 showed little narrowing but marked absence of haustra and some firmness of the marginal contours of the transverse and ascending colon. Exploration October 12, 1925 resulted in a diagnosis of chronic ulcerative colitis of the ascending and transverse colon. Treatment consisted of a vaccine prepared from the diplococcus of chronic ulcerative colitis obtained from other patients with chronic ulcerative colitis. Subsequent examination revealed

Fig 2 Case 2 Diffuse narrowing of the ascending colon with marked annular deformity of the proximal part of the transverse colon

rectal mucosa for 4 cm. Roentgenologic observation after barium enema revealed abrupt narrowing over a short segment of the transverse colon near the hepatic flexure. Attention is called in Figure 2 to the marked irregularity in the contour of the involved portion due to the deep ulceration. This filling defect might easily be confused with that resulting from an annular carcinoma except for its great length. There were no clinical signs of pulmonary disease and roentgenogram of the thorax gave negative results.

CASE 3 A manager of a Canadian packing firm aged 49 years came to the clinic July 4, 1929, with a history of difficulty with the bowels dating back to 1913 at which time a diagnosis of ulceration of the colon had been made and treatment with silver nitrate, ichthyol and glycothymolin had been instituted and clinical cure accomplished. In 1911 he had had a recurrence of the same or similar trouble. In the course of these attacks he had had four to six rectal discharges with urgency and the passage of blood and pus. Treatment similar to that given before had resulted in relief from symptoms. January 1, 1926, he had felt a certain uneasiness in the right side of the abdomen and examination had revealed tenderness and a mass. This had resulted in operation for drainage of an abscess in the right side of the abdomen which had been followed by a fecal fistula. Four months later resection of the right half of the colon with closure of the fecal

fistula had been done and after a stormy convalescence the patient had seemed free of symptoms until January, 1929, when he had begun to notice blood in the stools with frequency so that he had had to get up several times at night to move his bowels. This had continued with aggravation and partial remission until his admission to the clinic at which time he was having six to seven rectal discharges with blood and pus in 24 hours. The proctoscopic examination at this time showed evidence of old chronic ulcerative colitis and multiple small polyps. Roentgenoscopic examination of the colon exhibited a freely emptying enterocolostomy opening near the hepatic flexure and just distal to its point of attachment a short narrowed segment of transverse colon of rough contour similar in all respects to that shown in Figure 2. In Figure 3 the inadequate filling of the involved segment is contrasted with the good concentration of opaque medium in Figure 4 after a short period of treatment.

CASE 4 A railroad switchman aged 42 years came to the clinic May 7, 1928, stating that his trouble had begun rather suddenly with diarrhea in March, 1927, and that it had continued for 6 months with a movement of the bowel every 2 to 3 hours. The stools had been watery with small amounts of mucus and considerable blood. The patient had been hospitalized for 4 weeks during May and June and the diarrhea had subsided. On leaving the hospital he had been very weak and did not return to work until the following October. The movements of the bowels had been regular until early in March, 1928, when he had found great difficulty in moving them. He spoke of the condition as progressively increasing constipation with soreness in the left lower quadrant of the abdomen and blood in the stools. At this time in the general examination it was noted that the descending colon was palpable and cord like. After 6 months the trouble subsided. At the time of examination at the clinic proctoscopic examination did not show evidence of chronic ulcerative colitis but the mucosa just above the anus anteriorly was thrown into indurated folds as of an old rectal abscess. Roentgenologic examination revealed extensive spastic deformity of the distal segment of the transverse colon and proximal two thirds of the descending colon. In several short segments there was abrupt narrowing with considerable destruction of mucosa. The colon both proximal and distal to the involved portion was normal.

CASE 5 A barber aged 38 years came to the clinic in September, 1924, at which time the roentgenologic investigation showed an extensive irregular partly spastic filling defect involving the hepatic flexure and proximal third of the transverse colon. A similar deformity of the rectum was present and was assumed to be another probably the primary focus. A diagnosis of ulcerative rectal stricture with incontinent anal sphincter and a filling defect in the transverse colon was made. The patient had a his-

Fig 7 Case 10 There is one deformity at the hepatic flexure and another in the sigmoid. The former is healing; the latter shows evidence of active chronic ulcerative colitis.

Fig 8 Case 11 There is diffuse narrowing of the cæcum and proximal part of the ascending colon with mucosal destruction.

in the bowel probably the sanguinopurulent discharge from the lesion which was subsequently found although there was a suggestion of a lesion in the descending colon near the splenic flexure. Proctoscopic examination April 24 showed that the sigmoidal mucosa bled more easily than normal. Otherwise there were no rectal pathological lesions. Because of the patient's age and the history of bleeding exploration was advised. April 30 exploration revealed chronic ulcerative colitis from the middle of the transverse colon to the middle of the sigmoid flexure of the colon with the most intense disease in the splenic flexure. Under treatment with serum the patient was relieved of symptoms.

CASE 10 A woman aged 29 years came to the clinic August 1, 1929. She had had much trouble with abscesses and infections for 11 years. These had included an appendiceal abscess in 1918, cholecystitis in 1921, and streptococcal peritonitis in 1926 for all of which operations had been undertaken elsewhere. In November 1918 the patient had begun to pass blood and mucus in the stools with considerable cramping pains. Colonic irrigations with solution of potassium permanganate were undertaken without bringing relief. On admission to the clinic the complaint was of partial intermittent intestinal obstruction with cramp like pain in the right side and middle of the abdomen associated with periods of distention and bloating inability to

move the bowels and between such attacks, the passage of blood, pus and mucus in the stools. Proctoscopic examination showed that the mucosa was normal for 24 centimeters. Roentgenologic examination exhibited abrupt narrowing in the proximal half of the sigmoid colon with marked irregularity of the contour of the involved portion. The lesion resembled closely those observed in Cases 2, 3, 5, and 6. There was also a marked organic stricture in the distal limb of the hepatic flexure (Fig 7). Exploration September 6 disclosed two regions of chronic ulcerative colitis, one in the sigmoid colon and one in the transverse colon, near the hepatic flexure, the latter of which had caused a stricture. Cæcosigmoidostomy was done, serum was administered and marked clinical improvement resulted.

CASE 11 A woman aged 31 years came to the clinic October 13, 1925. She had had diarrhoea with the passage of 20 to 24 loose green stools in 24 hours without noticeable blood. She had also had numerous painful sores in her mouth on her lips and tongue. On admission her weight was 78 pounds and she had a temperature of 100.6 degrees F. Roentgenoscopic investigation disclosed considerable narrowing with evidence of mucosal destruction in the cæcum and proximal part of the ascending colon. There was some evidence of marked irritability of the terminal portion of the

Fig. 5 Case 6 The transverse colon is extensively involved and the deformity is typical of chronic ulcerative colitis. Disease is not evident elsewhere in the colon.

Fig. 6 Case 6 The arrows point to the involved segment of the transverse colon shown in Figure 5. Marked improvement has taken place after specific treatment.

the colon after some treatment had been given. Slight irregularity of the margins remained but the involved portion was more pliable and showed some return of haustral markings.

CASE 8. A printer aged 31 years came to the clinic April 8, 1919. He had been well up to 4 years before his coming to the clinic at which time he had begun to have generalized cramping abdominal pains associated with mucus in the stools and relieved by movements of the bowels and the passage of gas. After 3 months of this he had begun to have diarrhoea with 6 to 9 stools in 24 hours mixed with blood, mucus and much flatus. This had continued for about 2½ years and had resulted in a diagnosis of chronic ulcerative colitis being made elsewhere. The only improvement had been for several weeks in the latter part of November 1917 the trouble soon had recurred. Roentgenologic investigation done elsewhere at this time had revealed a narrowed descending colon of smooth contour without haustra apparently hyperirritable and unable to maintain a normal concentration of opaque medium. At the time of admission to the clinic he was having about 6 rectal discharges every 24 hours mixed with blood, mucus and pus. Proctoscopic examination at this time showed a normal rectal mucosa except that on the edges of the second and third valves there were some ulcers. At roentgenologic investigation the involvement of the sigmoid and descending portions

of the colon were not as extensive nor as severe as on previous investigation. But an area in the splenic flexure about 20 centimeters in length was found to be narrowed, smooth and hyperirritable and a roentgenologic diagnosis of localized chronic ulcerative colitis was made. After specific treatment had been given roentgenologic investigation showed that haustra had returned and that irritability was absent. A smooth sigmoid colon was the only residuum of the infection. The roentgenogram of the thorax at this time did not reveal abnormality. Treatment consisted of specific serum later of vaccine and examination in September 1919 showed clinical cure and that the patient was free of symptoms. Proctoscopic examination September 13 showed a bowel with normal mucosa for 25 centimeters. The roentgenogram did not give evidence of the defects which had formerly been noted.

CASE 9. A rancher aged 61 years came to the clinic April 13, 1919. He had suffered from so called gastritis for 15 or 20 years and from diarrhoea for 7 months with 10 to 12 stools daily and loss in weight of 50 pounds. There had been much rumbling and gurgling in the intestines. The diarrhoea was in the form of discharges containing considerable blood and mucus. Considerable difficulty in cleansing the bowel was encountered and the roentgenogram was unsatisfactory on account of the constant presence of a large amount of fluid material

toms referable to the disease in the colon varied from 4 months to 13 years, all but 6 having had symptoms for more than 2 years.

In 11 of the cases, the sigmoidoscopic examination did not give evidence of disease, in 6 others, there was no evidence of disease in the rectum but high in the sigmoid colon were irregular ulcers, or the mucosa of the sigmoid colon bled more easily than normal or, as in 2 cases, sigmoid polyps were seen on an inflammatory base. In 2 cases, irregular ulcers were noted in the rectum, in 2 typical lesions of chronic ulcerative colitis and in 2 evidence of healed lesions of the disease. In 11 of the cases there were complications of the chronic ulcerative colitis in 4 strictures of the colon, in 3, polyps in 1 case, arthritis, and in 3 cases fistula about the rectum.

Our treatment, after the diagnosis was established, included, primarily, specific serum and vaccine. Eighteen of the 23 patients received either the concentrated fasting serum or vaccine prepared from the diplococcus of chronic ulcerative colitis, or both. Four had to undergo ileocolostomy because of stricture. 1 submitted to ileostomy because of the extent and progression of the disease, caecostomy was done in 1 case because of the situation of the obstruction at the hepatic flexure and in the sigmoid, in another case ileostomy was performed later colectomy was done because of hæmorrhage, and later still ileosigmoidostomy.

Fifteen of the 23 patients are clinically cured. Three others are doing well but it is too early to speak of them as cured. Five have died: 1 patient from the subsequent development of carcinoma of the stomach, 1 from subsequent carcinoma of the ovary, 2 patients from extension of the disease into the small intestine after ileosigmoidostomy, and 1 patient from peritonitis after ileostomy.

Opportunity has not so far been afforded for a second roentgenologic examination in many of these cases. In 3, however, later roentgenograms showed complete disappearance of the defects.

The roentgenologic evidence of chronic ulcerative colitis is constant and characteristic although the stage, severity and extent of the process, and the degree of destruction of

the mucosa and thickening of the wall which has taken place may produce a limited variation in the picture. In a typical case, the disease progresses orad from the rectum, the seat of its inception, and proctoscopic examination reveals a typical appearance. When the disease is confined to the rectum, the roentgenologist may fail to detect significant changes, but when it has progressed to the more proximal segments, he points to the syndrome of narrowing and shortening, marked hyperirritability, loss of haustration, and signs of destruction of the mucosa as pathognomonic. The occurrence of chronic ulcerative colitis in one or more isolated segments of the colon with negative results in the rectum, is significant, although relatively rare, and although the appearance of the diseased portion is identical with the appearance of the colon that is affected typically with the disease, yet the atypical distribution frequently will give rise to confusion. The involvement may be gross and extensive, or the disease may be confined to a segment which is so short, and the narrowing may be so abrupt, that a filling defect characteristic of malignant disease is closely simulated. The diseased portion is subject to the same complications as is the colon in the ordinary case of chronic ulcerative colitis, namely, secondary infection, perforation, polyposis, stricture, and malignant change. Tuberculous colitis and amœbic colitis, which commonly begin in the proximal segments of the colon are the other ulcerative lesions of the colon which have a roentgenologic appearance similar to that of this type of chronic ulcerative colitis. Although typical cases of each present such characteristic data that misinterpretations are easily avoided mistakes will happen so frequently that the establishment of the correct final diagnosis will demand the closest co-operation of roentgenologist and clinician.

When one considers carefully the history of these cases, the changing and irregular proctoscopic picture, the variety of situation of the disease in the colon as revealed by the roentgen ray, and the subsequent disappearance of the lesions, one is confronted with two major questions: (1) whether chronic ulcerative colitis is blood borne, and (2) whether the

TABULATION—SUMMARY OF DATA

Case	Situation and extent of lesion as revealed by roentgen ray	Item of interest	Length of lesion in ft.	Time since onset	Stool	
					Result of culture	Result of examination for parasites
1	Entire transverse colon	60	3.7	8700	Not cultured	
2	Proximal transverse and ascending colon and cecum	57	4.5	7000	Not cultured	Negative
3	Proximal third of transverse colon descending colon distal sigmoid	57	3.75	10700	Diplococcus	Negative

ileum (Fig 8) Under symptomatic treatment and specific vaccine she made rapid progressive improvement so that she was dismissed 2 months later and returned to the clinic in March 1918 at which time she reported that she had gained 25 pounds in weight and had had normal formed stools for several months.

In the cases reported, the diagnosis before admission to the clinic had included amebic dysentery in 2, tuberculosis of the intestine in 5, cholecystitis in 2, malignant disease of the colon in 2, fistula in 2, dysentery in several and adhesions or no diagnosis in the others. Previous treatment had included colonic irrigations, care in a sanitarium for tuberculosis

injections of emetin, appendectomy, tonsillectomy, hemorrhoidectomy, hysterectomy, and other abdominal operations as well as medication by mouth.

Of the 23 patients, 15 were males and 8 were females. They came from ten states of the United States and two provinces of Canada: 7 from Illinois, 4 from Iowa, 2 from Indiana, 2 from Alabama, 1 from Kansas, 1 from Montana, 1 from New York, 1 from Nebraska, 1 from Texas, 1 from Minnesota, 1 from Manitoba, and 1 from Ontario.

The length of time before the patients came to the clinic over which they had had symp-

dealing with various phases, from case reports to classification of the organism and treatment

One of the most interesting features has been that, until recently, the majority of the cases have occurred in Chicago and the immediate vicinity. The reason for this is not quite clear although it may have been due to the fact that the profession there has been more on the alert for the disease or that the disease is to some extent endemic in that vicinity. Due to its marked similarity clinically and pathologically to tuberculosis, many cases doubtless pass unrecognized, so that it seems quite probable that the disease is more prevalent than is generally supposed. The increasing number of reported cases from widely scattered sections of the country lends credence to the belief that the disease is fairly common, and that increasingly accurate and scientific diagnostic methods are responsible for its detection

ETIOLOGY

As to the organism responsible for this disease, there exists much dispute regarding classification, division into strains, and cultural characteristics. Gilchrist's original work still holds today, a proof of its high quality, and all are agreed that the organism, as described by him is a yeast double contoured, with granular cytoplasm, reproducing in the tissues only by budding, but beyond this there is very little unanimity of opinion. Terminology, classification, cultural characteristics, and closely allied strains are subjects of debate

The earliest disputes arose over the question of terminology and classification. In his original article Gilchrist described the case as "A Case of Blastomycetic Dermatitis." In Busse's report, which appeared after Gilchrist's verbal communication of 1894 but before his article in 1896, the organism was given the name "*saccharomyces hominis*." Later disputes over classification and terminology have had for their basis minor cultural differences, with the result that numerous investigators have attempted to divide the whole group into subdivisions representing closely allied strains. One can read equally

authoritative communications on the subject and obtain diametrically opposed facts and opinions regarding cultural characteristics and classification. Although at first glance it seems irreconcilable, such discrepancies in no way mitigate against the value and reliability of the individual work. In the final analysis the macroscopic appearance of the cultures, the presence or absence in them of mycelia or aerial hyphae seem to depend on whether the cultures have been kept moist or dry, at incubator or room temperature and whether or not it is the first culture or the sixth or seventh subculture. Furthermore in many instances, after periods of artificial cultivation many strains reproduced by endosporeulation.

Recently Castellani claimed that there is a plurality of species and succeeded in isolating three types. Suggesting the term "*blastomycoides*" for the group he designates the three types as "*blastomycoides immittis* (Rixford and Gilchrist, 1897), *blastomycoides dermatitidis* (Gilchrist and Stokes, 1898), *blastomycoides tulaneensis* (Castellani, 1926)." Culturally, on artificial media, these organisms all grow mycelia with no sugar fermentation. In the body lesions, they are all round or oval, budding, double contoured with granular protoplasm and no mycelia. Michelson concluded that the reaction of the tissues in systemic blastomycosis is an allergic one, and that unfavorable conditions cause the organism to revert to the oidial or yeast stage. The yeast like growth is the resistant form, the aerial growth the saprophytic form.

In any event, from the standpoint of one who has had no experience in culturing the organism but has given considerable study to the conflicting views of authorities on the subject it seems justifiable to assume that we are dealing with a disease entity caused by a yeast like fungus. The organism is round or oval, varying in size from 5 to 30 micra, with an outer refractile capsule, a somewhat granular cytoplasm. It reproduces in the tissues by budding only, and grows readily on all ordinary media.

Predisposing factors in the matter of infection are quite evident in most of the reported cases. Most patients have lived in unhygienic surroundings, and infection has taken

disease starts in the rectum, and the organisms then migrate to other more favorable parts of the colon, or whether the disease affects the large parts of the colon, the rectum heals, and parts elsewhere fail to keep pace in healing. These problems undoubtedly bear on the problem of the portal of entry of the infection.

CONCLUSIONS

1 Regional, segmental localized or migratory ulcerative colitis is a form of chronic

ulcerative colitis which is more difficult to recognize than the usual form of chronic ulcerative colitis which begins in the rectum.

2 It presents a diagnostic problem for on its correct diagnosis depends the prognosis; needless operation and long care in sanitarium may be avoided. Specific treatment should be instituted as soon as the diagnosis is established.

LOCALIZED INFECTION CAUSED BY YEAST-LIKE FUNGI

WITH SPECIAL REFERENCE TO THE SPINAL INVOLVEMENT

T. BANTORD JONES, M.D., ROCHESTER, NEW YORK

From The Department of Surgery, The University of Rochester School of Medicine and Dentistry

IN view of the fact that biologists are far from unanimous in regard to the classification of various fungi, medical literature on this subject is a most confusing labyrinth. This is particularly true in the case of the disease known as 'blastomycosis.' Numerous attempts to simplify nomenclature and classification of the causative organism in this disease have resulted in its being described under several names. Since the majority of cases reported in this country have been reported as blastomycosis, the disease will be referred to under this name in the present discussion. In general it may be stated that the term 'blastomycosis' is used to designate a disease systemic or local caused by a yeast like organism which reproduces in the tissues by budding only. It is characterized by chronic inflammation, ulceration and abscess formation with marked debilitation.

HISTORY

The condition was first recognized as a distinct disease entity and the causative organism discovered by Gilchrist and was described by him before a meeting of the American Dermatological Society in 1894. It was subsequently reported by him in his excellent article, in 1896. Doubtless due to the fact that this case was clinically one of cutaneous lesions, succeeding reports and

descriptions of the disease were of a similar nature. Montgomery and Ricketts reported three similar cases in 1901 and a few months later Hyde and Ricketts abstracted all similar cases reported up to that time (17 in all) adding 3 of their own. The following year Walker and Montgomery reported the first case of cutaneous blastomycosis becoming systemic, claiming that previously reported cases of systemic blastomycosis had been primarily systemic with cutaneous lesions. In 1903, Eisendrath and Ormsby reported a systemic case beginning supposedly in the lungs and included in their report abstracts of 4 previously reported systemic cases, those of Busse and Buschke, Walker and Montgomery, Ormsby and Miller and Cleary. They claimed that their case was the fifth reported case of systemic blastomycosis. Bassoe's case reported in 1906, was the first one in which vertebral involvement was noted. Hektoen in 1907 reported 13 cases systemic and cutaneous, considering very thoroughly blastomycosis and coccidiosis (coccidioidal granuloma). Since his report most comprehensive articles have appeared from time to time such as those by Montgomery and Ormsby, Stober and Wade and Bel until at the present time the disease has become fairly well known. Within the past 10 years the literature contains some 100 to 150 articles on the subject.

Fig 3 High power field showing a budding form of the blastomycetes

Fig 4 Roentgenogram of cervical spine showing erosion of articulating facets between the seventh cervical and first thoracic and destruction of the transverse process of the seventh cervical. Note lateral buckling of cervical spine

culosis in that there is less central necrosis and sharper differentiation at the periphery of the lesion. The organism can usually be demonstrated in the tissues a single giant cell at times containing several. For details of the pathological findings the reader is referred to the descriptions of Hektoen, Montgomery and Ormsby, Stober and Wade and Bel, which are most complete.

In regard to the method of dissemination, once the organism has gained entrance to the body, there seems to be little doubt but that the organism at times circulates in the blood stream from which it can often be cultured. In this respect the disease differs somewhat from coccidioid granuloma which shows a marked predilection for the lymphatics. It therefore follows that in the course of systemic blastomycosis, depending on the duration of the disease, all the viscera have been known to be involved. However, some organs are rarely involved examples being the heart and thyroid. In 1904 Cleary reported a case in which he found the organism in the myocardium microscopically although there were no gross pathological lesions demonstrable. Michelson's case showed similar lesions. The only other case with myocardial involvement is that of Hurley, in which numerous blas-

tomycotic abscesses were found in the heart muscle. The only reported case of thyroid involvement is that of Michelson. In general, the relative frequency of involvement of the various organs in systemic blastomycosis depends on the usual factors involved in any such disease, namely, virulence of the organism, resistance of the patient, and the duration of the infection.

CLINICAL ASPECTS

The details of the clinical pictures of the systemic and cutaneous forms of the disease are well known, and it is unnecessary to dwell upon them here. The articles referred to above contain excellent descriptions of the clinical side of the disease in all its forms together with the differential diagnosis. The chronicity of the disease leading to extreme states of debility and emaciation with pulmonary, genito-urinary, neurological, or skeletal symptoms superimposed, have been ably presented and further repetition would be superfluous.

On the other hand, cases of purely localized blastomycosis seem to warrant some consideration, inasmuch as general systemic involvement can be prevented and a cure can be

Fig 1 Roentgenogram of the chest showing the abscess encroaching on the apex of the left lung

Fig 2 Low power field showing general tissue reaction and presence of giant cells. Note blastomycetes

place in the months when dampness and mold growth prevail. In fact Stober investigated the living quarters of some of his patients and found that practically all lived in damp houses often in the presence of decaying wood etc. He scraped samples of mold from the floor boards in some of the dwellings and in some cases cultured a mold very similar to that recovered from the patient.

As to the mode of infection or the portal of entry in most cases there is not much question. In the cutaneous forms of the disease it is probably due to direct contamination of a wound or abrasion. Many of the systemic cases on the basis of history alone lead one to believe that the upper respiratory tract is the main portal of entry. One case has been reported in which it seems quite probable that the gastro intestinal tract served as the point of entrance of the infection, the site being the stomach where a blastomycotic ulcer was found (Sihler). Although cutaneous lesions coincident with systemic infection are common, very few systemic cases can be traced to pre existing cutaneous forms of the

disease. Stober claims that this was true in only one of the cases appearing in his report. Nevertheless there are many cases as will be noted later in which no portal of entry can be determined with any degree of accuracy and these are the types with which the present communication is primarily concerned.

There is no evidence of contact infection no case having been reported in which anyone caring for a patient with the disease has become affected. On the other hand some care must be used in handling the organism in view of Stober's experience in which the breaking of a culture tube in the laboratory was followed by severe pharyngitis and laryngitis within a few hours in one worker while the other developed a chill with fever and purulent bronchitis within 6 hours.

PATHOLOGY

Pathologically the disease closely resembles tuberculosis the two being practically indistinguishable in some cases. Grossly the essential pathological picture is that of a chronic granulomatous lesion. Microscopically it closely resembles tuberculosis showing marked round cell infiltration with numerous somewhat atypical giant cells of the Langerhans type. It differs from tuber-

tract were negative except for slight evidence of an ulcerative colitis. Stereoroentgenograms of the cervical spine showed erosion of the transverse process of the seventh cervical vertebra with slight erosion of the articulating facets of the seventh cervical and first thoracic vertebrae on the left (Fig 4). A large (soft part) shadow extending downward into the posterior mediastinum and encroaching very slightly on the apex of the left lung could be seen (Fig 1). Roentgenograms of the chest showed the lungs to be clear.

A tentative diagnosis of a destructive process involving the seventh cervical and first thoracic vertebrae probably tuberculosis was made. Due to the fact that the lesion as seen in the X-ray film was atypical in many respects and that there was much doubt as to the correctness of the diagnosis of tuberculosis, an exploratory operation was performed on May 7, 1936, 10 days after admission to secure tissue for pathological examination. At this time, an extrapleural abscess containing about 10 cubic centimeters of pus was found running parallel to the second rib. Attempts to remove tissue from the interior of the abscess were unsuccessful. However the pus was evacuated and the wound closed without drainage. The character of the pus seeming to confirm the diagnosis of tuberculosis. Head traction was applied immediately.

Briefly, the postoperative course was steadily downhill. Pain increased in severity until finally it could no longer be controlled by narcotics. The temperature showed a daily rise to 39 degrees C. By repeated roentgenograms it was seen that the process in the spine was progressing rapidly; the abscess shadow enlarging. The first thoracic vertebra began to show bone destruction. About 20 days after operation the patient developed persistent cough with expectoration of large quantities of thick pus. Signs of pneumonia developed on the left and the patient's condition became critical. On June 4, 4 weeks after operation the incision broke down after which each inspiration was accompanied by a loud hissing sound as air was aspirated through the wound. The guinea pig inoculated on May 7 with the pus obtained at operation was autopsied on June 4 and no tuberculosis was found. Reports on the direct cultures of the same pus had been negative. On the evening of June 5 the patient's temperature rose to 42 degrees C, respirations and heart action became weaker until finally the patient died at 9:30 p.m.

An autopsy was performed immediately with the following findings. At the base of the neck, on the left several centimeters above the clavicle is a wound from which there has been free drainage. It is seen on dissection that a sinus tract leads down to a very irregular ramifying cavity with greenish colored necrotic walls. It is filled with very foul smelling grayish green semisolid material. The muscles are necrotic in many places. The large nerves arising at the base of the neck have suffered quite severely and many large nerve tracts have been eroded

through and the ends lie dangling free in the abscess cavity. The first three ribs, together with the abscess cavity, the three lower cervical and two upper thoracic vertebrae are removed intact. The abscess cavity is seen to extend downward anteriorly to the level of the third or fourth thoracic vertebra. It is immediately adjacent to the aorta and the esophagus, neither of which seem to be affected. Laterally the abscess cavity extends toward the apices of the lungs. On the left it has pushed before it the apex of the lung for a distance of 2 to 3 centimeters; the lung here is covered with a thick, tough fibrinous membrane which is layered over with grayish green necrotic exudate. It is impossible to express air from the lung into the cavity. Section of this lung with dissection of the bronchi fails to reveal any abnormality other than some congestion of the mucous membrane. No fistula was found. The lung tissue itself does not seem to be greatly affected. Despite the close proximity of the abscess wall the tissue seems to be everywhere air containing. In the lower portion of the left lung are found widely scattered elevated areas of consolidation about 6 centimeters in diameter. They are quite opaque and suggest small areas of tuberculous pneumonia. No tubercles can be found in any portion of either lung. The right lung is relatively normal throughout. The heart shows a very slight amount of scarring of the aortic valves but otherwise no abnormalities are found. The spleen is somewhat enlarged. On section the malpighian bodies are somewhat enlarged and irregular in size and shape. The stomach, duodenum and pancreas appear normal. The capsule of the liver is quite thickened and grayish opaque in color. The lobulation is rather coarse. The structures at the hilus appear normal. The adrenals appear normal. The kidneys present a somewhat granular appearance on stripping the capsule but on section they seem normal. The pelvic organs are normal. In the sigmoid about 4 to 5 centimeters above the anal orifice and extending upward about 10 centimeters is an area of rather extensive inflammation. There is a large amount of congestion and some hemorrhage below the mucosa. Over the surface is a grayish opaque fibrinous membrane. There is no true ulceration and the rest of the intestinal tract is negative. The spine is dissected free and split lengthwise. There is very extensive erosion of the outer portion anteriorly from the level of about the sixth thoracic. The first thoracic is the site of very extensive alteration. The bone destruction is extreme; the body of the vertebra has collapsed and the two vertebral discs are very close together. There are a number of areas of yellowish softening in the inner portion of the second and third thoracic vertebrae and in places these extend inward to the vertebral canal lifting up the dura, but there is no evidence that the process extends inward toward the pia arachnoid. The aorta and other large vessels show a moderate amount of atheroma. The brain is not removed.

effected if proper treatment is instituted. The success of the treatment is dependent on an exact and timely diagnosis. As was intimated above, lesions have been described in practically all parts of the body in the course of systemic infection. But the localized infection is rare, and brings up many interesting questions regarding the mode of infection, difficulty of diagnosis, prevention of dissemination of the disease, and treatment. The recognition of these localized lesions as blastomycosis would doubtless decrease the incidence of the systemic disease with its coincident high mortality.

The following case is reported as an example of a localized blastomycotic infection to emphasize the great difficulties encountered in making a diagnosis. Literally forced to a diagnosis of tuberculosis in the face of negative laboratory findings, although rebelling against it because of the extremely atypical clinical course, we made the true diagnosis of blastomycosis only after postmortem examination. Even so it was only after repeated sections had been cut and carefully studied by the pathologists that the organisms were discovered. They too were at first forced to consider the case as one of tuberculosis because of the lack of any other distinguishing findings, and their careful search over a long period was prompted only by the fact that the lesions were not typical of tuberculosis.

Case No. 796. A G. male Italian aged 29 years a casket maker was admitted to the Strong Memorial Hospital April 27, 1926, complaining of cramp like pain in the epigastrium of one week's duration. There were no other gastro-intestinal symptoms except for occasional attacks of diarrhea of short duration for one year preceding admission to the hospital. During this year patient had been unable to work because of bone and muscle pains and weakness in the left arm. These pains in the arm had increased in severity up to the time of admission. In addition the patient had experienced some vague generalized muscle pains but these were not severe. The weakness in the left arm had progressed rapidly from the time of onset until the time of admission, but he had experienced no muscular weakness in any other part of the body. The patient stated that he had lost considerable weight during the present illness. The patient's past history was essentially negative. He had come to this country 6 years before admission, having lived all his life in Italy. His general health had always been excellent with no

serious illnesses. He had served in the Italian Army during the World War and had been wounded in the right arm. Tonsillectomy had been performed 1½ years before admission. The family history was entirely negative.

Physical examination revealed a well developed but considerably emaciated young Italian appearing very ill, weighing 166 pounds (average weight 195 pounds). There was no general glandular enlargement but the epitrochlear were palpable. All the special senses were normal. There was a very slight diffuse enlargement of the thyroid but no evidence of increased activity or toxicity. The lungs were clear to auscultation and percussion. The heart was normal in all respects except for some tachycardia explainable on the basis of an increase in temperature which was 39 degrees C. The blood pressure was 123-80 and pulses were regular in force and rhythm. Abdominal examination failed to reveal any abnormality other than tenderness in the right lower quadrant without spasm or rigidity. Examination of the genitalia and rectum was negative. The deep reflexes were all present but thought to be slightly hyperactive.

The main interest and findings in the examination were found in the left hand and arm where atrophy of the muscles about the thumb and the intrinsic muscles of the hand attracted immediate attention. Fibrillary twitchings of the muscles of the hand were prominent. By actual measurement it was found that the left wrist was 3 centimeters smaller than the right, some difference in size between the two arms being evident all the way to the shoulder. There was marked muscular weakness in the left hand and arm especially in those muscles supplied the sixth and seventh cervical segments through the median nerve and eighth cervical and first thoracic through the ulnar. Sensory changes coinciding with the cutaneous distribution of sixth, seventh and eighth cervical and first thoracic were also marked. The reflexes were all present but slightly hyperactive. The right arm was normal.

Examination of the back showed a definite atrophy of the shoulder girdle on the left especially the infraspinatus and supraspinatus muscles. There was marked prominence over the lower cervical and upper thoracic spine with pressure tenderness over the sixth and seventh cervical and first, second and third thoracic vertebrae. All motions of the head and neck were painful and there was spontaneous pain over the left side of the neck and left shoulder. Except for these findings general neurological examination was negative. Examination of the blood showed the white blood cells to be 11,200 with 72 per cent hemoglobin. The differential count showed 74 per cent polymorphonuclears and 26 per cent lymphocytes. The blood and spinal fluid Wassermann examinations were negative. The spinal fluid was negative throughout. The urine had a specific gravity of 1.014, no albumin or sugar, no Bence Jones bodies and microscopically it was negative. X-ray studies of the gastro-intestinal

Parker's case was similar to these cases clinically but, unfortunately, the organism was not cultured nor was it discovered in microscopic sections, which somewhat weakens the case as one of blastomycosis.

There is a striking similarity in these 3 cases. All were young men, two being foreigners who had lived in this country only a short time. Pain in the back over the affected vertebrae was a constant feature and pain in the epigastrium was a symptom of all. This epigastric pain was doubtless reflex in origin due to compression of the spinal roots. In all 3 cases a clinical diagnosis of tuberculosis was made. Aspiration of the fluctuating mass in the case of Brewer and Wood, disclosing the presence of blastomycetes, gave the correct diagnosis and determined the type of treatment to be followed. The negative cultures and guinea pig inoculations in the 2 other cases prevented a correct clinical diagnosis.

In the face of negative cultures and inoculations, the only other diagnostic aid which can lead to a differential diagnosis of the bone lesions is the X ray. By those who have studied the X ray changes seen in blastomycosis the lesions are considered quite typical. Closely resembling tuberculosis in many instances, there is usually something atypical. In the present case, the involvement of the articulating facets with lateral curvature of the spine can be taken as an example. In Parker's case, the vertebral involvement spreading to the laminae transverse and spinous processes finally to include the rib is a picture which as he points out is practically unknown in tuberculosis.

A detailed description of the X ray findings in osseous blastomycosis is included in Stober's article. The essential features are that there is localized rarefaction, more patchy than in tuberculosis, accompanied by bone proliferation and bony periostitis. The epiphysis remains normal unless the joint is involved. Sequestered bone is not observed and the bone immediately surrounding the lesion is normal. Single or multiple lesions are frequently seen in the long bones.

CASES OF LOCALIZED INFECTION

No case of localized blastomycosis of the eye has been recorded. Apparently the cornea

and conjunctiva are particularly resistant to the infection, although, according to McKee, it is occasionally seen. In a review of the subject, he found only 3 cases of keratitis from which the blastomycetes were isolated. He reported a case of corneal ulcer from which he had obtained the organism. All these infections occurred in the course of systemic disease. In view of the frequency of the cutaneous forms of the disease especially about the face it seems rather remarkable that the eyes escape involvement.

Localized infection of the tongue has been observed by New of the Mayo Clinic, in a man 52 years of age. Except for the local condition in the mouth his general physical examination was negative. The diagnosis was made by biopsy, and a cure was effected by potassium iodide internally, iodine and radium locally. The correctness of the diagnosis in this case was doubted by Weiss, who pointed out that the lymphoid hyperplasia shown in the photomicrographs was not typical of the disease. He claimed that the illustration designated as 'pure culture of blastomycetes' might be the picture of any yeast as there were no distinguishing features shown. He concluded his criticism by saying that the fact that the lesion healed under potassium iodide and radium was no proof that it was blastomycosis. Besides this one case Copelli reported an undoubted case. Although there was no demonstrable systemic involvement in his case the patient had blastomycotic lesions on both feet.

In a case reported by Vinson, Broders and Montgomery the esophagus was the site of the disease. The patient was a man of 41 years of age with a tuberculous history. The sputum was positive for tubercle bacilli at the time of admission to the clinic. Roentgenograms of the chest showed active pulmonary tuberculosis. His symptoms of esophageal obstruction were confirmed by X ray and esophagoscopy. A biopsy of the mass obstructing the esophagus showed it to be blastomycosis. The sputum was negative for blastomycetes. There was some improvement in the patient's condition under treatment consisting of iodides by mouth, gentian violet intravenously, and esophageal

Microscopic notes An old thickened pleura presents near the outer surface some fresh pleurisy undergoing organization. The gray areas of consolidation in the lungs are found to be areas of early gangrene. There is some organizing pneumonia and a little fresh pneumonia in the neighboring alveoli. There is no evidence of tuberculosis. Spleen, pancreas, kidneys and liver appear normal. Sections of the intestine show a rather intense inflammation in the mucosa but very little otherwise. The sinus shows an extensive inflammatory reaction. There is fibrosis and degeneration of muscle fibers. Nothing suggesting tuberculosis is seen. Sections of bone show partial replacement of the marrow with fibrous tissue and some wandering cells. In places there are many giant cells but all are more the type seen in foreign body reactions than in tuberculosis. Many of these giant cells contain round spore like bodies with refractile capsules (Figs. 2 and 3). These spores vary from 8 to 14 microns in diameter. Each contains some granular material which nearly fills the space within the outer shell. It is interesting that the walls of the abscess cavity show no such organisms. No similar organisms can be found in any other sections.

Anatomical diagnosis Yeast infection of the cervical vertebrae with the formation of an abscess in the neck, lobular pneumonia with early gangrene, diphtheritic colitis.

A consideration of this case brings up the question as to the portal of entry of the organism. There were no cutaneous lesions and the lungs were negative clinically and by X-ray examination, nor were there any suspicious respiratory symptoms to render such clinical findings questionable. The X-ray shadow at the left apex was obviously due to a mass outside the thorax encroaching on the lung field. The pulmonary involvement found at postmortem examination was undoubtedly secondary to the spinal lesion. No other blastomycetic lesion was found so we are forced to admit that the portal of entry in this case is undetermined.

The difficulties of diagnosis are well illustrated. Clinically the case was peculiar and the initial diagnosis of tuberculosis became less probable as one followed the patient's progressive downhill course. The severity of the patient's illness and his rapidly progressive failure contradicted the diagnosis of tuberculosis. On the other hand the negative culture of the pus obtained at operation supported it, until a few weeks later it was found that the inoculated guinea pig failed to show any evidence of tuberculosis. In addition the

spinal lesion as seen in the X-ray picture (Fig. 4) was not typical of tuberculosis. The result was that no definite diagnosis could be made with the evidence at hand.

The case seems quite simple when viewed in the light of the later postmortem findings. However, the clinicians were not the only ones experiencing difficulty in diagnosing the case. Due to the fact that the organisms were not numerous, it required long careful study and many sections finally to establish the diagnosis. This doubtless also accounts for our negative cultures and animal inoculations.

SPINAL BLASTOMYCOSIS

The first case of blastomycosis which showed spinal involvement was reported by Bassoe in 1906. The spinal involvement in his case was metastatic in the course of systemic infection. The second case reported was that of Eisendrath and Ormsby, the preliminary report of which appeared in 1903, followed in 1907 by the final report. Stober in his series of 29 cases found spinal involvement in 20 per cent.

The present case is the third case on record in which blastomycosis of the spine existed as a primary or localized lesion. The other cases are those of Brewer and Wood and Parker. The former was quite similar to the present case. The patient was a Russian, aged 20 years, who had been in this country only 6 months. He complained of pain in the abdomen in addition to pain in the back. Except for the local condition of swelling and tenderness over the lumbar spine, physical examination was negative. The lungs were clear. Sputum and stool cultures were negative. The diagnosis was made only after aspiration of the abscess and blastomycetes were found in the pus. At operation the spinous processes and laminae of three dorsal vertebrae which were found to be involved were removed together with all involved soft parts. The patient improved and was discharged only to return 3 months later with other vertebrae involved (first, second and third lumbar). A similar operation was performed at this time with excellent results. The patient was last seen one year after operation at which time he was perfectly well.

view, while Stoddard and Cutler claim that the latter explanation is probably more correct.

The symptoms in these cases are those of unlocalized brain tumor or meningitis, the latter being due to secondary meningeal irritation. These cases invariably end fatally. Careful postmortem examination has failed to reveal any portal of entry or systemic disease in many of the reported cases.

There has been considerable dispute over the disease as it is encountered in the central nervous system. The cases mentioned and referred to in the present communication have appeared in the literature under the heading blastomycosis, except those of Stoddard and Cutler. It is quite apparent that the cases described in the literature are similar to those they describe as being due to torula infection. In fact they state that the brain involvement consisting of multiple gelatinous cysts is peculiar to torula infection alone.

Isolated cases of non systemic blastomycosis occurring in unusual sites have occasionally appeared in the literature. Hicks reported a case of a paronychia from which yeast cells were isolated. He classified the organism under the blastomyces. Weidman and Douglas described a tumor of the leg, clinically resembling sarcoma which proved to be blastomycosis. One instance of infection of an operative wound with blastomycetes has been reported (9). The mother and brother of the patient had cutaneous blastomycosis, but the patient had previously shown no evidence of the disease. A case, probably not blastomycosis but of sufficient interest to warrant mention, was reported by Rhoney. Following the ingestion of yeast cakes over a period of 2 years, the patient developed a severe cystitis. Urinary smears and culture showed no ordinary bacteria but budding yeast cells. Marked improvement with the disappearance of the organisms was obtained under treatment consisting of iodides and salicylates by mouth. Preis and Forro reported a case of urethritis under the name of blastomycosis. The patient was under treatment for lues and diabetes when he developed an acute urethritis from which a

pure culture of "saccharomyces" was obtained.

It is quite evident that localized blastomycotic lesions can occur in various parts of the body. In many instances the portal of entrance of the organism seems obvious while in others it is obscure. Doubtless many such infections, escaping early recognition, serve as the starting point of general systemic disease.

DIFFERENTIAL DIAGNOSIS

Blastomycosis is probably much more common than is generally supposed, many cases undoubtedly receiving the diagnosis of tuberculosis. The marked resemblance of the two clinically is so close as to be indistinguishable. In the absence of postmortem and pathological examination, it is obvious that many cases of blastomycosis are overlooked. The resemblance is present in all forms of the disease. There is one outstanding difference between the two, response to treatment. Except for the central nervous system where both diseases are uniformly fatal, tuberculosis usually shows some response to general hygienic care whereas blastomycosis never does. Despite the best upbuilding measures, blastomycosis continues to advance, a point which should be remembered when any case of "tuberculosis" does not respond satisfactorily to treatment.

Other diseases from which it must be distinguished systemically and locally are coccidioid granuloma and syphilis. The former is a very closely allied disease identical clinically except that it is more malignant, and more rapidly and always fatal. It has never been known to occur in anyone who has not been in the San Joaquin Valley in California. The only distinguishing characteristic is that the organism of coccidioid granuloma reproduces in the tissues by endospore formation whereas the blastomyces reproduces in the tissue only by budding. Except for this one point there are no distinguishing pathological characteristics except that microscopically coccidioid lesions present sharper differentiation at the periphery. From the standpoint of treatment and differentiation this is not so important as the same therapy is indicated in both diseases.

dilatation At the time of the report the patient was still under treatment

Five cases of primary localized blastomycosis of the larynx appear in the literature The first was that of Downing following which Sartory, Petges, and Claoue Jackson, and New reported cases All of these cases were similar clinically As in blastomycosis else where, the close resemblance to tuberculosis was a *confusing factor* Biopsy of the tissue in each case made the diagnosis Only one case became systemic and ended fatally the others remaining localized and responding well to treatment of potassium iodide One of the patients had remained well for a period of 9 years It is interesting to note that in those cases in which obstructive symptoms necessitated a tracheotomy, the skin surrounding the tracheotomy opening soon became involved

Meningitis due to the blastomyces occurs in only 12 per cent of the systemic cases according to Stober As a primary form of the disease, it is infrequent Rusk reported the first case in 1910 following which reports by Swift and Bull Barlow, and Wilhelmj appeared, making a total of 7 cases in all The diagnosis of primary meningitis was confirmed by postmortem examination in all but two of these cases no other blastomycetic lesions being found The two unautopsied cases were carefully examined clinically with negative results, so there is no reason to doubt that the infection was localized in the meninges These cases all presented the classical signs and symptoms of meningitis except that in most instances they lacked the acuteness seen in the usual forms of meningitis The majority showed blastomycetes in the spinal fluid In 3 of these cases there is some evidence to support the view that the upper respiratory tract served as the portal of entry In one case (Barlow) the pharynx was covered by an exudate in which blastomycetes were found In another (Barlow) the onset of the illness was with a coryza of 2 weeks' duration Some anosmia, pain and deafness in the right ear were noted The onset in the third case (13) was with a coryza of 2½ months' duration followed by otitis media A persistence of drainage and symptoms

prompted a mastoidectomy, at which only a small drop of pus was found Shortly thereafter postmortem examination showed a meningitis which proved to be blastomycetic in origin An excellent detailed discussion of this form of the disease is given by Wilhelmj who feels that it differs from the other forms of blastomycosis only in that the meninges are invaded early, with death occurring before systemic involvement takes place

Not only is the brain substance itself involved in the course of systemic infection (25 to 30 per cent of the cases) but localized brain involvement without any other demonstrable disease occurs not uncommonly Disregarding the differences of opinion in regard to minor cultural characteristics and terminology, we find that yeast infection of the central nervous system proper occurs in two forms localized abscesses and cystic degeneration of the gray matter The former occurs almost always in the course of systemic infection being metastatic in the course of a general blood stream infection or secondary to localized abscesses of the skull In Moore's case brain abscesses developed following the extraction of what appeared to be a perfectly normal wisdom tooth Abscesses of the face and orbit followed ultimately resulting in death from central nervous system involvement

In the cystic form of the disease as it attacks the central nervous system the portal of entry of the organism is not so obvious In addition the exact classification of the organism or organisms is considerably disputed Pathologically all reported cases seem to be quite similar There is a hyperplasia of the meninges with the formation of phagocytic giant cells with little or no reaction in the neuroglia or connective tissue elements of the cerebral gray matter The latter is the site of multiple cysts varying in size (many are discernible only with the microscope) Whether these cysts are formed by internal expansion and exudation around the infecting organism or by lysis of the surrounding brain substance by some toxic substance derived from the organism is a matter of dispute Freeman and Weidman who reported the twelfth such case in 1923, favor the former

In the treatment of the local lesions there are differences of opinion. Formerly copper sulphate was used, to be replaced later by the application of tincture of iodine. Desjardins advocates X ray therapy combined with diathermy. He feels that there is no difference in the results obtained if the treatment is given in one fourth skin doses every week or a full skin dose every 3 weeks. Filtration should be gauged by the thickness of the lesion although he states that usually no filtration is necessary. He strongly recommends that diathermy be used in connection with the X ray as the results seem to be much better than when X ray alone is used. Application of radium in preference to X ray has been used by some. Hedge claims that the results obtained by treatment with iodides by mouth, combined with X ray, cautery or radium have been disappointing in his hands and claims considerable success by the local application of carbon dioxide snow. He has developed a particular technique of application which he describes in detail. If we consider some of the results obtained by the combination of good surgical measures (complete excision) and iodides, before the use of X ray and radium became so universal we see that the results compare favorably with the latter.

PROGNOSIS

Experience has shown that in cases of localized blastomycosis, general systemic treatment combined with good surgery locally (excision) X ray or radium can accomplish a cure, provided treatment is not started too late in the course of the disease. Once the disease becomes systemic, however all treatment fails in most cases. Temporary improvement with periods of remission seems to be directly attributable to therapy in many instances but recurrences are common some times months and years after an apparent cure. How much can be accomplished by intravenous therapy and the possible development of sera depends on future work. Stober has placed the mortality for systemic cases at 90 per cent. From a consideration of the reported cases it seems that this figure, high as it is, is still a little low. On the other hand good treatment which consists of some form of

the therapy mentioned above, plus persistence, careful "follow up" with a renewal of treatment in case of a suspected recurrence, usually will bring about cure if the condition is localized.

SUMMARY

A case of primary or localized blastomycosis of the spine is here described, representing the third such case reported in medical literature. The diagnostic difficulties and problems of therapy are emphasized. A review of the literature of reported cases of other types of localized infection with the blastomycetes is presented.

This study seems to reveal the following: The human body is subject to infection by yeast like fungi to which the body is not particularly resistant, and for which there exists practically no natural immunity. Early in its course the disease is invariably local rapidly becoming systemic. The portals of entry (suspected) are exposed surfaces, the skin and mucous membranes, whether in the respiratory tract (nose, throat, larynx, trachea etc.) or the gastrointestinal tract (mouth, tongue, oesophagus, stomach). In view of the frequent history of the cutaneous form of the disease following contamination of skin abrasions, it seems probable that some such mechanism explains mucous membrane involvement. The insidious chronic course of the local lesions allows dissemination with subsequent systemic involvement, often before producing noticeable symptoms. Once generalized the prognosis is very poor despite the best treatment. Localized lesions although obstinate, can be cured by potassium iodide internally combined with either radical surgery, X ray, radium or diathermy locally. The usual treatment for tuberculosis, with which this disease is most often confused, in no way influences blastomycosis. In fact, in many instances this form of treatment allows the disease to progress to a point where the best of treatment is of no avail. All suspected, but atypical, cases of tuberculosis should be scrutinized carefully to rule out blastomycosis.

As in every other disease, syphilis must be ruled out. Here the difficulties are not so great. The local lesions of the two diseases vary considerably. The Wassermann reaction if negative, aids in eliminating lues.

The cutaneous lesions of blastomycosis must be differentiated from epithelioma as well as syphilis and tuberculosis. This applies to the disease as it affects the tongue, larynx and œsophagus. Microscopic examination of the pus which can be expressed from the honeycombed pockets at the edge of the lesions usually will disclose the blastomycetes. If the organisms are not found, a biopsy of the lesion should rule out a new growth.

The final diagnosis of blastomycosis rests on the discovery of the organism. The simplest procedure is to find it in smears from the local lesions or in sections of tissue removed. As a rule it is readily obtained from the skin lesions. In the case of localized abscesses it is often more difficult to find the organism. Since the organism grows well on all ordinary media, failure to find it in smears of pus is not serious. However, it should be borne in mind that the abundant spreading growth seen on the media may very well be mistaken for a contamination, and the culture discarded. In all obscure cases resembling blastomycosis such 'contamination' cultures should be examined carefully to avoid this error.

In addition to obtaining the organisms locally, they can frequently be cultured from the blood stream and urine in the systemic disease, from the cerebral spinal fluid when the central nervous system is involved and from the sputum in pulmonary involvement.

Conflicting views are given by authorities regarding the susceptibility of laboratory animals especially guinea pigs, to infection. Guinea pigs are most often used for animal inoculation since a search is being made for tubercle bacilli. The reason for the discrepancies is probably to be found in the work of Davis. He discovered that while male pigs are particularly susceptible, usually succumbing to the infection, female pigs resist the disease and usually survive, their recovery being characterized by a low grade immunity. In the inoculation of pigs no special selection of male pigs has been made.

TREATMENT

It is quite apparent that localized blastomycotic lesions readily give rise to systemic infection. It therefore follows that the earlier the diagnosis and treatment the better the prognosis. There is abundant evidence to show that localized blastomycosis responds well to proper treatment and can be cured. The treatment may be divided into general systemic therapy and local measures. All agree that all patients whether the condition is local or systemic, should be treated by iodides by mouth. The iodides are usually administered as potassium iodide in solution in amounts varying from 10 to 200 minims per day. This treatment has proved its value in most cases. Recently the question of intravenous therapy has received considerable attention. Sanderson and Smith carried out a series of experiments in which they studied the effect of gentian violet on cultures of blastomycetes. They found that gentian violet in a 1:500,000 dilution prevented the growth of cultures. They suggest the intravenous injection of gentian violet in doses of 0.005 grams per kilogram of body weight in systemic cases. In Brazil where the disease seems to be quite common Pupo used local applications and intravenous injections of methylene blue and acriflavine in some cases. In others he used alternate intravenous injections of 10 cubic centimeters of a 1 per cent methylene blue and 5 cubic centimeters of 0.5 per cent solution of trypanflavine. He claimed considerable success with both methods. However the intravenous therapy has not established itself on the basis of its achievements and it is not justifiable to use it as a substitute for the older treatment of iodides by mouth. As an adjunct to the latter treatment in resistant and progressing cases it should be tried in view of the seriousness of the disease. Lately experimental work has been done (6) which shows that passive immunity with the development of a precipitin in the serum can be produced in laboratory animals by the injection of extracts of the blastomycetes. The work as yet has not been carried far enough to be of any therapeutic value although future work may accomplish considerable in this direction.

THE CULTURE OF TUBERCLE BACILLI FROM THE URINE

A REPORT OF ONE THOUSAND TWO HUNDRED CULTURES

DR THEODORE VON HUTH BUDAPEST HUNGARY AND FREDERICK LIEBERTHAL M.D. CHICAGO
 From the Urologic Clinic of the Royal Hungarian Palatine Péter Univerzita at Budapest Professor G. von Elyes Director

IN the presence of tuberculous disease of the kidney and generally speaking of the remainder of the genito urinary tract, it is the surgeon's task to decide which organ is discharging the organisms and to remove the diseased organ from the body, provided conditions permit. The kidney is a vital organ which plays an important role in the clinical pathology of tuberculosis, because failure to diagnose the disease at an early stage and to remove the kidney before the disease is far advanced may carry with it serious consequences for the patient. Our modern technical methods, however make early diagnosis possible in many cases. Bilateral renal tuberculosis can no longer be considered a frequent disease. Its early recognition is made possible by the use of ureteral catheterization and the bacteriological examination of the urine obtained separately from each kidney.

For a long time the direct growth of tubercle bacilli by artificial culture upon various media has been considered very uncertain and troublesome if not almost impossible. With the development of modern bacteriology it has been possible to perfect such culture media as have proved satisfactory for this purpose. The Koch bacilli are very sensitive in cultures and the development of the colonies requires a much longer time than do those of the staphylococcus streptococcus bacillus coli, and other groups. Furthermore these last mentioned organisms are not so sensitive toward contamination as are the tubercle bacilli.

The method used in the clinic of Professor von Huth for the culture of tubercle bacilli from the urine is the method of Loewenstein Sumiyoshi upon the culture medium of Lubeau modified by Hohn. This procedure has been tested in a series of 300 cases of urogenital tuberculosis and has proved itself not only more convenient but more accurate than any previously employed methods for the determination of the presence of Koch bacilli in

the urine. The cultures have been grown upon the Hohn egg medium as well as the glycerin potato. The recipe for the Hohn egg medium is as follows:

- 1 Three fresh eggs are carefully cleansed by rubbing the end with alcohol.
- 2 The ends of the eggs are perforated with a sterile scalpel previously cleansed by careful rubbing with an alcohol sponge.
- 3 The contents of the eggs are allowed to drain into a sterile beaker, the bottom of which is covered with sterile glass pearls about the size of a small pea. By careful rotation of the flask for 3 to 4 minutes with a gentle shaking motion, the contents are thoroughly mixed (care being taken that no foam should form).
- 4 After this the contents are measured off in sterile graduated and
- 5 A third of the volume of 5 per cent acid glycerine bouillon is added.
- 6 The mixture is poured into an Erlenmeyer flask.
- 7 Five to 6 cubic centimeters is poured into a sterile test tube warmed to 84 degrees C then gradually to 87 degrees C (caution—not over!) and allowed to remain 15 minutes at this temperature.
- 8 The tube is then allowed to cool slowly at an angle so as to form a slant.
- 9 To each test tube is added 0.8 cubic centimeter of sterile bouillon without glycerine and the tube stoppered with a cotton plug.
- 10 The tubes are then tested for sterility by 24 hours incubation at body temperature and placed on ice for subsequent use.

It was our practice at first to remove the bladder urine under sterile precautions, with a catheter. But lately this method has been abandoned because the contaminating organisms which might come from the urine are rapidly destroyed by treatment with 15 per cent sulphuric acid. They are not resistant to sulphuric acid and so do not reach the culture medium. Further we need not fear confusion with smegma bacilli. In 1,200 cultures smegma bacilli were not found, nor were they found in Ziehl Neelsen or O-O smears. In 45 cases smegma smears were made and stained according to the usual methods but no smegma

Days	Tube
18 to 21	8
21 to 28	29
29 to 35	59
36 to 42	20
More than 43	16

The cultures should be examined every 2 days. It is not necessary to moisten the egg media with the condensed water (the bouillon at the bottom of the tube), but the potato glycenn should be turned carefully every 2 or 3 days so as to moisten the inoculated surface to prevent drying. As a result of this the colonies grow more rapidly and luxuriantly.

Unless great care is used to maintain sterility the cultures may become contaminated with streptococci and staphylococci bacilli coli and other organisms as well as molds of various kinds. Due to their rapid and luxuriant growth even as early as 24 hours after contamination these colonies can spread over the surface of the medium and completely suppress the tubercle bacilli colonies even though the latter bacilli may have been present in the urine in large numbers.

The 15 per cent sulphuric acid mentioned completely destroys the contaminating organ-

Fig 8 Showing method of inoculating the egg medium tube. The cotton stopper of the culture tube is held in the palm and little finger of the right hand.

Fig 7 Bovine type of organism growing on egg medium.

Fig 10 Human type of organism growing on glycerin potato medium.

isms. Hence their appearance on the medium is evidence of careless unclean technique. It is imperative therefore that immediately after treatment of the urinary sediment with the acid we maintain a strictly sterile technique.

In the culture the tubercle bacilli appear as small pin point sized grayish white colonies (Figs 1 and 2). Often they cover the surface of the medium in the form of a pale, dull layer which is distinguishable from the surface luster of the medium in the areas in which they are developing. As the colonies grow larger and older they rise more and more from the surface coalesce in numerous places, and form verrucous structures as in Figures 3, 4 and 5. From then on their color changes according to the type of organism. The human type is

Fig 9 The cotton stopper of the culture tube is jammed on centimeter below the mouth of the tube.

medium and which shows the verrucous character of the older colonies

Fig 4 Human type of organism growing on egg medium showing the verrucous character of the colonies

Fig 5 Colonies of human type of organism

bacilli were found. We are confident that there is no reason to fear confusion with smegma bacilli.

Tubercle bacilli are very resistant to strong inorganic acids. On many occasions the 20 minute acid treatment of the urinary sediment prescribed by Loewenstein has been far exceeded, sometimes 60 to 90 minutes being consumed. In spite of this, the cultures grew luxuriantly, even if somewhat more slowly than when the sediment was subjected to the acid treatment for only 20 minutes.

We have used the 15 per cent sulphuric acid prescribed by Loewenstein since we considered the 10 per cent sulphuric acid prescribed by Hohn as of insufficient strength.

The experiments made with Dr. Gal of this clinic illustrate the great resistance of the Koch bacilli. Mature cultures of tubercle bacilli were subjected to powerful X rays. These experiments showed that after an exposure of 18 skin erythema doses the cultures still remained viable, and after transfer to a second culture tube, grew luxuriantly in 18 days despite the fact that the X rays exert a powerful destructive action on young cells. With an

exposure of 30 skin erythema doses the bacilli were completely destroyed and failed to grow upon re inoculation in a new tube.

In making the cultures, four tubes have been used in each case so that sufficient reserve tubes might be available should one or two tubes become contaminated. Each urine specimen was inoculated upon three Hohn egg medium tubes and one glycerin potato tube. At first before the technique was sufficiently perfected the cultures sometimes became contaminated with molds, in spite of the most careful technique. Molds are apparently more resistant to sulphuric acid than tubercle bacilli because they remain viable after even one hour's treatment with the acid. If only a small mold colony grows upon the medium it does not interfere with the growth and spread of the tubercle bacilli colonies. But larger numbers of such contaminating colonies tend to spread over the surface of the medium and suppress the development of the cultures.

The optimum culture temperature of tubercle bacilli is 37.5 degrees to 38.5 degrees C. But according to our experience they also develop fairly well at 40 degrees C.

Fig 11 Early form of renal tuberculosis showing a papillitis in the upper pole

Fig 12 Early tuberculosis with papillitis in upper pole

Fig 13 Early renal tuberculosis showing a cavity in the upper pole which is not connected with the pelvis

separated specimens. The results are shown in Table I

The time of development is longer on potato medium, 3 to 5 weeks being necessary (Figure 10). With experience, however one can see the colonies earlier with the aid of a magnifying glass, although this is sometimes difficult because of the similarity in color between the potato and the colony itself (Table II)

TABLE III—SUMMARY OF RESULTS

	Tubes
Egg medium cultures	900
Positive	547
Negative	280
Contaminated	39
Glycerin potato medium cultures	300
Positive	132
Negative	141
Contaminated	27

Especially important are those cases in which repeated Ziehl Neelsen and Osol smears of the urine were negative and the cultures later proved positive. Among 200 cultures we had 50 such cases. In several cases the guinea pig test was negative and the cultures positive. This control was carried out in about 10 cases. In many cases in this latter group there was only a minimal functional defect in the diseased organ and only a small leucocyte count in the separated urines. Operation in such cases revealed an incipient renal tuberculosis, a beginning papillitis, a mild beginning granular tuberculous pyelitis, or a fresh tuberculous infarct. In a few cases histological check was necessary to confirm the diagnosis of renal tu-

berculosis. Figures 11, 12, and 13 show several such cases with early lesions. In Figure 11 a papillitis in upper pole is shown, in Figure 13 a small cavity not connected with pelvis.

Because of its absolute reliability and simplicity, the culture method is of greater value than the guinea pig inoculation method. This is easily understood when we consider how troublesome the guinea pig test is and how much longer it requires for a diagnosis. After inoculation the guinea pig is subject to epidemics to sepsis, and other infectious processes which render the results uncertain. Four to six weeks are usually necessary to establish a diagnosis. The pigs have to be controlled constantly and in addition to an autopsy a histological check may eventually be required. All of these annoyances and uncertainties are eliminated with the culture method. Further, the gallinaceous type is apathogenic for the guinea pig and produces no lesions in the animals, while it produces a beautiful growth upon egg medium.

That the culture method has as yet not taken a foremost place in urologic diagnostic procedure is due, no doubt, to lack of acquaintance with the technique of culturing tubercle bacilli. But we are assured that whoever trains himself in this method and adheres to the few necessary conditions mentioned will soon be convinced of its simplicity and reliability and will consider it far superior to the guinea pig test.

grayish white, the bovine type brick red with a yellowish tinge (Fig 7) In the accompanying photomicrographs the types are distinguished by the black appearance of the bovine and the white appearance of the human type It sometimes happens that the two types occur in mixed culture but in 1,200 cultures we saw this only once (Fig 6) The bovine type is especially beautiful on glycerin potato The gallinaceous type appears as slimy, moist colonies Various foreign authors have reported the occurrence of this type In spite of the most careful search for this organism it was never found in our cultures The clinical picture of the bovine type of infection is characterized by remittent fever, low temperature in the morning and high temperature in the evening Fever reacts only slightly to antipyretics In the second stage metastatic nodules appear the sites of predilection being (1) the bone marrow, (2) the kidney, and (3) the skin In the kidney a small pinhead to pea sized yellow nodule forms in the cortex or in the medulla These nodules may break down and give rise to cavity formation The striking feature in the reported cases is that the bladder is only slightly involved or not at all while in the human or bovine infections the involvement of the bladder is especially marked The urine contains very little pus and the bacilli appear in great numbers some times intracellularly These organisms are not pathogenic for the guinea pig and hence should be cultured according to the method of Loewenstein Sumyoshi on egg medium The growth of this organism on this medium as well as on glycerin potato is characteristic

The technique of culturing tubercle bacilli from the urine is as follows If the urine is cloudy and rich in sediment 50 to 100 cubic centimeters will suffice If however the urine is clear or slightly turbid 250 to 300 cubic centimeters is necessary The total quantity is centrifuged in divided portions From the combined sediment a Ziehl Neelsen and an Osol smear are made Then 5 cubic centimeters of 15 per cent sulphuric acid is added to the combined sediment and the whole well shaken until a homogeneous mixture forms This is allowed to stand for 20 minutes with frequent shaking The mixture

is then poured into a sterile centrifuge tube and centrifuged 3 to 5 minutes at a speed of 3,000 to 3,500 revolutions per minute The supernatant liquid is decanted and the sediment is used for the inoculation of the medium This is done with a platinum loop which is well flamed before inoculating The centrifuge tube and culture tube are taken in the left hand as in Figure 8 being so held that dust cannot drop into either tube The platinum loop with glass handle is held in the thumb and index finger of the right hand the cotton stopper removed from the culture tube with the little finger and palm of the right hand as in Figure 8 The loop is inserted into the sediment in the centrifuge tube and the culture slant streaked with a side to side motion while the loop is being withdrawn the loop not being allowed to come in contact with the condensed water The cotton stopper of the culture tube is replaced, the stopper well flamed and then jammed 1 centimeter below the top of the tube with the previously flamed glass handle of the platinum loop as in Figure 9 To prevent evaporation of the condensed water and the drying of the medium the tube is hermetically sealed by pouring melted paraffin over the stopper The procedure with glycerin potato is similar the surface of the potato being inoculated by streaking and the tube sealed in the same manner When ureter catheter specimens of urine are used smaller quantities will have to suffice

At first we washed the sediment with sterile water two to three times according to the specifications of Sumyoshi and then inoculated But since this increases the danger of contamination and since the quantity of acid which the platinum loop can transfer to the medium is so minute as not to alter appreciably the hydrogen ion concentration of the medium, we have eliminated this step Hence without being washed the sediment is immediately inoculated on the egg medium and glycerin potato Smears for diagnosis are made from the first colonies to appear The average appearance for colonies on egg medium is 8 to 20 days From the clinical material of the Illyes clinic 300 specimens of urine were cultured making a total of 1,200 tubes Of these 250 represent bladder urine and 50

Fig 1 The anterior aspect of the uterus showing the peritoneal surface elevated over the tumor by dark red and purplish lobules

Fig 2 Section through the anterior wall of the uterus showing large caverns which were filled with blood. An arrow points to the perforation through a wall of the cavern from which the hæmorrhage occurred

follows "In the posterior wall there was a circular, elevated portion, of spongy softness, 2 centimeters in diameter, the mucous membrane covering it was thin, slightly 'hobnailed' and of bluish red transparency. The corresponding peritoneal surface was also tumefied convex, of bluish transparency and the blood vessels of the peritoneum were very distinct and full. A section made through the tissue was immediately covered with dark fluid blood after removing which a delicate framework with isolated dark spots became visible. In the cavities within the framework and communicating with each other there was fluid blood. The appearance of this tumor on the whole therefore resembles the cavernous ectasia so frequently met with in the liver excepting that the framework was much thicker than is usual in similar vascular tumors." Virchow (17) in 1867, reported another hæmangioma the size of a cherry which was purely cavernous within the substance of the uterus. Almost 30 years later

in 1893, Boldt recorded the third case in which he found a hæmangioma in the uterus of a multipara, 37 years of age, who had been bleeding for an entire year, and profusely for the past 4 months of the year. Boldt stated that on performing a vaginal hysterectomy on this patient he found a tumor in the anterior aspect of the uterus which reached to the fundus and was the size of an English walnut. It was lobulated slightly firmer than its uterine surroundings and dark red in color, mottled with purplish spots which were soft like recently coagulated blood. Many large cavities were discernible in a microscopic study of the sections. Boks, in 1917 reported a case of cavernous hæmangioma in a patient, 33 years of age, who had had two children, the second being 7 years old when the patient was examined. Menstruation had been normal up to the time an abortion occurred 4 years previously. For 6 months the bleeding had been more profuse and prolonged. The last menstruation, however, was of one day's duration and a week later severe abdominal pain set in. The patient was admitted to the

HÆMANGIOMA OF THE UTERUS

EDMUND HORGAN MSc MD FACS WASHINGTON

HÆMANGIOMATA have rarely been found in the uterus. Although they occur in nearly all the tissues of the body, they are most frequently found in the skin and liver. Of the 20 cases of hæmangioma of the uterus reported in the literature, only 4 are of the true cavernous type so that the report of an additional case seems justified. An attempt will also be made to classify the recorded cases and to differentiate the true cavernous hæmangioma in the wall of the uterus from the hæmangiomatous fibromyoma in the uterus and from the telangiectatic hæmangioma of the pelvis.

Cavernous hæmangioma were first systematically studied by Rokitsky who, when he discussed them in his *Handbuch der pathologischen Anatomie*, in 1846, and in his treatise, 'Ueber die Cavernose Blutgeschwulst,' in 1854, gave them the name 'cavernous blood tumors'. He described them as neoformations and stated that 'the anastomosis of the tumor with the venous vascular system is through very fine venous offshoots'.

MacCallum in 1924 further differentiated them. "A true hæmangioma," he stated, "is distinguished from dilation of capillaries or venules belonging to the general circulation by the fact that its blood channels grow independently without regard to the laws which govern the distribution of such vessels. It thereby forms a mass which is somewhat withdrawn from the general circulation and although supplied with artery and vein does not stand in any intimate anastomotic relation with the adjacent circulation. True hæmangioma are most commonly divided into a simple or telangiectatic form in which the abundant capillaries though widened maintain fairly well their form as tubes with parallel walls, and the cavernous form in which the character of erectile tissue is approached with large, irregular blood spaces opening abundantly into one another. It is not very apparent, however, where the line of division can be sharply drawn between these groups."

HÆMANGIOMATA OF THE UTERUS

Virchow (18) stated that "cavernous angioma of the uterus is very rare if one does not include telangiectatic angioma." It is difficult to draw the line sharply between the true cavernous hæmangioma and the fibromyoma with dilated and tortuous vessels. The similarity between these two forms was pointed out by Kelly and Cullen, who called attention to the fact that 'the blood supply of a myoma may be so copious that the tumor in reality becomes an angiomyoma.' Reder described such a case of angiomyoma which 'looked red like a tomato' was soft and felt cystic. The tumor had an enormous blood supply some sinuses being as large as a finger.

To determine exactly the number of genuine cases of cavernous hæmangioma among the reported cases of hæmangioma of the uterus is difficult because of the frequent lack of complete pathological and histological data and because of the failure in some of the reports to distinguish between the true cavernous hæmangioma of the uterine wall without fibromyoma and hæmangiomatous fibromyoma of the uterus. In the following classification the 20 cases collected from the literature have been grouped as accurately as could be determined. Nineteen of the cases have been divided into three varieties of hæmangioma; the remaining case is a doubtful one and has been grouped separately.

- 1 The true cavernous hæmangioma in the wall of the uterus without fibromyoma to which we have added a case (Table I)
- 2 The hæmangiomatous fibromyoma (Table II)
- 3 The telangiectatic hæmangioma in the pelvis (Table III)
- 4 A doubtful case of hæmangioma in the cavity of the uterus (Table IV)

TRUE CAVERNOUS HÆMANGIOMA
IN THE WALL OF THE UTERUS

Klob, in 1864 first described a true cavernous hæmangioma of the uterine wall as

TABLE I—TRUE CAVERNOUS HÆMANGIOMATA IN THE WALL OF THE UTERUS

Year	Author	Age of patient	Operation	Result	Pathological findings
1864	Klob		Autopsy		In posterior wall of uterus there was a circular elevated portion of spongy softness. The mucous membrane covering it was thin slightly lobulated and of bluish red transparency. The corresponding peritoneal surface was also thickened and of bluish transparency.
1867	Vurchow		Autopsy		A tumor the size of a cherry purely cavernous within the substance of the uterine wall.
1893	Boldt	37	Vaginal hysterectomy	Recovery	A tumor in the upper anterior surface of the uterus reaching to the fundus. It was the size of a walnut lobulated dark red mottled with purplish spots.
1897	Boks	33	Abdominal hysterectomy	Recovery	A tumor in the anterior wall of the uterus.
1900	Horgan	38	Abdominal hysterectomy	Recovery	A uterus two to ten times the size of a normal uterus. A tumor about 5 cm. in diameter in the anterior wall of the uterus. The peritoneal surface elevated with dark red and purplish lobulations. The mucous membrane elevated and lobulated. A demonstrable opening into one of the blood caverns. Large blood caverns in wall of uterus.

an angioma. The removal of an angiomatous fibromyoma, 4.5 inches in diameter, together with the uterus enlarged to the size of a turnip, has been reported by Shaw. The patient was a woman, 65 years of age, who had suffered extreme abdominal pain and collapse. There was atheroma of the uterine arteries. Sections showed the fibromyomatous tissue to contain a very large number of thin walled blood vessels. Microscopically, the collections of bright red blood in the tissue were found to consist of angiomatous tissue, each vessel lined with a definite layer of endothelium. Hirschberg described the case of a woman, aged 64 years, on whom a total extirpation of the uterus was performed to relieve hemorrhages which had persisted over a period of 8 weeks. An examination of the specimen showed a myoma of the uterus near the cervix. The tumor contained clotted blood with blood sinuses lined with typical endothelial tissue. In this group of cases the hæmangiomatous tissue was found to be within fibromyomata which were either interstitial, submucous, or subperitoneal (Table II). In the true cavernous hæmangiomas of the first group, the hæmangiomatous tissue was in the uterine wall and no other tumor was present.

TELANGIECTATIC HÆMANGIOMATA OF THE PELVIS

In a discussion of telangiectatic hæmangiomas the cases recorded by Horne, Pantzer,

and Wright are of interest. In 1906, Horne reported a case of hæmatoma on the anterior wall of the uterus of a patient 35 years of age. When the abdomen was opened the uterus was found to be about the size of a 4 months' pregnancy, its elevated portion formed by a fluctuating mass. A longitudinal incision in this mass allowed a large amount of black, tar like blood to escape. The cavity of the hæmatoma did not communicate with the uterine cavity. As the removal of the uterus was thought inadvisable, drainage was established through the abdominal wall from the incision which was not closed. Oozing of blood continued up to the time of the patient's death 3 weeks later. Autopsy was not performed and the true pathological condition was not determined. Pantzer, in 1911, reported a case of telangiectatic hæmangioma in the pelvis of a patient 26 years of age. The hæmangioma was found to be in the peritoneum covering the front of the uterus, the right half of the bladder, the right fallopian tube and the contiguous portion of the right broad ligament. He ligated the right ovarian and right uterine arteries and placed a suture in the uterine wall encircling the tumor. Two years later he had occasion to observe the result of the ligations when he operated on this patient for acute appendicitis. He found the hæmangioma to have entirely disappeared although there were some enlarged vessels in the right broad ligament. An interesting case was reported by Wright of a patient operated

Fig. 3. Photomicrograph of tissue from the anterior wall of the uterus showing numerous large caverns in the hemangioma. The larger caverns are toward the peritoneal surface. One fairly large cavern can be seen under the mucous membrane.

Fig. 4. Photomicrograph of the wall of a cavern of the hemangioma showing its endothelial lining.

hospital because of hemorrhage. At operation a tumor was found in the anterior wall of the uterus. Much blood escaped from the tumor when it was incised. A study showed it to be a cavernous hemangioma (Table I).

HEMANGIOMATOUS FIBROMYOMATA

Virchow (17), Ouhé, Michel, Reder, Bell and Clarke, Shaw and Hirschberg have each reported one case and Kelly and Cullen have reported 5 cases of hemangiomatous fibromyomata of the uterus. Virchow (17) in 1867 reported his observations on the pure cavernous hemangiomata of the uterine wall and the hemangiomatous fibromyomata. In 1901 Ouhé reported a case in which a dissection of the uterus revealed a fibroma the size of an almond, in the fundus. The tumor was permeated by numerous engorged vessels with thrombosed veins at its periphery. The tumor, which was probably associated with an abortion, was reported as an angiomatous fibromyoma although in the discussion Jeannel refers to it as a "deciduoma." Two years later in 1903, Michel reported the removal of

a tumor from a woman 45 years of age whose only symptom had been menorrhagia. The tumor which had grown rapidly to the size of a child's head and which Michel called a uterine fibroid was found in the anterior wall of an enlarged uterus. The tumor had a large number of capillaries and isolated small muscle fibers and microscopically it resembled placental tissue. The angiomatous fibromyoma found by Reder which was red like a tomato has been referred to above. The tumor was large with an enormous blood supply. When Reder thinking it a cyst punctured it he had difficulty in controlling the hemorrhage but succeeded in doing so and in removing the tumor. Under the title "Angiomatous Fibromyoma of the Uterus" Bell and Clarke reported a case in 1906 of a woman aged 41 years on whom a hysterectomy was performed to remove a uterine tumor. The bulk of the tumor consisted of unstriped muscle fibers but some portions of it were very vascular. Kelly and Cullen have mentioned briefly 4 cases of angiomatous fibromyoma and have given a detailed report of a fifth case. In this case a large tumor was situated in the left uterine wall. Scattered throughout the tumor were numerous dark blue vascular areas varying from 0.5 to 1.5 centimeters in diameter. The areas were composed of blood vessels present in a honeycombed appearance the individual vessels of widely varying diameters being closely packed together. The walls of the vessels were smooth and glistening. The entire picture the authors thought suggested

TABLE III—TELANGIECTATIC HÆMANGIOMATA IN THE PELVIS

Year	Author	Age of patient	Operation	Result	Pathological findings
1906	Horne	35	Exploratory laparotomy. Open 1 g. of hæmatoma and packed with gauze	Death	A fluctuating mass in front of the uterus. The mass was incised and about 300 grams of tar-like black blood came out. No common cavity with uterine cavity.
1911	Pantzer	26	Ligation of right ovarian and right uterine arteries and suture of uterine wall around tumor	Recovery	A telangiectatic angioma under the peritoneum covering the front of the uterus (the right half of bladder the right tube and the contiguous part of the right broad ligament).
1916	Wright	35	Removal of tumor and uterus	Recovery	A mass in the right broad ligament below the tube and an ovary and intimately associated with the uterus. It was smooth and glistening of rubbery consistency and bluish black in color.

TABLE IV—DOUBTFUL CASE OF HÆMANGIOMA IN THE CAVITY OF THE UTERUS

Year	Author	Age of patient	Operation	Result	Pathological findings
1906	DeLee and Mann	34	Abdominal hysterectomy		The uterine walls hypertrophied and fibromatous. A tumor the size of a large nut in the uterine cavity. If a final examination showed it to be an angioma. Bendt recalled it a place tal polyp.

When her third child was born she had a post partum hæmorrhage about 1 hour after delivery which was controlled by ergot. One week after her third child was born, when she was 23 years old she had a sudden hæmorrhage from the vagina the flowing being profuse for several days. Ice bags were applied to the abdomen and ergot was administered. When the patient was 24 she underwent an operation for the removal of the right ovary and fallopian tube. She had not menstruated for 4 months previous to this operation, but 2 months later menstruation began again and remained normal for 4 years. Then at the age of 28 the patient had a sudden and severe vaginal hæmorrhage. For 15 minutes or more the blood gushed violently. It then began to clot and many large clots were passed. The bleeding caused considerable weakness. A hypodermic injection of a drug was given in the arm by the attending physician and the vagina was packed. The packing had to be renewed daily because of the profuse flow of blood. The bleeding stopped after 5 days. Three or 4 years later the patient had another sudden hæmorrhage the bleeding continuing for several days although it was not as severe as the previous one had been.

The patient became pregnant at the age of 34 and went to full term being delivered in April 1913 normally and without complications. Six months later in October there was another sudden hæmorrhage 1 week after menstruation which lasted for several days and forced the patient to remain in bed. The vagina was again packed. Following this attack the menstrual flow was normal and there was no intermenstrual bleeding up to the menopause in January 1924. As stated before 'spotting' was observed in May of that year.

On December 12 1924 while seated talking to a friend the patient had a sudden and profuse gush

of blood from the vagina which thoroughly saturated her clothes and continued for some time with lessening force. She was treated with morphine hypodermically and with ergot. Two further gushes occurred during the ensuing week. After the onset, the bloody vaginal discharge remained continuous and confined the patient to her bed up to the time she was seen in consultation 19 days later.

Physical examination. The patient was a middle-aged woman fairly well developed although not well nourished. Her skin and sclera showed a yellow tinge and her breasts were small and wrinkled. The findings of the heart and lungs were within normal and the abdominal wall was only slightly rotund. There was a low midabdominal operative scar. On palpation of the abdomen no areas of tenderness or masses were detected. On pelvic examination the introitus was found to be relaxed because of an old laceration of the perineum. There was a profuse bloody vaginal discharge with clots. The cervix was enlarged and fairly soft. The uterus was about twice its normal size with its fundus forward and not freely movable. The left appendage could not be distinctly felt.

Laboratory observations. The clinical laboratory examinations showed the urine to be normal the blood to contain 3 500 000 red cells per cubic centimeter and the hæmoglobin to be 40 per cent. On January 2 1925 the patient was given 500 cubic centimeters of citrated blood intravenously.

Operation. On January 3 1925 the abdomen was opened through a low midline incision. Exploration revealed numerous adhesions of the omentum on the anterior surface of the uterus and the broad ligaments. These were separated with difficulty the separation causing considerable bleeding. The uterus was found to be about twice its normal size with a soft lobulated tumor mass in the anterior

TABLE II—HEMANGIOMATOUS FIBROMYOMATA

Year	Author	Age of patient	Operation	Result	Pathological diagnosis
1867	Vuchow				Telangiectatic myoma
1901	Ouléd	26	Abdominal hysterectomy		Angiomatous fibroma
1903	Michel	45	Abdominal hysterectomy		Angiomyofibroma
1904	Reder		Abdominal hysterectomy	Recovery	Angiomyoma
1906	Bell and Clarke	41	Abdominal hysterectomy	Recovery	Angiomatous fibromyoma
1909	Kelly and Cullen		Hysterectomy		Angiomatous fibromyoma
1909	Kelly and Cullen		Hysterectomy		Angiomatous fibromyoma
1909	Kelly and Cullen		Hysterectomy		Angiomatous fibromyoma
1909	Kelly and Cullen		Hysterectomy		Angiomatous fibromyoma
1909	Kelly and Cullen	45	Hysterectomy	Recovery	Angiomatous fibromyoma
1913	Shaw	65	Abdominal hysterectomy		Angiomatous fibromyoma
1924	Hirschberg	64	Hysterectomy	Recovery	Hemangioma of myoma

on by Dr T S Cullen. This patient was a white woman, aged 38 years, who had a cystic tumor to the right of, and posterior to, the uterus. At operation "a mass was found in the right broad ligament. It was found to be vascular and any attempt to separate it from the uterus produced marked hemorrhage. A supravaginal hysterectomy was performed, the tumor and uterus being removed without disturbing their relationship." The pathologist reported a tumor in the right broad ligament made up of large cavernous blood vessels, microscopic study of the tissue showed "blood spaces filled with blood elements the supporting structure being connective tissue forming trabeculae" (Table III).

A DOUBTFUL CASE OF HEMANGIOMA IN THE CAVITY OF THE UTERUS

Siegel, Delval, and Marie in 1906, reported what they considered to be a uterine angioma in a patient, 34 years of age on whom they performed a subtotal hysterectomy. The uterine walls were hypertrophied and fibromatous. The tumor which was found in the uterine cavity on the anterior wall was the size of a large nut, soft, vascular and surrounded by a clot. The histological examination showed an angioma filled with hæma-

tin crystals. Bender who saw the specimen and discussed the case called it a placental polyp (Table IV).

CASE REPORT

A white woman aged 46 years was seen in consultation with Dr Milton H. Prosper on January 1, 1925. The patient was confined to bed and had been since the sudden onset of a vaginal bloody discharge on December 12, 1924. The patient's family history had no bearing on the case, neither was there any history of blood or circulatory disease except in the patient's mother who had died of arteriosclerosis at the age of 72 years.

Menstrual history. Menstruation began when the patient was 14 years of age. It was of regular occurrence and of 4 to 5 days duration. The flow was free with no cramps, backache or headache. Menopausal pause occurred in January, 1924, although a few drops of blood were noted in May of that year.

Marital history. The patient who was married when she was 17 years of age had had four pregnancies all except the last one terminating a few weeks before the full term. The patient's four children—three daughters and one son—and her husband were all living and well.

Personal history. As a child the patient had had whooping cough and measles at 14, malaria and at about 21 she frequently had had sore throat. In July, 1902, the right ovary and fallopian tube were removed. The patient had always been in fairly good health and was able to nurse all her children and do her own housework.

History of illness. The patient experienced no difficulty with her first labor at the age of 19 years.

CLINICAL EXPERIENCE WITH NEW LOCAL ANÆSTHETIC DRUGS

WILLIAM R MEEKER M D F A C S , MOBILE ALABAMA

In the production of novocain the efforts of workers in the field of synthetic drugs have been rewarded with decided success. For several years this drug has most nearly fulfilled the requirements of the ideal local anæsthetic, rendering the use of cocaine for infiltration anæsthesia almost obsolete. One of the most important advantages is the possibility of safely injecting large quantities of the solutions. This factor has been largely responsible for the development of regional anæsthesia to its present scientific basis.

The toxicity of novocain, however, is not an entirely negligible factor. When local infiltration was limited to minor operations, the injection of small quantities of weak solutions kept the method well within the limits of safety. But with the introduction of regional methods, larger quantities of stronger solutions have been employed.

While the safety of these methods have been repeatedly demonstrated, the sphere of usefulness would still be further extended by the introduction of a drug even less toxic than novocain. It is reasonable to expect that synthetic chemists will produce such a drug. Many intended substitutes for novocain have been produced recently by research chemists and have been subjected to pharmacological investigation. McElvain and his co workers at the University of Wisconsin have produced upward of 30 such preparations.

In initiating this research, it was believed that a series of local anæsthetics, combining within their structure the groups known to give anæsthesia with various nitrogen rings allied to the ring found in cocaine would include one or more compounds which would give the powerful anæsthetic effect of cocaine without its toxicity.

In general, these substances are piperidino or substituted piperidino alkyl benzoates and piperidyl or substituted piperidyl benzoates. All contain the piperidino or piperidyl groups with any substitutions being made in the 2 (alpha) or 3 (beta) positions. They resemble

cocaine and procaine in having the necessary benzoyl or aminobenzoyl groups and particularly cocaine, in containing a nitrogen ring, which is absent in procaine. The local anæsthetic No. 33C (gamma 2 methyl piperidino propyl benzoate hydrochloride), to be discussed specifically later, differs in addition from procaine in not having the benzoyl group substituted. The chemical preparation of these anæsthetics may be found in the papers of S. M. McElvain and co workers.

The merit of any substance for local anæsthesia should be determined by the following standards originally formulated by Braun: (1) the drug must produce a diffusible, complete, and lasting anæsthesia, (2) following systemic absorption it should be less toxic than cocaine in proportion to its anæsthetic power, (3) it should not produce irritation and painful infiltration (anæsthesia dolorosa) or cause local tissue damage, but should be absorbed without after effects such as hyperemia, exudation, or necrosis, (4) it should be soluble in water and its solution should be stable, (5) it should be readily sterilizable by heat, preferably in solution, (6) unless more powerfully anæsthetic and at the same time less toxic than any known substance, the drug should be compatible in solution with adrenalin.

The research workers of a prominent pharmaceutical house performed extensive laboratory experimentation on these drugs and then submitted their data to me for selection of those compounds most likely to give satisfaction in clinical use. While animal experimentation is of great value in the determination of toxicity and local tissue effects, the ultimate efficiency of a new drug will depend upon its action in practical use. In general, experiments performed upon laboratory animals show greater variation and are therefore of less value than those performed upon man.

Ten of these preparations were selected for trial because of low toxicity and high anæsthetic power. The anæsthetic potential was first determined by dermal wheals on the

wall. The right tube and ovary had been removed. Exploration of the abdomen did not reveal any other pathological condition. The entire uterus with the left tube and ovary were removed. The patient was dismissed from the hospital in 15 days.

Pathological report. The specimen was that of the uterus, the left tube and the ovary. The uterus was about twice its normal size. The surface of its anterior wall was raised by a tumor mass within the wall, about 5 centimeters in diameter. Its peritoneal surface was elevated with dark red and purplish lobules. On section the surfaces showed large caverns filled with blood (Fig. 1). The mucous membrane of the anterior wall was elevated and lobulated. There was a demonstrable opening from one of the blood caverns into the cavity of the uterus (Fig. 2). A microscopical examination showed numerous large caverns lined by a thin endothelial layer and supported by connective tissue trabeculae (Figs. 3 and 4). The pathological diagnosis was cavernous hæmangioma in the wall of the uterus.

September 24, 1929, the patient was in good health and had had no vaginal discharge since the operation.

TREATMENT

No treatment other than hysterectomy has been advised for hæmangioma of the uterus when this procedure can be carried out with safety. In the reported cases of true cavernous hæmangiomata in the wall of the uterus, there has been no difficulty in doing hysterectomy nor has there been any difficulty in doing myomectomy or hysterectomy in the reported cases of hæmangiomatous fibromyomata. Telangiectatic hæmangiomata of the pelvis, on account of the extensive involvement of the pelvic structures, have presented a difficult condition to treat surgically when they could not be removed. In Hone's case, the tumor was opened and packed in Pantzer's ligation of the right ovarian and the right uterine arteries and suture of the uterine wall had to be used to lessen the amount of blood supplying the area involved. The use of radium for any one of these varieties of hæmangiomata has not been reported.

SUMMARY

Aside from its rarity, the case being reported is interesting because the aperture in the wall

of a cavern of the hæmangioma allowed an escape of blood into the cavity of the uterus. This aperture in the wall more than likely resulted from a gradually increasing tension within the cavern with a corresponding stretching of the wall, thereby producing necrosis of a small area and finally perforation with hæmorrhage. The aperture which was clearly demonstrated in the uterus removed at operation suggests the possibility of the previous hæmorrhages having occurred through similar openings.

human skin. This is an attractive method because it parallels clinical usage. It involves direct action on the terminal nerve filaments and sensory end organs of the skin. Anæsthesia is but very little dependent upon pressure within the layers of skin because control wheals of physiological salt solution do not produce anæsthesia. Anæsthesia therefore results from a direct chemical action upon the nerve endings. By this method anæsthetic potential may be determined both by duration and by minimal anæsthetic concentration.

TECHNIQUE

The thighs and anterior abdominal wall were closely shaved. Dermal wheals were

TABLE III—DURATION OF ANÆSTHESIA OF ONE HALF PER CENT STRENGTHS OF NO. 33C WITH THE ADDITION OF 5 DROPS 1:1000 ADRENALIN TO 100 CUBIC CENTIMETERS

then raised with a special local anæsthesia syringe and finest hypodermic needle. The needle was thrust beneath the skin surface with bevel downward. At the moment the needle point entered the epidermis injection began, which was always endermic and not subcutaneous. The area of wheals was estimated as the size of a dime and required 0.8 cubic centimeters of solution each. It is important that all wheals be as nearly the same size as possible and contain the same amount of solution all of which has been injected intracutaneously. Adequate controls were employed consisting of novocain and salt solution, so that a mere disturbance of sensation was not interpreted as anæsthesia. Progressive series of dilutions in physiologic salt solution were injected as $\frac{1}{2}$, $\frac{1}{4}$, $\frac{1}{8}$, $\frac{1}{16}$, $\frac{1}{32}$, $\frac{1}{64}$ and $\frac{1}{128}$ of one per cent.

All wheals were made upon the writer by himself. The skin of thighs and abdominal wall is of such thickness that accurate wheals may be raised painlessly when the substance is anæsthetic. The sensitiveness of the skin and the rapidity of absorption vary in different areas of the body. It also varies in different individuals depending upon familial traits, exposure, vocation, etc. By employing the same skin area in the same individual these factors remain constant. The duration of anæsthesia in the same cutaneous area may also be shortened by previous brisk massage, heating or muscular exercise because of the improved circulation and consequently more rapid absorption. In these tests the subject remained seated and sources of external heat were avoided. Wheals were marked with a

CLINICAL SURGERY

FROM THE SURGICAL SERVICE NEW YORK HOSPITAL

A TECHNIQUE FOR SUBTOTAL THYROIDECTOMY IN EXOPHTHALMIC GOITER

EUGENE H. POOL, M.D., F.A.C.S., NEW YORK

A VARIETY of methods are followed by experienced operators in performing subtotal thyroidectomy for Graves' disease. Most of these are reliable and relatively safe as carried out by an extremely skilled surgeon, especially the one who has devised or developed the method. But in this field it is particularly difficult to emulate an outstanding operator and to do the operation with the same degree of skill as he. An effort has therefore been made to develop a procedure which may be followed with reasonable assurance of success by the average operator.

The chief requirements of the operation are expedition, control of hemorrhage at all times, adequate removal of thyroid tissue, and preservation of the parathyroid glands and recurrent laryngeal nerves. Expedition and control of hemorrhage will minimize immediate dangers. Remote failures notably persistence or recurrence of symp-

toms, are often due to insufficient removal of thyroid tissue. Only a small portion of each lateral lobe should be left and this must be a definite part, namely that which is in relation to the recurrent nerves and parathyroids. The parathyroids usually lie in or on the posterior surface of each lobe and the recurrent nerve runs from below upward from the posterior to the mesial aspect of this posterior part.¹ Therefore, on anatomical grounds the part to be left is definitely indicated (Fig. 1), namely the posterior and posteromesial portions. This forms a triangular mass on cross section leaving the portion which is in contact with the lateral aspect of the trachea. The preservation of this part with careful technique will prevent tetany and avoid injury to the recurrent nerves.

The method which is presented is reasonably simple and appears to meet the indications. While much of the procedure is employed by others notably, Richter, certain details are not generally recognized. Each lobe is freed. This is done by dividing the isthmus and dissecting it from the trachea. The superior thyroid vessels are ligated

Fig. 2. Curved transverse incision

circle of mercurochrome as soon as raised so that the center of the endermic infiltration was easily identified for testing after the wheal had disappeared. Tests for sensation were made by scratching the area with a wooden applicator or with a needle as is done in vaccination.

Table I expresses both duration of anæsthesia and minimal anæsthetic concentration. Novocain was used as a basis of comparison, physiologic salt solution as a control. The figures indicate duration of anæsthesia in minutes. It will be seen that all substances are more powerfully anæsthetic than novocain and that No. 33C and No. 50 are more powerful than all.

Table II shows the duration of anæsthesia in $\frac{1}{4}$ and $\frac{1}{16}$ per cent strengths after being boiled for 5 minutes. It will be observed that all retain their anæsthetic potency after sterilization by boiling.

Table III shows the duration of anæsthesia of the $\frac{1}{2}$ per cent strengths after the addition of adrenalin, in the proportion of 5 drops of the 1:1000 solution to 100 cubic centimeters of anæsthetic mixture. It will be observed that novocain is potentiated more than any of the other drugs in the proportion to its anæsthetic power alone. Nos. 56 and 56C were made more irritating by the addition of adrenalin. Irritation with these was so marked that necrosis and sloughing of the wheal area resulted. This would, of course, prohibit its use in clinical work.

The results of these tests indicate the superiority of No. 33C. It was so reported to the pharmaceutical house and they then began the manufacture of No. 33C in an amount sufficient for clinical trial. Its further suitability and ultimate efficiency should then depend upon its action in practical clinical work.

In the employment of any new drug in clinical work, it should first be used in terminal infiltration. The total amounts of

solution are different in terminal infiltration, field block, and nerve block. The technique of injection also influences the production of toxic symptoms. When the solution is distributed within the operative field proper, much of it escapes when the parts are incised and more is sponged from the tissues. But when the anæsthetic is deposited a distance from the operative field as it is in the regional method, the total quantity injected is absorbed. In certain regions the absorption is more rapid than in others, for example in the sacral canal and on either side of the vertebral column, a fact which accounts for a great likelihood of toxic manifestations in paravertebral and sacral anæsthesia.

The following operations were performed by the terminal infiltration method. Dermal wheals were first raised with finest hypodermic needles, after which the underlying tissues were well infiltrated. Further infiltration was carried out as necessary during the course of the operation. These operations were painlessly performed, there were no indications of toxic effects whatsoever during the operation and no interference with healing afterward. Clinical experiences are thus far very encouraging. It is now used routinely in all local anæsthetic work at the Mobile City Hospital and it is planned to use it in sacral and spinal anæsthesia.

CONCLUSIONS

Local anæsthetic drug No. 33C (gamma 2 methylpiperidino propyl benzoate hydrochloride) produces a diffusible complete and lasting anæsthesia, it compares favorably with novocain in systemic toxicity, it causes no local tissue damage or consequent interference with healing, its solutions do not deteriorate by boiling, and are compatible with adrenalin. Clinical experience thus far is very favorable and if it continues as satisfactory in more widespread use this drug promises to be the local anæsthetic of choice.

Fig 8 Diagrams showing division of fascia above isthmus division of tissues mesial to lateral lobe and division of isthmus

roid (Fig 4) This can be done readily near its attachment to thyroid cartilage No effort need be made to repair the muscle at the close of the operation

The steps of the operation are as follows

Curved transverse incision (Fig 2) of appropriate length depending upon the size of the gland The incision should not be so low as later to fall into the depression between the clavicles The incision is carried through the deep fascia The large anterior jugular veins and, in some cases, the lateral jugular veins are encountered and are divided between clamps The ribbon muscles are then widely exposed (Fig 3) by separating and lifting the upper flap, if necessary, as high as the incision of the thyroid cartilage The sternohyoids are then separated in the midline and retracted

As they are retracted the mesial borders of the sternohyoids are encountered somewhat laterally In large glands this muscle may be very much thinned and at times it is adherent to the thyroid, and in such cases it may be somewhat difficult to recognize it While the sternohyoid is retracted, the mesial edge of the sternothyroid is dissected free If the two muscles are then elevated with a retractor the insertion of the sternothyroid is usually well defined, as in illustration (Fig 4) The muscle is divided close to its insertion The sternothyroid is then stripped from the lobe by blunt dissection The same procedure is done on the opposite side

Fig 10 The whole lobe is easily lifted.

Fig 11 Clamps placed near extreme posterior part of lobe and gland cut and removed anterior to them

and divided. The inferior and middle thyroid veins are ligated and cut, and the outer surface of the lobe freed. The whole lobe may then be lifted thus demonstrating clearly the part to be left. Resection, leaving any amount which is desired, can then be done readily with little hæmorrhage and with easy control of such bleeding as occurs.

One feature in the exposure must be emphasized. The sterno-thyroid is inserted along the oblique line of the thyroid cartilage. In this area

it is in close relation to the mesial aspect of the upper part of the lateral thyroid lobe. As the muscle is here fixed obviously it cannot be retracted so as to give adequate exposure of the upper part of the gland. For this reason many surgeons divide both the sternohyoid and sterno-thyroid muscles. A little reflection will convince one that the sternohyoid having a much higher insertion may be widely retracted and that it is in general necessary to divide only the sterno-thyroid.

FROM STATE UNIVERSITY OF IOWA COLLEGE OF MEDICINE

FLEXOR PLASTY OF THE THUMB IN THENAR PALSY

A. STIFINDLER, M.D., F.A.C.S., IOWA CITY, IOWA

ELEVEN years ago¹ and in the years following the writer proposed a new operative procedure for the relief of one of the most disturbing disabilities of the hand, namely thenar palsy.² Because of its simplicity and reliability he considers the method of definite value in the treatment of this condition.

The most disabling feature of thenar palsy is the inability of the thumb to execute opposition movements. Even the more primitive motions of the hand depend upon opposition of the thumb; this, indeed, is one of the principal functions of the thenar muscles. It is true that to a limited degree, opposition may be substituted by other muscles. The lack of the abductor and of the short flexors of the thumb may be partly compensated by the action of the adductor of the thumb together with the long flexor. These muscles are not capable of placing the end of the thumb in opposition to the tips of the little and fourth fingers, but they enable the thumb to be held against the radial side of the index finger so that the holding of objects between the two fingers becomes possible. The condition is some what better if the short flexor of the thumb is functioning, but in neither case is opposition of the thumb substituted by the long flexor and the adductor to a degree at all comparable with the normal, nor is it satisfactory for every day use.

It was for these reasons that the writer 12 years ago conceived the idea of substituting the lost opposition action by a portion of the long flexor of the thumb. The indication for the operation is the presence of a well functioning long flexor of the thumb. The technique is as follows:

The incision is made along the radial side of the thumb beginning at the level of the interphalangeal joint and reaching proximally to a point about one half inch beyond the metacarpophalangeal joint. The lateral cutaneous nerve of the thumb can easily be avoided. By retracting the skin toward the ulnar side the long flexor of the thumb is exposed as it lies in its sheath. It is followed up above to its insertion into the end phalanx and below to the point where it emerges from under the short thumb muscles. In dissect-

ing the tendon proximally care should be taken to avoid injury to the branches of the median nerve as they enter the thenar group, in case part of the thenar group has escaped paralysis.

The sheath of the long flexor of the thumb is now incised its full length and the tendon exposed. The edges of the sheath are caught by fine forceps. The tendon is lifted out and is carefully split longitudinally into two equal halves commencing distally close to its insertion, and continuing proximally as far as the thenar muscle group. Next, the radial half of this tendon is freed at the distal end by cross incision and is brought out of the sheath (Fig. 1). The sheath of the long flexor is now reunited over the remaining half of the tendon by means of fine interrupted silk or catgut sutures, the radial flap emerging through a hole in the reconstructed sheath (Fig. 2). This radial tendon flap brought out of the sheath is attached to the periosteum of the basal phalanx in the following manner. The thumb is adducted maximally and both phalanges are fully flexed. This position is carefully maintained throughout the remainder of the operation and also during the postoperative fixation. Then with a curved forceps, a tunnel is made into the soft part around the dorsal aspect of the basal phalanx of the thumb and a short longitudinal incision (one half inch) is made down upon the point of the forceps. The free radial flap of the long flexor tendon is carried through this tunnel the end of the tendon is roughened, and under normal tension it is now sutured through the second dorsal incision above the metacarpophalangeal joint of the basal phalanx, about one fourth of an inch above the metacarpophalangeal joint (Fig. 3). For this purpose silk is used. One may pass the tendon through a drill hole into the phalanx as one wishes but it has not seemed to be necessary in the cases we have operated upon. Both incisions are closed in layers. The hand is bandaged in the position described, namely, with the thumb in full flexion both in the metacarpophalangeal and interphalangeal joints and the thumb metacarpal in full adduction. The thumb should be, as it were, entirely buried in the palm and must be left in this position for 3 weeks. After 3 weeks muscle exercises and active and passive motion are instituted.

Fig. 12. Resection completed

The pyramidal lobe and fascia above the isthmus are then divided so as to expose the trachea (Fig. 5). The pyramidal lobe is subsequently removed. A special curved clamp is usually passed down along the trachea between it and the isthmus without hemorrhage (Fig. 6). The isthmus is clamped on either side of this and divided. The two halves of the isthmus are then dissected from the anterior aspect of the trachea with little or no bleeding (Fig. 7). (We have never noted trachitis from the removal of the whole of the isthmus and in several cases where some of the isthmus has been left a recurrence has been noted in this tissue with marked deformity.) Clamps are then placed close to the mesial aspect of the lobe above the isthmus and the tissues divided between them. The superior pole is ligated and divided (Fig. 9). The whole lobe is then readily lifted as the lateral portion slides mesially (Fig. 10). The middle thyroid veins are ligated and divided and the lobe then is attached by a small vertical posterior portion. After the large inferior veins are ligated re-

Fig. 13. Michel clips are used for skin sutures double forceps facilitating their application

section is readily done. One method which is usually satisfactory for this step is as follows: clamps are placed from $\frac{1}{4}$ to $\frac{1}{2}$ inch from the extreme posterior part of the lobe and the gland cut and removed anterior to them (Fig. 11). Only three or four clamps are necessary. Complete hemostasis is usually easily secured by mattress sutures passed through the tissues beneath the clamps. The same procedure is performed on the other lobe (Fig. 12). The sternohyoids are brought together and sutured in midline.

A drain is usually introduced. It is placed laterally and is drawn in by a curved clamp which is passed between the muscles and brought out under the anterior margin of the sternomastoid. On removal of the drain this muscle slips over the tract and prevents adhesion of the superficial to the deep parts with the resulting depression or dimple. The fascia is united with fine chromic sutures and the skin with Michel clips. We have found it useful to use the double forceps in applying the clips. This enables the operator to hold the two edges of the skin wound in apposition with one hand, while he applies the clips with the other.

Fig 4 Traumatic ulnar palsy Pre operative (b) maximum opponens action possible

Fig 5 Seven months after operation a Range of abduction b patient can now touch fifth finger with considerable power

the ulnar side of the thumb but prefer the radial side of the thumb as there is less danger of subsequent scar contraction. In our earlier cases occasionally a scar contraction over interphalangeal and metacarpophalangeal joints of the thumb developed, but did not materially interfere with its opposition ability. If the incision is placed on the radial side of the thumb this can be avoided. Also it must be remembered that the liberated tendon slip should be passed well around the radial side to the back of the basal phalanx.

The average time of observation of all cases

was 4 years, but many of the cases have been observed for a much longer period, the earliest case dating from May 17, 1917. These statistics show that the results in general were sufficiently satisfactory to warrant the recognition of this method.

In later years two other methods have been advocated namely, that of Ney and of Bunnell. Without abrogating the merits of these methods which are both admirably conceived and thoroughly rational, the writer, nevertheless, recommends his own method for its simplicity and reliability of results.

Fig. 3. Fixation of the radial flap into periosteum. Tension properly obtained with full flexion of thumb in all joints.

Fig. 2. Tendon sheath reconstructed over remaining ulnar half of flexor longus pollicis. Radial half tunneled around the back of the phalanx.

The analysis of the failures is of interest. In the one case of birth palsy, failure was due to improper indications. The principal condition of a well functioning long flexor of the thumb did not obtain. In the other case, one of infantile paralysis the failure was due to adhesions which were formed following prolonged immobilization after operation, and interphalangeal contracture resulted. Re operation was not permitted.

We believe that most of the failures are due to two factors: either improper indications that is, absence of the long flexor of the thumb, or, neglect of after treatment, especially insufficient immobilization. It cannot be emphasized too strongly that the thumb must be held in the palm in flexed position after the operation for at least 3 weeks, since otherwise the tendon slip implanted into the base of the phalanx will not subsequently develop proper tension.

The kinetic effect of the flexor plasty of the thumb is readily understood. The tendon slip deflected to the back of the basal phalanx acts exactly in the direction of the *opponens pollicis*. Upon contraction the long flexor of the thumb will therefore not only flex the end phalanx but will also cause the metacarpal to swivel over the greater multangular by means of this detached tendon slip. This swivelling motion will carry the tip of the thumb into opposition to the tips of the little and ring fingers when full flexion of the thumb is executed (Figs. 4 and 5).

Since the earlier description of the operation several minor details of the technique have been introduced.¹ We no longer place the incision over

¹Nils Silvershield (Acta chirurg. Scand. 1928, no. 266) has practiced a modification wherein the entire tendon of the long flexor is transplanted. However, loss of flexion of the end phalanx results.

Fig. 1 Extensive involvement of almost the entire stomach

Fig. 2 The resected specimen showing the duodenum at the left and the esophageal opening at the right

stomach was suitable for anastomosis it was necessary either to remove the entire stomach or to do nothing. The duodenum was divided about 1 centimeter below the pylorus and the duodenal stump was closed. The stomach was then freed from its omental attachments throughout its entire length. By using the stomach as a tractor about 4 centimeters of the lower end of the esophagus could be seen below the diaphragm. A Brunner right angle rubber covered clamp was placed on the esophagus as high as possible and the esophagus was then severed about 1 centimeter above the cardiac sphincter. The stomach was then free and was removed (Fig. 2). The proximal loop of the jejunum was next brought up through an opening made in the transverse mesocolon and its side was anastomosed to the distal end of the esophagus with the use of one continuous row of silk and one row of chromic catgut sutures. A few interrupted silk sutures were added for reinforcement. A small jejunal tube was passed through the mouth down the esophagus and into the distal loop of the jejunum for a distance of about 15 centimeters below the anastomosis and was left in place.

Crossly the walls of the stomach were thickened, non-elastic and leathery. Although the entire stomach was involved the process was most marked in the distal third where the wall was 2 centimeters thick and the lumen was reduced to a rigid tube approximately 2 centimeters in diameter. An ulcer 10 by 8 by 4 millimeters was situated on the posterior wall near the lesser curvature at the junction of the proximal and middle thirds of the stomach. The lymph nodes were not found to be involved. Microscopic examination showed the typical diffuse scirrhous carcinoma of the linitis plastica type with carcinomatous cells infiltrating the submucous and muscular layers of the wall of the stomach (Figs. 3 and 4).

Convalescence was uneventful. Fluids were given by proctoclysis and 1000 cubic centimeters of 10 per cent glucose solution was given intravenously daily for 8 days. Small amounts of water were introduced through the jejunal tube on the sixth day. The amount was gradually increased until on the ninth day 2700 cubic centimeters of liquid nourishment including milk and cream, broth, fruit juices and water was given through the tube without distress. There was complete absence of nausea and vomiting. The jejunal tube was removed on the twelfth day and feeding was continued by mouth. On the sixteenth day soft and semisolid foods were given. The patient left the hospital on the twenty second day in good general condition. At that time she was taking her feedings at ninety minute intervals 2500 calories daily without discomfort. In a recent letter 40 days after the operation the patient reported that she was feeling well, gaining in strength and eating four meals each day. Untoward symptoms have not appeared.

INDICATIONS FOR TOTAL GASTRECTOMY

In a review of the cases in the literature in which the stomach has been removed completely it is found that practically all the operations were done for diffuse scirrhous carcinoma of the leather bottle or linitis plastica type. In a few cases a large ulcerating adenocarcinoma of a low grade of malignancy was found without lymphatic extension or apparent metastasis. In one case Butler removed the entire stomach for a lesion that proved to be a large benign ulcer. In linitis plastica where the disease is characteristically local with very little tendency toward extension beyond the stomach or metastasis until late in the course of the disease complete gastrectomy offers the only chance of cure. The results of palliative or

At the last report from the patient 9 months after operation she stated that her general health was good. Her diet had been general and she was taking four meals a day without any special symptoms. The only distressing phase of the report was the fact that she had not gained weight.

TOTAL GASTRECTOMY WITH REPORT OF A SUCCESSFUL CASE¹

E STARR JUDD M.D. F.A.C.S. ROCHESTER MINNESOTA

AND

JAMES M. MARSHALL M.D. ROCHESTER MINNESOTA

Fellow in Surgery The Mayo Foundation

IN spite of the fact that 45 years have passed since Conner performed the first total gastrectomy in man, only about 70 cases have been reported in the literature. Conner's patient moribund at the time of operation, died on the operating table. Thirteen years later Schlatter performed the first successful gastrectomy. His patient lived nearly 14 months and then died of recurrence of carcinoma. This case proved that the entire stomach could be removed successfully, that a functioning oesophago-enterostomy could be accomplished and the subject live in comparative comfort and health without a stomach.

Czerny and Kaiser in 1878 did pioneer work in total gastrectomy by planning and executing the operation in dogs. They attempted removal of the entire stomach and anastomosis of the oesophagus to the duodenum. One of their dogs lived 5 years, but at necropsy a small pouch of gastric tissue was found even though they had felt certain at the time of operation that the removal had been complete. Nevertheless their experiments were fundamental and pointed the way toward interesting physiological studies in gastrectomized animals. They also proved that the operation was technically feasible and of possible value in dealing with extensive malignant lesions of the stomach. Curiallo and Pachon, in 1893, and others since have successfully performed the operation in cats and have proved histologically postmortem that the entire stomach had been removed. They concluded that the animal was quite healthy without a stomach except that it had to be coaxed to eat and that although the stomach was not essential to digestion it might play a part in the initiation of appetite and hunger pains. Mann at The Mayo Clinic has devised a two-stage operation for use in dogs that renders the procedure much less difficult. At the present time he has 3 dogs on which total gastrectomy was performed more than 4 years ago. The general health of all 3 animals is excellent. The erythrocyte count and percentage of haemoglobin have remained within normal limits. He concludes that a dog without a stomach becomes just as hungry as a dog with a stomach and also that the gastrectomized animal can vomit just as a normal dog can.

We use the term total gastrectomy here only in reference to those cases in which the entire stomach has been removed. Many operations have been reported as total gastrectomy which in reality were subtotal gastrectomies because a small portion of the cardiac or pyloric end of the stomach was not excised. Finney and Rienhoff have carefully reviewed 67 cases from the literature in which they believed total gastrectomy had been performed. Since then Stahnke has reported a case. Six total gastrectomies had been previously performed in the clinic. The most successful was the operation performed by W. J. Mayo. His patient lived 4 years and was in reasonably good health during that time. Walters has recently performed the operation and his patient is alive and well 23 days after operation. Because of the rarity of this operation we are reporting the case of a patient operated on by one of us (Judd) 5 months ago.

A woman aged 62 years came to the clinic July 9, 1920 complaining of stomach trouble of 10 months duration. The onset had been rather insidious. There had been dull gnawing pain in the mid epigastrium with some gas and belching coming on regularly 2 to 3 hours after meals. It could be relieved only by taking more food. There had been no vomiting since the onset but rather a steady and progressive increase in the severity of the symptoms. Gradually the patient had noticed that the capacity of the stomach was decreasing, and during the 3 months prior to admission regurgitation had frequently taken place if too much had been eaten at one time. Alkalies of various kinds had been taken without relief. There had not been haematemesis or melena. She had lost about 10 pounds most of it in the last 3 months.

On examination the patient appeared to be fairly well nourished. She weighed 118 pounds. A firm freely movable slightly tender mass was palpable in the epigastrium just above the umbilicus. Fractional gastric analysis showed maximal total acidity to be 38 and free hydrochloric acid 12. Roentgen ray examination revealed an extensive scirrhus type of carcinomatous deformity involving almost the entire stomach (Fig. 1). The haemoglobin was 77 per cent, erythrocytes numbered 4,430,000 and the leucocytes 6,200 and the differential count was normal. Examination of the urine was negative as were the Wassermann reaction of the blood and roentgenogram of the chest.

At operation July 13, 1920 the stomach was found to be somewhat reduced in size. Its walls were thickened throughout and the entire stomach was evidently involved with a diffuse scirrhus carcinoma of the intussus plastica type, a typical leather bottle stomach. Lymph nodes could not be felt and there was no evidence of intra-abdominal extension or metastasis. Since no portion of the

Fig. 1 Extensive involvement of almost the entire stomach

stomach was suitable for an anastomosis it was necessary either to remove the entire stomach or to do nothing. The duodenum was divided about 1 centimeter below the pylorus and the duodenal stump was closed. The stomach was then freed from its omental attachments throughout its entire length. By using the stomach as a tractor about 4 centimeters of the lower end of the esophagus could be seen below the diaphragm. A Brunner right angle rubber covered clamp was placed on the esophagus as high as possible and the esophagus was then severed about 1 centimeter above the cardiac sphincter. The stomach was then free and was removed (Fig. 2). The proximal loop of the jejunum was next brought up through an opening made in the transverse mesocolon and its side was anastomosed to the distal end of the esophagus with the use of one continuous row of silk and one row of chromic catgut sutures. A few interrupted silk sutures were added for reinforcement. A small jejunal tube was passed through the mouth down the esophagus and into the distal loop of the jejunum for a distance of about 15 centimeters below the anastomosis and was left in place.

Crossly the walls of the stomach were thickened, non elastic and leathery. Although the entire stomach was involved the process was most marked in the distal third where the wall was 2 centimeters thick and the lumen was reduced to a rigid tube approximately 2 centimeters in diameter. An ulcer 10 by 8 by 4 millimeters was situated on the posterior wall near the lesser curvature at the junction of the proximal and middle thirds of the stomach. The lymph nodes were not found to be involved. Microscopic examination showed the typical diffuse scirrhous carcinoma of the linitis plastica type with carcinomatous cells infiltrating the submucous and muscular layers of the wall of the stomach (Figs. 3 and 4).

Convalescence was uneventful. Fluids were given by proctoclysis and 1000 cubic centimeters of 10 per cent glucose solution was given intravenously daily for 8 days. Small amounts of water were introduced through the jejunal tube on the sixth day. The amount was gradually increased until on the ninth day 2700 cubic centimeters of liquid nourishment including milk and cream, broth, fruit juices and water was given through the tube without distress. There was complete absence of nausea and vomiting. The jejunal tube was removed on the twelfth day and feeding was continued by mouth. On the sixteenth day soft and semisolid foods were given. The patient left the hospital on the twenty second day in good general condition. At that time she was taking her feedings at ninety minute intervals 2500 calories daily without discomfort. In a recent letter 40 days after the operation the patient reported that she was feeling well, gaining in strength and eating four meals each day. Untoward symptoms have not appeared.¹

INDICATIONS FOR TOTAL GASTRECTOMY

In a review of the cases in the literature in which the stomach has been removed completely it is found that practically all the operations were done for diffuse scirrhous carcinoma of the leather bottle or linitis plastica type. In a few cases a large ulcerating adenocarcinoma of a low grade of malignancy was found without lymphatic extension or apparent metastasis. In one case Butler removed the entire stomach for a lesion that proved to be a large benign ulcer. In linitis plastica where the disease is characteristically local with very little tendency toward extension beyond the stomach or metastasis until late in the course of the disease, complete gastrectomy offers the only chance of cure. The results of palliative or

¹ At the last report from the patient 9 months after operation she stated that her general health was good. She had been general and she was taking four meals a day without any gastric symptoms. The only drawback phase of the report was the fact that she had not gained in weight.

Fig 3 A section from the stomach wall showing the typical diffuse infiltration of the carcinomatous cells (X 50)

Fig 4 Same section as shown in Figure 3 (X 250)

incomplete operations in these cases have been uniformly disappointing

TYPES OF OPERATION

Cesophagojejunostomy is probably the operation of choice in most cases. In an analysis of the end results, Finney and Rienhoff found that of 26 patients in whom the cesophagus was anastomosed to the jejunum 58 per cent recovered and 47 per cent died as compared to the 30 patients on whom cesophagoduodenostomy was done and of whom 47 per cent recovered and 53 per cent died. In 9 cases in which anastomosis was not done the cesophageal stump being closed and either the duodenum or jejunum brought out and sutured to the skin, all the patients died, either from shock or from a spreading infection from the cesophageal stump. Usually the jejunum has been brought up through an opening made in the transverse mesocolon as is done in ordinary posterior gastrojejunostomy, but a few successful cases have been reported in which an antecolic anastomosis had been done. In most cases cesophagoduodenostomy would be a more difficult procedure because of the difficulty in getting sufficient mobilization of the duodenum to prevent tension on the line of anastomosis.

COMPLICATIONS

Patients on whom total gastrectomy is done are often poor surgical risks. Twenty five per cent of the deaths in the reported cases have been attributed to surgical shock. Of the immediate postoperative complications peritonitis is the most common it caused approximately 60 per cent of the deaths. Hemorrhage, cesophageal fistula and duodenal fistula are rare complications. Rienhoff and Kocher each reported a case of persistent postoperative stomatitis which progressed to eventual enteritis and death. In Reid's case stomatitis was a distressing complication for several weeks but the patient recovered and lived 18 months. Most of the patients who have lived have seemed to have had strikingly uneventful courses. Vomiting was mentioned in only a few instances.

Changes in the blood similar to those seen in pernicious anemia have been commented on by Moynihan and Hartman as late complications. Moynihan's patient lived 3 years and 8 months and at necropsy evidence of profound anemia was found. There was complete absence of recurrence of the carcinoma and practically no dilatation of the jejunum that had been used for the anastomosis. Hartman, reporting on one of W. J. Mayo's patients, studied the changes in the blood carefully over a considerable period. The patient lived 4 years after the operation and

apparently died from the anæmia, but details concerning the death were not available. Mann and Graham performed gastrectomy on dogs that lived more than 4 years apparently in good health without signs of anæmia or other physiological disturbance.

RESULTS

Complete follow up data are not available in many of the reported cases so that an accurate analysis of the end results cannot be made. Zikoff's patient lived 4 years and 8 months. W. J. Mayo's patient lived 4 years, and Moynihan's 3 years and 8 months. Perhaps some have lived longer. Most of the patients who are reported to have lived for longer periods have had 'almost' total gastrectomy, a small portion of the cardiac end of the stomach having been left. Most of the patients of whom we have records, that have survived the operation, have eventually died of a recurrence of the carcinoma. However, it is a fact often mentioned in the case reports that these patients live in apparent comfort and good health except during the last few weeks before death. They take a wide variety of food even three meals a day are sometimes taken with little if any, digestive or metabolic disturbance.

BIFID OS CALCIS

JAMES WARREN SEVER, M.D., F.A.C.S., Boston

IT is my purpose to call attention to a hitherto undescribed condition of clinical importance, which should not be confounded with a disease the result of a pathological process. Three cases are presented which were discovered during routine X-ray studies of patients at the Children's and Infants' Hospital.

I have carefully investigated all available and pertinent literature and have been unable to find a description of such a condition. My associates in roentgenology recall seeing no previous examples.

DEVELOPMENT OF OS CALCIS

According to Cray, the epiphyseal center of the body of the os calcis appears at the sixth month of the fetal life and the center for the posterior tuberosity at about the tenth year. No mention is made of a double center of the body of the os calcis.

Keibel and Mall in their book *Human Embryology*, state that the chief center of the calcaneus develops at the sixth month. They state that the chief nucleus is endochondral and also that a periosteal nucleus appears frequently in the fourth and fifth fetal month. It is generally agreed that the center for the posterior tuberosity appears at about the age of 10 years but as has been shown by X-ray studies¹ at the Children's Hospital several years ago that is usually 3 years too late.

Bifid os calcis is significant from a clinical standpoint as the condition may be easily mistaken for a fracture the result of a fall or of some other injury to the foot. The condition may not be mistaken for fracture in the very young children but a diagnosis of fracture may be made in children who are walking. Roentgenograms of both feet should always be taken. If present the condition is usually found to be bilateral.

Fig. 4. Roentgenogram of Case 3.

Figs. 5 and 6. Os calcis removed in Case 3.

CASE 1. E. P. aged 2 years reported to the Out Patient Department at the Children's Hospital with the history of having fallen down stairs a week previously. Physical examination revealed no apparent injury. The patient was referred to the orthopedic department for treatment of the feet as both feet were badly pronated. The child showed a limp on walking but there was no swelling and no local tenderness when she walked. X-ray pictures were taken which showed bifid ossa calcis. The line of separation divided the anterior one third from the posterior two thirds. Patient was treated for pronation and a year later October 1927 X-ray pictures were taken of the carpal bones to see whether development was normal. At that time patient was 3 years of age. He showed only two centers of ossification in the carpal bones which according to Priors table denotes delayed anatomical development. However the cleft in both ossa calcis had fused and disappeared. He was seen and roentgenographed 1 or 2 years later and no further abnormality was observed (Fig. 1).

CASE 2. An infant 8 months old a full term child weighed at birth 6½ pounds but was an idiot. Roentgenograms (Figs. 2 and 3) showed bilateral bifid ossa calcis with the line of cleavage between the anterior one third and the posterior two thirds as in Case 1. No other anatomical change was observed.

CASE 3. D. N. 10 months old male entered the hospital February 27 1929. The child was a patient at the Infants' Hospital being treated for leukemia. He weighed at birth 8 pounds and was full term child of normal delivery. He had a large spleen and liver and the usual blood picture of leukemia. In the course of routine X-ray examination the bifid condition of the ossa calcis was discovered. The child eventually died and we were fortunate enough to obtain one oss calcis.

The roentgenograms showed both feet with the usual type of bifid oss calcis as described above. Figures 5 and 6 show the oss calcis removed but no real signs of cleavage in the gross specimen. Figure 6 shows the oss calcis sectioned longitudinally and demonstrates the separation clearly. This line of separation or septum was cartilaginous in nature.

The pathological report on the gross specimen and section from the septum is as follows: The bone was carefully removed and on external examination appeared to be quite normal in form. It was composed chiefly of cartilage and on the external surface no true bone was found (Fig. 5). The specimen was split at right angles to the defect which was seen in the X-ray film. The ossified portion of the bone cut with exceptional ease. The cut surface presented two centers of ossification the largest measuring 11 by 12 millimeters and the smaller 4 by 7 millimeters. Separating these centers of ossification was a septum 1.5 millimeters in width composed of a whitish gray cartilage like tissue (Fig. 6). Microscopically the bone consisted of a normal cartilaginous shell in which were the two centers of ossification the septum being composed of cartilage fibrous tissue and bone. The bone in some portions was completely ossified in others it consisted of a new bone matrix and in some areas merely of osteoblastic tissue. The bone spicules were heavier and more numerous on the septal sides than along the peripheral borders. The remaining portion of the septum consists of cartilage and fibrocartilaginous tissue which in places shows evidence of beginning bone formation. The ossified portions of the bone contain only a few well formed bone spicules and an abundant active marrow. The anomalous condition of the

Figs. 7 and 8. Photomicrographs of specimen in Case 3.

bone while it now shows an abnormal ossification does not however appear to be a diseased process but rather a congenital condition which in the course of time would be lost had the child lived (Figs. 7 and 8).

Here then we have a new, and so far as I know, an undescribed developmental condition. It may be associated as in Case 1 with other anatomical delays of ossification. If the patient lives the defect disappears probably by the time he is 3 years of age. Before that age, it is important that the condition be recognized and that in case of injury it be distinguished from fracture.

When the first case was observed one foot only had been examined with the X-ray and I believed we were dealing with a most unusual fracture of early childhood.

I am indebted to Dr. Vogt of the X-ray Department of the Children's Hospital Boston for the X-ray plates and to the Pathological Department for their interest in the pathological reports on these cases.

SPONTANEOUS FRACTURES OF THE OS CALCIS

BILATERAL OSTEO ARTHROPATHIES IN A TABETIC PATIENT

NORMAN CAPEVER FRCS (FAC) ANN ARBOR, MICHIGAN

From the Department of Surgery (Orthopedic Division) University of Michigan Hospital, Ann Arbor, Michigan

THE subject of this communication was an apparently healthy woman, aged 54, who presented herself at the University Hospital on April 12, 1929 with a slightly painful swelling of her left ankle and the history that in November 1928, she had twisted her foot between two boards. After the injury there was considerable swelling and she treated the condition as a sprain and continued to walk. The swelling however, did not completely disappear. One day in February, 1929, while walking, she felt something "slip" in the left ankle and there was some pain and sudden swelling. Of late she had been able to be on her feet only for about half the day because she tired easily. The foot was painless, however.

CLINICAL PROGRESS

Examination. She walked into the clinic. The left foot showed an edematous swelling surrounding the ankle and a small ecchymosis over the head of the astragalus. The ankle joint showed slight loss of dorsiflexion and there was marked diminution of subastragaloid joint movement. No tenderness could be elicited. There was no evidence of any other joint involvement. The blood Kahn reaction was negative. A ray examination was made the lateral view of which is reproduced (Fig. 1). It will be observed that there was an oblique comminuted fracture of the os calcis with compression of this bone and involvement of the subastragaloid joint. There was bone sclerosis at the fracture site, some apparent absorption of the posterior edge of the astragalus and marked osseous proliferation and fragmentation extending upward behind the astragalus deep to the tendo achillis. A diagnosis was made of spontaneous fracture of the left os calcis and the possibility of a neurotrophic joint was considered. No evidence of malignant disease elsewhere being found and the pupils being observed not to

react to light the cerebrospinal fluid was examined and its Kahn reaction was 4 plus. In addition to this and the remarkable absence of pain in the left foot there was loss of ankle jerk and of deep tendo achillis tenderness on the right side. Neurological examination by Dr C. D. Camp confirmed the diagnosis of tabes dorsalis.

Operation upon the left foot. It was decided to arthrodese the subastragaloid joint. On April 2, therefore I exposed this joint through Kocher's incision, dividing the peroneal tendons and the external lateral ligament. There was considerable scar tissue and much irregularity of the posterior articular surface of the os calcis with the piled up osteophytic mass behind it. The fracture site was exposed as a deep groove running anterior to this articular surface and ending in a pit like excavation at the tarsal sinus. From this two sequestered portions of bone were removed. The cartilage was now removed from the articular surfaces of the subastragaloid joint together with neighboring bony excrescences and the wound closed.

Postoperative course. The painless nature of the postoperative course was noteworthy and the wound healed by first intention. The patient was discharged on June 19 with the left foot in a cast after having a course of antituberc treatment. On July 3 a brace was fitted to the left leg. On July 24 she returned on account of edema of the right leg and ankle. This was considered to be of purely circulatory origin as there was no history or evidence of trauma and X-ray examination was negative. A reproduction of this view is given in Figure 3.

On August 14 the patient returned having had for 2 days swelling and instability of the left knee and it was evident that she had a neurotrophic lesion here. The left foot showed excellent healing with bony ankylosis of the subastragaloid joint (Fig. 2). While waiting for a brace for the left knee she drew our attention once more to the swelling of the right ankle which although painless now showed considerable thickening of the os calcis and definite interference with subastragaloid movement. New X-rays were taken on August 23 and a well marked transverse fracture of the os calcis was demonstrated with considerable sclerosis and irregularity of the bone ends (Fig. 4).

Operation upon the right foot. On August 28 I operated upon the right foot. Much disorganization was found at

FIG. 1. Left foot before operation.

FIG. 2. Left foot four months after subastragaloid arthrodesis.

FIG. 3. Right foot July 24, 1929.

FIG. 4. Right foot August 23, 1929. Roentgenogram taken before operation.

the fracture site the line of which passed immediately behind the posterior articulation of the subastragaloid joint. There was some upward displacement of the posterior fragment and much soft scar tissue between the bone surfaces. The cartilage was removed from the subastragaloid joint and the scar tissue from the fracture. The fragments were approximated and the wound closed.

Pathological report by Dr A. S. Warthin on tissue removed from the left os calcis: A chronic osteoarthropathy. A vascular granulation tissue filling marrow spaces and causing necrosis and absorption of the bone. Not a pyogenic osteomyelitis but probably a syphilitic osteitis.

In view of the last phrase of this report and the view that I held from the clinical standpoint that this was a neurotrophic lesion, I was much interested to know Dr Warthin's opinion upon the right foot, which was as follows:

Spec 1 (Soft tissue from capsule): Chronic productive inflammation with necrosis of bone, marked fibrosis, degeneration of cartilage, vascular granulation tissue. Possibly syphilitic.

Spec 2 (Bone after decalcification): Chronic productive osteitis with necrosis of bone, new formation of atypical

bone and cartilage. Vascular fibrosis of marrow spaces. Most probably syphilitic but no gummatous areas found.

In conversation Dr Warthin told me that he regarded these lesions to be of the type usually classified as Charcot joints but that in his opinion, apart from the neurotrophic condition, there is usually a local syphilitic process.

SUMMARY

This case is remarkable (1) on account of the multiplicity of the lesions which from the clinical point of view are neurotrophic, (2) upon the rapidity of onset of the lesion in the right foot as demonstrated by the roentgenograms taken at an interval of one month and (3) the satisfactory healing both of bone and soft tissues after operation.

NOTE:—Since the above article was written this patient has had further misfortune, this time sustaining (on the 25th of November) a spontaneous fracture of her right tibia and fibula at their upper end. This occurred while she was standing quite still supporting her weight on crutches. The condition of the feet remains excellent.

SOLITARY TUBERCULOMA OF THE BLADDER

J. A. BOWEN, M.D., BOSTON

Department of Urology, Peter Bent Brigham Hospital

AND

G. A. BENNETT, M.D., BOSTON

Department of Pathology, Peter Bent Brigham Hospital and Harvard Medical School

BECAUSE of the difficulty encountered in differentiating solitary tuberculoma from carcinoma of the bladder without microscopic examination and because after a careful search through the literature we have been unable to find any mention of this condition, the following case is reported:

Mr M. I. P., Surgical No. 33744, a white male aged 47 years entered the hospital April 15, 1929 complaining of hematuria. The family history was irrelevant. The past history was negative except that about 10 years ago he had a series of abscesses of the scrotum which were incised and drained and which finally cleared up after about 8 months.

The onset of his present illness occurred about 5 weeks ago with frequency, nocturia, and slight burning on urination. These symptoms gradually increased in severity and about 2 weeks ago he had a brisk hemorrhage from the urethra. The hematuria was total for about 36 hours then gradually disappeared. He has had two similar attacks since then. His general health has remained unaffected.

The physical examination was quite negative except for large ragged tonsils, slight induration of the left epididymus

and several scars over the left scrotum and slight tenderness of the left lobe of the prostate.

Blood count showed white blood cells 7,400, red blood cells 5,200,000, hemoglobin 75 per cent, Wassermann reaction was negative. The urine was grossly bloody. X-ray examination of his chest was negative.

The day following admission to the hospital cystoscopic examination showed a fungating ulcerated lesion with a greyish green bleeding surface about the size of a half dollar situated in the dome of the bladder and surrounded by a border of induration. The remaining mucosa and the urethral orifices were normal in appearance. The bladder outlet was obstructed somewhat by a small median bar formation. A diagnosis of carcinoma of the bladder seemed logical and surgical removal was advised.

On April 17, under nitrous oxide-oxygen anesthesia the tumor surrounded by a margin of normal mucosa was resected. Since the induration extended upward along the urachus this structure together with the umbilicus was removed. The bladder was closed over a large mushroom catheter.

Pathological report: The excised specimen consisted of the fundus of the bladder, the middle umbilical ligament and the false ligaments of the bladder with the separately excised umbilicus. The umbilicus showed no abnormality whatsoever although sections were taken for histological examination. The bladder specimen when examined from

One day in February, 1929 while walking, she felt something "slip" in the left ankle and there was some pain and sudden swelling. Of late she had been able to be on her feet only for about half the day because she tired easily. The foot was painless however.

CLINICAL PROGRESS

Examination. She walked into the clinic. The left foot showed an edematous swelling surrounding the ankle and a small ecchymosis over the head of the astragalus. The ankle joint showed slight loss of dorsiflexion and there was marked diminution of subastragaloid joint movement. No tenderness could be elicited. There was no evidence of any other joint involvement. The blood Kahn reaction was negative. X-ray examination was made the lateral view of which is reproduced (Fig. 1). It will be observed that there was an oblique comminuted fracture of the os calcis with compression of this bone and involvement of the subastragaloid joint. There was bone sclerosis at the fracture site, some apparent absorption of the posterior edge of the astragalus and marked osseous proliferation and fragmentation extending upward behind the astragalus deep to the tendo achillis. A diagnosis was made of spontaneous fracture of the left os calcis and the possibility of a neurotrophic joint was considered. No evidence of malignant disease elsewhere being found and the pupils being observed not to

react to light the cerebrospinal fluid was examined and its Kahn reaction was 4 plus. In addition to this and the remarkable absence of pain in the left foot there was loss of ankle jerk and of deep tendo achillis tenderness on the right side. Neurological examination by Dr. C. D. Camp confirmed the diagnosis of tabes dorsalis.

Operation upon the left foot. It was decided to arthrodese the subastragaloid joint. On April 22 therefore I exposed this joint through Kocher's incision dividing the peroneal tendons and the external lateral ligament. There was considerable scar tissue and much irregularity of the posterior articular surface of the os calcis with the piled up osteophytic mass behind it. The fracture site was exposed as a deep groove running anterior to this articular surface and ending in a pit like excavation at the tarsal sinus. From the two sequestered portions of bone were removed. The cartilage was now removed from the articular surfaces of the subastragaloid joint together with neighboring bony excrescences and the wound closed.

Postoperative course. The painless nature of the postoperative course was noteworthy and the wound healed by first intention. The patient was discharged on June 19 with the left foot in a cast after having a course of antiluetic treatment. On July 3 a brace was fitted to the left leg. On July 24 she returned on account of edema of the right leg and ankle. This was considered to be of purely circulatory origin as there was no history or evidence of trauma and X-ray examination was negative. A reproduction of the view is given in Figure 3.

On August 14 the patient returned having had for 2 days swelling and instability of the left knee and it was evident that she had a neurotrophic lesion here. The left foot showed excellent healing with bony ankylosis of the subastragaloid joint (Fig. 2). While waiting for a brace for the left knee she drew our attention once more to the swelling of the right ankle which although painless now showed considerable thickening of the os calcis and definite interference with subastragaloid movement. New X-rays were taken on August 23 and a well marked transverse fracture of the os calcis was demonstrated with considerable sclerosis and irregularity of the bone edges (Fig. 4).

Operation upon the right foot. On August 28 I operated upon the right foot. Much disorganization was found at

Fig. 1. Left foot before operation.

Fig. 2. Left foot four months after subastragaloid arthrodese.

Fig. 3. Right foot July 24, 1929.

Fig. 4. Right foot August 3, 1929. Roentgenogram taken before operation.

a cellular appearing greyish white hard tissue with an overlying hemorrhagic and necrotic surface. External to the bladder musculature there were numerous areas from 1 to 11 millimeters in diameter which showed a greyish yellow irregular border with softened necrotic centers.

The hardness of the entire specimen, the proliferative ulceration of the mucosa, the thickened mucosa with the greyish white streaks running through the muscularis and the large puckered necrotic mass of indurated fat external to the bladder musculature all simulated an infiltrating tumor of the bladder wall. The neoplastic appearance was further substantiated by the marked puckering of the peritoneal surface overlying the fundus of the bladder.

Microscopic examination. Sections taken to include various portions of the entire specimen revealed a wide spread inflammatory process characterized by areas of necrosis, lymphoid plasma and epitheloid cell infiltration and the presence of giant cells (Fig. 4). The section which included the ulcerated mucosa showed an abrupt transition from slightly thickened and infiltrated bladder mucosa to an area of ulceration the base of which contained a formless necrotic debris with here and there well formed tubercles about the margin. The white bands described streaming through the muscularis in the gross proved histologically to be areas of fibrosis heavily infiltrated with lymphocytes, plasma cells and in many instances they contained small tubercles. The necrotic areas external to the muscularis in the fatty tissue revealed small and large conglomerate tubercles with characteristic formless necrosis, a heavy lymphoid infiltration, marked epitheloid cell proliferation and very numerous giant cells. Sections

stained by appropriate methods revealed scattered acid fast rods which were morphologically typical of tubercle bacilli. There was no extension of the tuberculous process up into the middle umbilical ligament.

About 36 hours after operation the patient began to have difficult respirations and physical examination showed dullness over the right lower chest anteriorly with slight tubular breathing, diminution of the breath sounds and reduced excursions. The X-ray diagnosis was massive collapse of the lung. This condition cleared up very slowly and for a number of days the patient had a severe productive cough with considerable pain over the right side of his chest. Repeated examination of his sputum failed to reveal tubercle bacilli and a chest tap was nonproductive. His wound healed rather slowly because of persistent urinary drainage due to the small size of his bladder. Twenty-eight days after operation his wound was completely healed and he was voiding small amounts of urine frequently.

From this time until his discharge from the hospital a month later his wound occasionally reopened and drained small amounts of urine for short periods of time. His chest cleared gradually and upon discharge still showed a mottling fibrosis of the right middle lobe anteriorly. On discharge the urine was clear, sterile and showed no evidence of the tubercle bacillus.

October 21, 1929. The patient reports that his health has been excellent since operation. He has gained weight. The function of the bladder is entirely normal and the urine is free from evidence of disease. He has had no further difficulty in regard to the lungs.

Fig. 4 Photomicrograph showing characteristic tubercle formation in bladder wall

Fig. 5 A diagrammatic sketch illustrating the relationship and extent of the bladder tuberculoma

above downward was somewhat triangular in shape the apex of the triangle extending upward along the middle umbilical ligament toward the umbilicus. The external surface on this side of the specimen was covered over by peritoneum which in the mid portion or directly opposite the excised bladder mucosa showed a very extensively puckered central area (Fig. 1). This area measured approximately 2 centimeters in diameter and in addition to being hard and retracted was definitely injected over the peritoneal surface. The bladder or inner surface of the specimen was roughly circular in shape and measured 5 centimeters in diameter (Fig. 2). In the center of the excised mucosal surface there was an irregular ulceration of the mucosa which measured approximately 2 centimeters in diameter. This ulceration presented a hemorrhagic irregular and in part slightly undermined surface with a greyish yellow necrotic base and very little excavation. The deepest part of the ulceration was only 2 millimeters below the surface of the surrounding bladder. Be-

tween the mucosal and the peritoneal surface of the excised specimen the musculature of the bladder wall and the extravascular fat were included. A single longitudinal section was made directly through the ulceration carried through the bladder wall and extended upward into the center of the middle umbilical ligament (Fig. 3). The surface made by this incision revealed a markedly thickened bladder wall with small pinkish white irregular islands of what appeared to be smooth muscle tissue. These islands were separated by irregular varying sized bands of dense white tissue extending outward from the thickened and fibrous submucosa through the muscularis and into the adjacent fat. The ulceration on the cut surface showed

a cellular appearing greyish white hard tissue with an overlying hemorrhagic and necrotic surface. External to the bladder musculature there were numerous areas from 1 to 11 millimeters in diameter which showed a greyish yellow irregular border with softened necrotic centers.

The hardness of the entire specimen the proliferative ulceration of the mucosa the thickened mucosa with the greyish white streaks running through the muscularis and the large puckered necrotic mass of indurated fat external to the bladder musculature all simulated an infiltrating tumor of the bladder wall. The neoplastic appearance was further substantiated by the marked puckering of the peritoneal surface overlying the fundus of the bladder.

Microscopic examination. Sections taken to include various portions of the entire specimen revealed a wide spread inflammatory process characterized by areas of necrosis lymphoid plasma and epithelioid cell infiltration and the presence of giant cells (fig. 4). The section which included the ulcerated mucosa showed an abrupt transition from slightly thickened and infiltrated bladder mucosa to an area of ulceration the base of which contained a formless necrotic debris with here and there well formed tubercles about the margin. The white bands described streaming through the muscularis in the gross proved histologically to be areas of fibrosis heavily infiltrated with lymphocytes plasma cells and in many instances they contained small tubercles. The necrotic areas external to the muscularis in the fatty tissue revealed small and large conglomerate tubercles with characteristic formless necrosis a heavy lymphoid infiltration marked epithelioid cell proliferation and very numerous giant cells. Sections

stained by appropriate methods revealed scattered acid fast rods which were morphologically typical of tubercle bacilli. There was no extension of the tuberculous process up into the middle umbilical ligament.

About 36 hours after operation the patient began to have difficult respirations and physical examination showed dullness over the right lower chest anteriorly with slight tubular breathing diminution of the breath sounds and reduced excursions. The X-ray diagnosis was massive collapse of the lung. This condition cleared up very slowly and for a number of days the patient had a severe productive cough with considerable pain over the right side of his chest. Repeated examination of his sputum failed to reveal tubercle bacilli and a chest tap was nonproductive. His wound healed rather slowly because of persistent urinary drainage due to the small size of his bladder. Twenty-eight days after operation his wound was completely healed and he was voiding small amounts of urine frequently.

From this time until his discharge from the hospital a month later his wound occasionally reopened and drained small amounts of urine for short periods of time. His chest cleared gradually and upon discharge still showed a mottling fibrosis of the right middle lobe anteriorly. On discharge the urine was clear sterile and showed no evidence of the tubercle bacillus.

October 21 1929. The patient reports that his health has been excellent since operation. He has gained weight. The function of the bladder is entirely normal and the urine is free from evidence of disease. He has had no further difficulty in regard to the lungs.

above downward was somewhat triangular in shape, the apex of the triangle extending upward along the middle umbilical ligament toward the umbilicus. The external surface on this side of the specimen was covered over by peritoneum which in the mid portion or directly opposite the excised bladder mucosa showed a very extensively puckered central area (Fig. 1). This area measured approximately 2 centimeters in diameter and in addition to being puckered and retracted was definitely injected over the peritoneal surface. The bladder or inner surface of the specimen was roughly circular in shape and measured 5 centimeters in diameter (Fig. 2). In the center of the excised mucosal surface there was an irregular ulceration of the mucosa which measured approximately 2 centimeters in diameter. This ulceration presented a hemorrhagic irregular and in part slightly undermined surface with a greyish yellow necrotic base and very little excavation. The deepest part of the ulceration was only 2 millimeters below the surface of the surrounding bladder. Be-

tween the mucosal and the peritoneal surface of the excised specimen the musculature of the bladder wall and the extravascular fat were included. A single longitudinal section was made directly through the ulceration, carried through the bladder wall and extended upward into the center of the middle umbilical ligament (Fig. 3). The surface made by this incision revealed a markedly thickened bladder wall with small pinkish white irregular islands of what appeared to be smooth muscle tissue. These islands were separated by irregular varying sized bands of dense white tissue extending outward from the thickened and fibrous submucosa through the muscularis and into the adjacent fat. The ulceration on the cut surface showed

Fig 1 Steel die used in cutting out islands

Fig 2 Illustrating method of undercutting skin between islands. Dotted portions and arrows indicate successive positions of scalpel

penses The foil pattern is placed upon the donor site of skin. The scalpel follows its periphery as it cuts through the skin just to the fat. A steel die resembling a cork borer or punch but having certain important differences well described in the accompanying drawing (Fig 1) is used. With a twisting motion of the thumb and index finger this die bores out islands of skin at equal distances from one another throughout the area of the graft. The cutting edge of the die measures one fourth of an inch in diameter and its flange is one sixteenth of an inch deep.¹ While each island is being bored out it is helpful to hold the surrounding skin under tension. This is accomplished by placing the index finger of the left hand to the right of the punch, the middle finger to its left and then pulling the skin apart with them while rotating the skin in a direction counter to that of the punch. The openings are made 1.5 centimeters apart. The next step is the most difficult one. A sharp pointed narrow bladed scalpel is necessary for its accomplishment. As shown in Figure 2, the point is pushed into the incision made by the punch for each island *a* keeping just the full thickness of the skin until its point comes out through the punch incision to the left of it but over the top of the corresponding island, *b*. With a sawing motion it is advanced to islands, *c* and *d*, the skin surrounding which is similarly undercut. The blade is then reversed and the 180 degrees of the circle from *b* by *e* to *d* is completed in the same manner. As the scalpel enters each circular punch incision, an

Fig 3 Typical sieve graft covering entire popliteal space

assistant slightly depresses each island with a knife handle or other suitable instrument in order to prevent its injury. When each of the openings has been similarly undermined it is only necessary for one to undermine the peripheral edges of the graft in the usual manner and to cut through a few strands of overlooked tissue before the entire perforated or sieve graft will be freed. This having been obtained, the donor site will be found still to contain small islands of skin equally spaced within the fat and fascia. The dressing for it is a simple one—vaseline gauze covered with dry gauze strapped firmly with adhesive.

All fat is then removed from the graft with curved scissors and it is sutured into the wound with interrupted stitches of silk worm gut or horse hair. The approximation of the edges must be very accurate and if any depressions exist in the ulcer it must be sewed into them. For dressing the grafted area Blair's sea sponge technique is generally employed. The graft is pressed into contact in order to express all serum and blood clot. It is then covered with a layer of xeroform vaseline gauze mesh or ordinary vaseline gauze wiped until very little vaseline remains upon it. Then four layers of dry flat gauze are surmounted by very large, flat sea sponges which have been sterilized in bichloride and wrung out in dry towels just before using. Large sponges are necessary. One sponge if possible should cover the entire graft and extend well over the suture lines. Thus even pressure will be exerted. If only a portion of the wound has been grafted, the other part may safely be treated by the Carrel technique 48 hours later without fear of injury to the graft.

It is our practice to remove the sponge only after 10 days, provided infection is not indicated by local signs or fever. At this time we inspect the graft, remove stitches, trim away any necrotic

THE SIEVE GRAFT—A STABLE TRANSPLANT FOR COVERING LARGE SKIN DEFECTS

BEVERLY DOUGLAS M.D. Sc.D. F.A.C.S. NASHVILLE, TENNESSEE
From the Department of Surgery, Vanderbilt University, Nashville, Tennessee

THE recent work of Blair on the full thickness skin graft and of Blair and Brown on large split grafts has demonstrated the feasibility of attempting transplants of dimensions larger than heretofore employed. Surgeons proficient in plastic work are now encouraged to undertake to cover defects at one stage which formerly would have required several.

With the increasing interest in the use of grafts of large size it is more than ever necessary to stress the factors contributing to the safety of grafting because if a graft fails, the patient's loss is in a way proportional to the size of the graft.

A new method of skin transplantation which we first devised and used in May 1928 has, we believe, greatly increased the safety of the use of large grafts. This has been called the "sieve" graft method because the graft is uniformly perforated with small round openings. A year's experience with this method has convinced us of its worth.

In general the safety of skin grafting depends on (1) attention to constitutional disease, (2) attention to local infection in the wound and (3) attention at operation and afterward to mechanical details.

The nature of the sieve graft especially satisfies the third condition because it provides for constant drainage over the entire surface. It also offers a better opportunity to overcome any post-operative wound infection. In this respect the sieve graft is as satisfactory as the small deep graft.

HISTORICAL

In none of the original articles of Wolfe or Krause on skin grafts does one find any reference to the advisability of perforating grafts for purposes of drainage. Vogel and Foersterling first suggested perforating Thiersch grafts in 1917. In most of the articles of later date, notably those of Blair, Brown and Blair, and in Davis's text on plastic surgery, one does find the suggestion that full thickness grafts be perforated. In Davis's text there is a photograph of a saddler's punch with which he advises that perforations should be made "to allow the escape of any blood or secretions which may collect." Most authors are agreed that small holes "insure drainage of blood and serum." The work herein described demon-

strates the practical value of combining several operative steps in one. In a single step, adequate drainage openings are cut throughout the entire graft and enough islands of uninjured skin are left behind to insure healing of the donor site. In leaving behind enough skin to grow out and close the donor site, the sieve graft resembles the small deep graft of which it is the negative image (if we regard granulations as the black part and skin as the white part of the picture). At the end of the operation, however, more skin will have been transferred to the area which has most needed it than the latter type of graft could afford.

INDICATIONS FOR THE USE OF THE SIEVE GRAFT

The sieve method will provide firm, safe healing without contracture in a defect upon any portion of the body. The cosmetic result accomplished is very nearly as good as that obtained by the Wolfe-Krause graft and it may, therefore, prove valuable in the future for plastic work upon the face.

TECHNIQUE

The wound to be grafted is prepared before and at operation in the same manner as that described by Blair for the full thickness graft. (1) A pattern is outlined on transparent cellophane with a pen before the day of operation. This is made about one fourth larger than the wound. It is transferred to tin foil and a single letter "E," is punched near the lower border for easy orientation. At operation the usual iodine alcohol or picric acid alcohol preparation is made. General anesthesia is usually employed but local anesthesia lends itself readily if there be any special reason for its use. Usually four lines of intradermal infiltration enclosing the pattern augmented by injection of 3 cubic centimeters subcutaneously at eight points equally spaced within the area to be lifted will suffice. At times where small varicose venules are present a more massive infiltration will be necessary.

The technique by which the sieve graft is removed is not difficult after the practice of one or two sittings. It does not require a longer time than an ordinary full thickness graft provided one includes the closure of the wound of excision with which closure the sieve method entirely dis-

Fig 5 Contracture from burn illustrating maximum extension possible before operation and healed result 60 days after first operation Sieve graft is visible in popliteal region Contracture relieved

Fig 6 Chronic leg ulcer before operation and after application of sieve graft

never stable. The ulcer measured 15 by 5 centimeters in center of scar about 22 by 8 centimeters. Preliminary treatment consisted in excision of the varix of the left saphenous vein and of the ulcer with surrounding and underlying scar. March 16, 1929. Operative repair patterned full thickness sieve graft was applied to lower one half of wound. March 28, 1929. Small deep grafts were applied April 5, 1929 and April 15, 1929 to the remaining portions of the granulating area. Result: healing was complete May 12, 1929 and area has remained healed to present time. Patient is now going about his active pursuits as a farmer.

CASE 6. I. F. aged 42 years. The predisposing causes of the ulcer were obesity, syphilis, aortitis, hypertension and varicose veins of both legs. The immediate cause was a bilateral thrombophlebitis 22 years ago. An ulcer formed on the right leg 8 years ago and on the left leg 6 years ago. Both ulcers were excised by Dr. Howard King 6 years ago. The appearance on admission to the hospital is shown in Figure 7. Both legs showed marked brawny swelling. Two punched out ulcers were present on the right leg about 5 centimeters above the ankle, one 6 by 6 centimeters, the other 4 by 5 centimeters. Two small ulcers were present on the medial surface of the left leg about 3 centimeters above the ankle, the first about 3 by 4 centimeters and the second 2 by 3 centimeters in size. Preliminary treatment consisted in antiluetic course, bilateral excision of saphenous varices and of scarred tissues surrounding and underlying ulcers by Dr. Alfred Blalock. March 22, 1929. Under local analgesia, full thickness patterned sieve graft was applied to the granulating area of the left ankle. April 17, 1929. A similar graft was applied to the right leg. April 30, 1929. Grafts were taken except for one or two narrow areas at the edge of the second which were grafted with small deep grafts. Areas were practically healed on June 6, 1929 as shown in photograph. While this patient is a very recent one, results in previous cases indicate that healing will be stable (Fig. 7).

¹Grateful acknowledgment is made to the assistance of this work is due to each of the men whose names are mentioned.

The ideal graft for filling in large skin defects must possess the following properties:

1. It must be capable of being so cut that its removal will leave behind a wound which will heal rapidly without further grafting and with only slight scarring.

2. It must be able to take hold and grow upon a moderately infected surface.

3. It must provide complete healing in a reasonably short time.

4. It must inhibit scar formation and subsequent contracture—a point especially important in defects over joints.

5. It must produce a skin surface so pliable that healing is stable and resistant to minor injuries.

6. It must effect a good, though not necessarily an excellent cosmetic result.

Weighing each of the types of grafts in general on the basis of these points, our experience is as follows:

1. The Ollier Thiersch graft fails from the standpoint of resisting infection and of preventing contracture, and the surface healed by its employment is easily eroded.

2. The small deep graft is ideal from every standpoint but two, viz. it fails to prevent contracture and often fails to give a good cosmetic effect.

3. The Wolfe Krause or full thickness grafts are excellent from the standpoints of stable healing, cosmetic effect, and prevention of contracture. However, if the graft is large, a defect is left behind at the donor site which will require

Fig 4 Typical appearance of donor site in early and late stages. The early stage shows islands left behind in removing graft. The late stage shows that the islands have furnished pigmented skin for the entire area.

portions, and reapply the pressure dressings. Within 12 to 18 days the perforations will usually be found entirely epithelialized and the pressure may be discontinued.

The islands for reasons now being verified experimentally will require a slightly longer time than this period to accomplish healing of the donor site, but their healing will be found to proceed with absolute certainty and a pigmented epithelium will result. These islands have the appearance of small deep grafts but are not to be confused with them. In reality, since they have not been undercut they are fortresses of strength. The epithelium from them has great healing power. One need not undermine the edges of the wound nor otherwise attempt closure. In every case the wounds have healed uneventfully and with almost full pigmentation.

In order that the reader may be able to form an adequate estimate of the safety of this graft and of results obtained through its use we give brief abstracts describing the course to date of every case in which it has been employed.

ABBREVIATED ABSTRACTS OF SIX CASE RECORDS

CASE 1 W. K. aged 8 years suffered a burn of the left thigh and popliteal space in January 1918. An ulcer measuring 12 by 7 centimeters persisted near the popliteal space for 10 months and resulted in a scar which caused extreme flexion contracture of the knee. Treatment consisted in excision of the scar, tendon lengthening by Dr. R. W. Billington, extension of knee and two-stage grafting. First a full thickness patterned sieve graft was applied to the flexible portion of the wound at the crease of the popliteal space, second small deep or Davis grafts were applied above and below the first graft. Result: healing with good function in 90 days after entering the hospital. Walking with 120 degrees of extension after 2 months. No recurrence. (See Figure 5.)

CASE 2 P. B. aged 48 years suffered a burn of the left thigh, perineum and popliteal space in 1910. Ulcers of

thigh and popliteal space persisted for 18 years. The ulcers and accompanying scar caused extreme flexion contracture of left knee and were excised at Nashville General Hospital in 1918. No grafting was done. Patient was admitted to the Vanderbilt Hospital February 25, 1918. Multiple ulcers were present from posterior fold of left buttock to middle third of leg. The largest ulcer was in the popliteal space and measured 7 by 11 centimeters; the edges were indurated and hard. Diagnosis: epitheliomatous degeneration of ulcer in cicatrix of burn or so-called Marjolin ulcer. Diagnosis was confirmed by biopsy. Preliminary treatment consisted in complete excision by wide margin of ulcer bearing area. Operative repair: first stage a full thickness patterned sieve graft was applied to the entire popliteal space (Fig. 3); second stage small deep grafts from abdomen were applied to area above the sieve graft and third stage small deep grafts from abdomen were applied to area below the first graft. Healing was complete 55 days after excision of the ulcer. Area remained healed for 2 months since which time he has had a local recurrence of the cancerous lesion in the form of a warty growth which he has refused to have treated. In the 9 months which have followed this growth has increased in size from 0.5 centimeters to 3 centimeters in diameter. The remaining portions of the wound have remained solidly healed and the patient has been able to earn full wages as a stoker of furnaces.

CASE 3 V. M. aged 39 years had had varicose veins for 19 years. These were treated by ligation 17 years ago. Varicose ulcers had been present on the outer surface of the left leg in the middle third for 14 years. When patient entered the hospital several shallow ulcers were noted in the middle third of the leg. Preliminary treatment consisted in wide and deep excision of ulcer bearing area including scar. Operative repair: first stage a patterned full thickness sieve graft from the thigh was transplanted to the lower half of the wound; second stage small deep grafts were applied to the remaining upper portion of wound. Healing was very slow. Patient was sent home with an Unna paste bandage. Area was entirely healed and dry dressing was applied 4½ months after operation. Patient is doing well wearing an elastic stocking although the swelling of the extremities and high blood pressure continue. The leg has shown a slight superficial ulceration during the present week or 2 months after complete healing.

CASE 4 J. B. aged 57 years. The predisposing cause of ulcer was arteriosclerosis with extreme hypertension. The immediate cause was a wound of the leg at the ankle 2 years before admission to the hospital with evidence of local thrombophlebitis. The ulcer measured about 9 by 5 centimeters. In the center was a large area of white scar above the left internal malleolus. Preliminary treatment consisted in per arterial femoral sympathectomy by Dr. George Johnson followed 9 days later by deep and wide excision of the scarred area including the ulcer. Dr. Barney Brooks who performed the second operation swung a flap of good skin up over the tibial crest which had necessarily been exposed during the dissection. Operative repair: full thickness sieve grafts were fitted to the remaining portions of the wound in two stages. Grafts were complete takes but stitch lines along back of the leg broke down slightly and required a few small deep grafts on August 6. Healing was not complete until January 14, 1919 or 8½ months after the excision. Since then for 10 months healing has been solid (Fig. 6).

CASE 5 W. R. aged 50 years. The predisposing factors were moderate arteriosclerosis with hypertension, varicose veins of indefinite duration, certainly more than 10 years, an injury at site of ulcer 20 years before admission, healing

- 7 The grafts averaged 110 square centimeters per operation
- 8 Five of the 6 patients had skin applied to ulcers extending over joints
- 9 Results in all cases have been satisfactory

CONCLUSION

The sieve graft provides a safe and useful means of closing large defects in the skin

PSEUDOMYXOMA PERITONÆI ORIGINATING FROM MUCOCELE OF THE APPENDIX¹

JAMES C MASSON M D F A C S ROCHESTER MINNESOTA

Division of Surgery The Mayo Clinic

AND

ROBERT A HAMRICK M D ROCHESTER MINNESOTA

Fellow in Surgery The Mayo Foundation

CYSTIC dilatation of the appendix, although relatively rare, may be the precursor of the pathological entity known as pseudomyxoma peritonæi. In this condition of the peritoneum, masses of gelatinous pseudomucinous or mucinous material are distributed over the surface, either as a homogeneous layer or as multiple cystic masses. Pseudomyxoma peritonæi is most often seen in women and is usually associated with a ruptured pseudomucinous cystadenoma of the ovary. It is also found in both men and women following rupture of a mucocele of the appendix. Werth is credited with coining the term pseudomyxoma peritonæi in 1884 because the gelatinous masses which he found over the peritoneum in a case of ruptured ovarian pseudomucinous cystadenoma was proved by Hammarsten to be of pseudomucin instead of mucin. He thought the peritoneum underwent myxomatous degeneration. Fraenkel in 1901, first reported the condition in the male. In his case it had followed rupture of a mucocele of the appendix. He retained the term pseudomyxoma peritonæi because of the gross similarity of the gelatinous exudate to that found in the cases previously reported, under the same name in women. Olschhausen probably gave the first correct idea as to the means by which this condition originates. He believed that epithelial cells from the lining of the ruptured cyst were transplanted to the peritoneum, that there they took root and continued to secrete the gelatinous material.

Cystic dilatation of the appendix may take the form of true hydrops in 0.9 per cent of all cases, according to Dodge. More commonly, it takes the form of mucocele. Norment mentioned that Fere was the first to apply the term, retention cyst, hydrops, or mucocele, to that portion of the appendix in which dilatation had occurred. The condition was first recognized by Virchow, and he considered his case as one of colloid degeneration of the appendix. Elbe, on the basis of examination at necropsy, reported the incidence of cystic appendices to be 0.5 per cent, and on the basis of examination of surgically removed appendices 0.7 per cent. Corning reported that 0.54 per cent of surgically removed appendices are cystic, Kelly and Hurdon gave 0.42 per cent, and Ribbert, a little more than 1 per cent. Castle reported from the literature a frequency of 0.2 per cent of mucocele of the appendix in 13,158 necropsies. Dodge, in 1916, also made a careful review of the literature and was able to find only 147 cases. In Norment's study of 45,000 appendices surgically removed at The Mayo Clinic, 36 cysts were found. The average age of patients in these 45,000 cases was 41 years. The youngest patient was 4 years of age, the oldest patient was 65 years of age. Sixty-one per cent were in males.

It is commonly thought that before a mucocele of the appendix can occur, there must be some point of obliteration or obstruction of the lumen of the appendix. Probably the most important factor in the production of such obliteration of a

Fig 7 Old varicose leg ulcers showing condition before operation, after wide and deep excision, and the healed result following sieve grafting. Perforations have rapidly epithelialized.

further grafting—a distinct disadvantage. Furthermore, infection may readily cause its total loss.

The sieve graft satisfies all of the demands enumerated. Two valuable properties possessed by none of the above varieties deserve especial mention: (1) the perforations, by providing adequate drainage, make it resistant to infection, thus insuring a very high percentage of takes; (2) the donor site requires no further grafting and heals with a good cosmetic result.

Regarding our 6 cases as illustrative, we see that it has been used on very extensive wounds after a preliminary debridement and treatment of constitutional disease had made surgical repair possible. From photographs and actual tracings the 8 grafts used on the 6 patients measured approximately 32, 129, 116, 77, 103, 77, 97, and 225 square centimeters respectively, or an average of 110 square centimeters to a graft. The fourth and sixth patients had two grafts each. At least 90 per cent of each grafted surface has taken infection in 2 cases notwithstanding. Of the 6 patients, 1 had a history of a burn, another a burn with an epithelioma in the scar, 3 others varicose veins, 2 of them complicated by arteriosclerosis, and 1 by syphilis. In the sixth, or Case 4, an injury had caused an ulcer upon a leg in which the vessels were already sclerosed.

With such patients the healing process even after appropriate constitutional and local measures has the odds against it. It is noteworthy that each of the 6 patients have been followed carefully through the efforts of the Social Service and

the results have been such that every one of them has been able to get on his feet again and pursue his routine duties. While there have been a few small superficial excoriations at the suture lines, there have never been any within the confines of the graft proper. The only ulceration came 2 months after complete healing (Case 2) and in this instance was due to a local recurrence of an epithelioma.

Figure 7c shows that the perforations heal so quickly that the resulting scar is negligible, yet the very skin left behind by punching them has served to heal the donor site completely and with pigmented epithelium (Figure 4b).

SUMMARY

1. Increasing experience with skin grafts of large size makes it imperative to study the factors contributing to the safety of grafting.

2. An original method is described for obtaining a new type of full thickness graft which has been named the sieve graft because of its uniform perforation with round openings.

3. In this method the excision of the transplant and the potential closure of the donor site is provided for in one operative step.

4. Through its use a large area of skin may be transplanted in a single piece while perforations provide constant drainage of its entire extent.

5. Infection is overcome and the safety of the graft greatly enhanced by adequate drainage.

6. Results are shown through the histories of 6 consecutive cases which received a total of eight transplants of this kind.

marsten's method for chemical analysis of the gelatinous contents of two mucocysts and found them to be pseudomucin. Phemister also reported a reaction of pseudomucin.

A paper was published recently by Naeslund on the experimental production of pseudomyxoma peritonæi. He ligated the appendix in newly born rabbits about 1.5 centimeters from the tip and then cut across the appendix just distal to the ligature. The distal stump was left open and the vascular supply through the meso-appendix was not disturbed. In most of the animals little mucous cysts developed between the cut stumps of the appendix. Part of them burst, and mucous material spread over the peritoneum. In some animals small cysts about 1 centimeter in diameter filled with mucus developed in the mesentery, intestines, and peritoneum. The little cystic nodules were covered with epithelium. At times cylindrical mucosal epithelium would grow into the serosa of the bowel and into the wall of the bowel forming nests of this epithelium in glandular or cellular arrangement, within the sacs were collection of mucus. He found experimental and clinical conditions to be similar. Phemister was unable to produce cysts by artificial ligation of the appendices of dogs.

The prognosis of pseudomyxoma peritonæi resulting from mucocyst of the appendix is much more favorable than of that which arises from pseudomucinous cystadenoma of the ovaries. Seelig outlined four possible courses of events following the escape of pseudomucin from the cystic appendix: (1) the exudate may be limited in its escape, to the right iliac fossa; in such cases, firm adhesions establish themselves forming a connective tissue capsule; (2) the exudate may escape to various and multiple intraperitoneal sites, sometimes, in this form, the material may become delicately encapsulated and may hang from the intestinal peritoneum as little polyps; (3) it is possible for the exudate to be absorbed entirely, and (4) there may be wide dissemination of the exudate with a tendency to marked secretory activity on part of disseminated material. There is accompanying adhesive peritonitis.

Several authors have reported pseudomyxoma peritonæi associated both with pseudomucinous cystadenoma of the ovary and with mucocyst of the appendix. In such cases, the cystadenoma or the mucocyst or both, may be found to be ruptured (Figs. 1 to 7).

REPORT OF CASES

In the following six cases of pseudomyxoma peritonæi the origin was the appendix. Five of

Fig. 3. Lining of mucocyst showing columnar epithelium.

the patients were women, one patient was a man. The average age was 57 years. The youngest patient was aged 37 years and the oldest, 69 years.

CASE 1. A woman aged 50 years had had an attack of appendicitis 25 years before she was seen at the clinic. During June and July, 1921, she had reported attacks of nausea, vomiting, pyrexia, and pain in the right lower quadrant of the abdomen. In August an appendiceal abscess was drained, and she was advised to undergo appendectomy sometime later. She returned to the clinic for this operation in April, 1922.

A mucocyst involved the tip of the cæcum and the surrounding peritoneum. All the diseased tissue was dissected out and removed. Free mucoid material was not found scattered over the peritoneal cavity, although there was some in close proximity to the appendix opposite a perforation 1.5 centimeters from the base. There was no evidence of involvement of the uterus and ovaries.

The patient is living without symptoms 6 years and 6 months after operation.

CASE 2. A woman aged 69 years gave a definite history of disease of the gall bladder extending back 4 years or more from the time when she came to the clinic. General examination revealed a small umbilical hernia and the questionable presence of a fluid wave in the abdomen. Roentgenographic examination of the thorax gave evidence of tuberculosis, probably not active in the apices of both lungs.

Cholecystectomy for gall stones was done April 27, 1920. At the time of this operation a large amount of gelatinous material, which was thought to have its origin in the pelvis, was found in the abdomen. Much of this material was removed. Three weeks later abdominal hysterectomy

Fig. 1. left. Large mucocoele of appendix dark areas where rupture is almost ready to occur are shown

Fig. 2. Mucocoele of appendix apparently developing in diverticulum

portion of the lumen is an old or recent inflammation of the appendix which has regressed. Other factors which may act in a similar manner are kinking of the appendix, adhesions around the appendix, or a malignant condition of the appendix. One case was reported in which a polyp was thought to be the factor in producing the obstruction resulting in the formation of a mucocoele. However, Dodge mentioned 5 cases of mucocoele in which the appendiceal lumen was said to be patent. *Diverticulum of the appendix with constriction of the proximal portion of the lumen* may be another etiological source for the formation of the mucocoele. MacCarty and McGrath found diverticula in 17 of 5,000 appendices examined. Moschowitz found the condition in 4 of 1,500 appendices. Gardham, Choyce and Randall are of the opinion that such diverticula frequently lead to pseudomyxoma peritonæi.

Mucocoeles of the appendix may be sausage-shaped, banana shaped, fusiform or globular and may vary in size from about 15 centimeters in diameter to 3 centimeters or less in length. In cases in which the epithelial lining of the cysts can

be distinguished it is made up of the columnar or cuboid type of cell. The walls of the cysts may be thick and may contain varying proportions of the different coats of the appendix. On the other hand they may be as thin as tissue paper, and there may be saccular formations in them. The absence of infective organisms from the involved portion of the lumen is considered a necessary condition for cystic development. Mucocoele may be found in any situation in the abdominal cavity in which it is possible for the appendix to be. A few appendiceal mucocoeles reported in the literature have been in hernial sacs and within the inguinal canal.

Authors differ as to the identity of the gelatinous content of the mucocoele. Dodge in his review mentioned that chemical examination of the contents was made in 6 cases. In 3 the reaction was that of mucin, in 2 of pseudomucin and in 1 case of colloid. Trotter stated that the microchemical reaction is that of mucin. Castle mentioned that careful chemical analysis of the content of mucocoele of the appendix proved it to be pseudomucin. Norment in his study used Ham

Fig 6

Fig 6 Mucocoele near the tip of an appendix

Fig 7

Fig 7 Multiple diverticula of appendix

a mass which could be felt by both abdominal and pelvic examination

At abdominal exploration June 21 1920 appendectomy for colloid carcinoma of the appendix was done. There were multiple regions of metastasis in the mesentery of the small intestine and in the omentum. The appendix and a large mass of colloid material was removed from the right iliac fossa and several nodules of colloid material were removed from the omentum.

Following operation the patient was given thorough courses of deep roentgen ray treatment. When last heard from 8 years after operation she was in good health and had no knowledge of evidence of recurrence.

In reviewing a series of cases in which unruptured mucocoele of the appendix had been found at operation it was notable that in several instances a mucocoele had developed following drainage of a ruptured appendix or of an appendiceal abscess. In the first case reported in this paper a mucocoele had developed following drainage of an appendiceal abscess. The mucocoele in turn, had ruptured and had produced a localized form of pseudomyxoma peritonæi. This series of events took place in the relatively short space of 9 months following drainage of the appendiceal abscess. Before the mucocoele could form the local region must have become sterile as a result of the reaction of the tissues, helped by the drainage operation. Undoubtedly, the appendiceal lumen was constricted at one or more points

by the scarring produced by the acute inflammation. The probable course of events in this case may be described as follows. A portion of the epithelial lining beyond a constriction had not been destroyed and continued its function of secreting mucus after the regression of the inflammation. This, in turn, produced a cystic pocket of mucoid material, or a mucocoele. As the cystic pocket expanded from the pressure of the secreting cells, rupture took place at some point of lowered resistance. With the outpouring of the gelatinous content, some secreting epithelial cells may have been carried along with it. These cells attached themselves to the peritoneum and continued to secrete gelatinous material.

The condition known as pseudomyxoma peritonæi begins in the way described. The reaction of the peritoneum to the gelatinous material varies. Usually the peritoneal tissues react as they would to a foreign body, with the production of adhesions and walling off with connective tissue of the mucoid secretion.

Also an attempt is made to absorb the foreign material. Sometimes the reaction of the peritoneum appears to be passive, as in the third case reported. An excellent prognosis may be given in such a case following removal of the offending lesion and mechanical scooping out of most of

Fig 4 Mucocele of appendix which had ruptured

together with bilateral salpingo-oophorectomy and appendectomy was performed. The entire peritoneum was congested and reddened and much colloid myxomatous material was present in the abdominal cavity. As much of this material as possible was removed. The ovaries were small and were the site of bilateral chronic oophoritis. The oviducts both of which were affected with chronic tuberculous contained much caseous material. In the appendix was a colloid carcinoma which had ruptured and which was the source of the myxomatous peritonitis.

The patient received several treatments by radium and roentgen ray and is living in fair health 4 years and 8 months after the last operation.

CASE 3. The mother and two aunts of a woman aged 61 years had died from carcinoma. The patient gave a history definitely typical of duodenal ulcer and extending back over several years. On general examination of the abdomen there was some generalized tenderness which was more marked over McBurney's point. Roentgenographic examination of the stomach gave evidence of the presence of a duodenal ulcer.

September 27, 1921 appendectomy and gastroduodenostomy were performed. About 2 liters of jelly like colloid myxomatous material was removed from the abdominal cavity. The appendix was filled with colloid material and was ruptured near its end. The organs of the entire abdomen were covered with the gelatinous material and as much of it as possible was scooped out. There did not appear to be any grafting of the gelatinous growth on the peritoneum. The mucoid material was simply in contact with it. The ovaries fallopian tubes and uterus were in good condition.

Treatment by roentgen ray was given after operation. The patient is now living 11 years after operation.

CASE 4. For 7 or 8 years a woman aged 61 years had felt as if she had a mass in the lower right quadrant of the abdomen. This had increased about three times in size during the 18 months before she came to the clinic and the increase had been associated with some tenderness and pain in the right groin. Also the right thigh had been swollen for 18 months. General examination revealed a smooth rounded cystic tumor occupying the right side of the abdomen and flank and extending within two fingers breadth of the right costal margin. There appeared to be

marked edema of the mesial portion of the right thigh but no noticeable edema of the ankles.

At operation June 5, 1917 the abdominal mass was found to be a large retroperitoneal gelatinous myxomatous tumor attached to the end of the appendix. When the mass was opened it was found to be filled with colloid myxomatous material and was divided into two compartments each of which contained about half a liter of this substance. The lower pocket extended down underneath Poupert ligament and bulged in the anterior portion of the thigh. These cavities were emptied of their contents and were wiped out as clean as possible. The appendix was removed. There was a mucocele at its tip which had perforated thus forming the gelatinous masses. Pelvic examination at the time of operation gave negative results. The patient was treated with radium introduced through a drainage tube.

The patient returned to the clinic 2½ years later with a tumor about 15 centimeters in diameter on the inner surface of the right thigh. The tumor had increased markedly in size during the previous 6 months. It extended midway to the knee and mesially to the vulva. There was also an abdominal tumor extending from the right iliac fossa to the umbilicus.

February 20, 1920 the neoplasm on the thigh was opened and drained. It was found to have pockets which were filled with gelatinous material. This material apparently had worked its way downward from the abdominal growth and it probably had followed the psoas muscle. Three rubber tubes were put in for treatment by radium.

The patient was advised to have an abdominal operation later but this was not performed. She died in 1920 5 months after the last operation. The pathologist's report at the time of the second operation was pseudomucinous cystadenoma. Microscopic evidence of a malignant condition was not found. There was an interval of 10 to 11 years from the time of onset of symptoms to death and of 3 years and 4 months between the primary operation and death.

CASE 5. A man aged 37 years had noticed a gradual progressive swelling of the abdomen over a period of a year. He had undergone abdominal paracentesis on two occasions elsewhere during this time and each time about 3 liters of yellowish fluid containing flakes and strandy mucus had been removed. Early morning abdominal cramps was another of his symptoms. General examination revealed the abdomen to be distended to grade 2 and a fluid wave and shifting dullness were present.

Abdominal exploration was done October 23, 1922. The abdomen was completely filled with gelatinous material and fluid. There were cystic implantations on the mesentery, visceral peritoneum and liver. The omentum was markedly infiltrated and was about 10 centimeters in thickness. The surgeon considered the appendix to be the original source of the gelatinous ascites. The abdomen was closed after exploration. The pathologist's report of tissue removed from the region of the appendix was of mucinous cystadenoma of the appendix.

The patient was given several courses of deep roentgen ray treatment after operation. Some improvement of his condition was noted for several months but later the course was steadily downward and symptoms of intestinal obstruction appeared. The patient died April 29, 1923, 2½ years after operative diagnosis and 3½ years after the onset of symptoms.

CASE 6. A woman aged 64 years had been troubled for a year with soreness and pain in the right lower quadrant of the abdomen. The pain was sharp and colic like at times and on some occasions nausea and vomiting had been associated. Pyrexia had not appeared. General examination revealed in the right lower quadrant of the abdomen

much value. Secondary operations may be necessary for further removal of mucoid material and to give relief from obstructive phenomena. All but one of the patients whose cases are reported in this paper had treatment by roentgen ray or radium.

Old inflammation is a large factor in the production of mucocele of the appendix. Other factors are considered.

CONSTANT VACUUM ASPIRATION TREATMENT OF EMPYEMA

A SIMPLE DEVICE IN CREATING VACUUM

EDWARD E. MANSUR, M.D., JEFFERSON CITY, MISSOURI

THOUGH empyema has been one of the earliest conditions falling within the realm of surgery, few changes and improvements have been published. Its treatment by one or the other of the accepted methods has given results apparently good enough to satisfy the average surgeon.

Empyema is such a frequent sequela of pneumonia and pulmonary injuries that it has its quota of patients in all general hospitals. During the peak of respiratory troubles, especially of the streptococcus type, it will be found well up in front, in point of numbers of cases in the surgical wards. The goal desired in the treatment of this affection must be the restoration of the patient's partially collapsed lung back against the parietal chest wall as in the normal.

The surgical attack may be divided into two methods: the closed method in which repeated aspiration of the pus is done, and the open method or direct drainage, in which an opening through the chest wall is made and for a time maintained with or without rib resection.

Many years ago attention was called to the fact that creation of a moderate degree of vacuum between the chest wall and the collapsed lung was a thing to be desired. Elaborate hydrostatic suction apparatus was devised and used. It was soon found that this apparatus cluttered up the patient's room and his bed, restricted the patient's movements and required much supervision. Mechanical devices were built and found to require too much supervision. These measures were never popular, not because the creation of intrathoracic vacuum failed to give excellent results, but because the known means of applying this method to the patient was coupled with so much apparatus and supervision.

If a large group of postoperative cases, in which the patients have been treated by simple drainage in the usual way, without vacuum, are studied, it will be found that many of these chests show a permanently crippled lung. This may be seen in the radiogram if not in the postmortem examination. Fibrous tissue, dipping far into the

SUMMARY OF CASES OF PSEUDOMYXOMA
PERITONÆI OF APPENDICEAL ORIGIN

Case	Age years	Sex	Type of disease	Comment
1	50	F	Localized in right iliac fossa	Living without symptoms of recurrence 6 years and 6 months after operation
2	67	F	Generalized pseudomyxoma peritonæi colloid carcinoma of appendix associated with tuberculosis of fallopian tubes	Living in fair health 4 years and 8 months after operation
3	61	F	Generalized pseudomyxoma peritonæi passive reaction of the peritoneum	Living apparently without recurrence of symptoms 11 years after operation
4	61	F	Retroperitoneal origin from appendix with extension to peritoneum and thigh	Died 3 years and 1 month after operation and 10 to 11 years after onset of symptoms
5	37	M	Generalized pseudomyxoma peritonæi	Died 2 years and 5 months after operation
6	64	F	Generalized colloid reaction of ovaries peritoneum colloid carcinoma of appendix	Living apparently without symptoms of recurrence 8 years after operation

the gelatinous material. In spite of the inherent resistance of the organism helped by surgical procedures, some of these cases of pseudomyxoma peritonæi progress and death results. This can take place although microscopic evidence of a malignant condition cannot be found in the regions involved, as in the cases of the two patients in this series who died from the disease. Most likely deaths under such circumstances are due to pressure and adhesions associated with the pseudomucinous abdominal masses. Intestinal obstruction and dysfunction of the different viscera are potent factors in the outcome. If a malignant condition is present, its influence on the course of the disease is similar to that of a malignant growth anywhere. However a neoplasm in the appendix is of a slow growing, low grade type.

It might be mentioned that in 3 of the patients whose cases are reported here, the number of leucocytes was 14 000 to 16 000 in each cubic millimeter. An explanation of this is not afforded unless it lies in the fact that the hematopoietic system was stimulated by the low grade inflammatory reaction which takes place in the peritoneum as a result of the presence of the gelatinous material. Hemoglobin varied from 67 to 78 per cent. Although some of our patients reported definite, gradual enlargement of the abdomen, all lost from 6 to 19 pounds in weight.

Mucocoeles of the appendix are found more frequently in males than in females. Nevertheless

strange as it may seem only 1 of our 6 patients with pseudomyxoma peritonæi of appendiceal origin was a man. In none of the 5 women were the ovaries involved with pseudomucinous cystadenoma. Also, pseudomyxoma peritonæi of appendiceal origin is mentioned in the literature as being most frequently confined to the pelvis. Nevertheless in only one of the cases reported was the disorder limited to the pelvis. The tabulation gives a summary of the length of life of the patients since operation. All but one of them received treatment by either roentgen ray or radium. Two of them have died, and in each of these two cases the course was progressively downward. Those who are living have no knowledge of evidence of recurrence of pseudomyxoma peritonæi.

The treatment in these cases is mainly surgical. This treatment is followed by either radium or roentgen ray. Removal of the appendix with the mucocoele is most urgent. Also, removal of as much of the gelatinous material as possible is worth while. Treatment by radium or roentgen ray after operation appears to be of value in these cases, especially if a malignant condition is present. However a favorable reaction cannot always be expected. Secondary operation may be necessary for further removal of mucoid material which has collected or to overcome obstructive phenomena.

SUMMARY

Six cases of pseudomyxoma peritonæi of appendiceal origin are reviewed. One of these cases was in a man and 5 were in women. The ovaries were not involved with pseudomucinous cystadenoma. The average age of the patients was 57 years. Two of the patients had colloid carcinoma of the appendix. There was no operative mortality.

Two of the patients have died from the disease in periods of 2½ to 3 years after operation. In one of these patients the onset of symptoms was 10 to 11 years before death and in the other, 3½ years. The 4 other patients are living from 4 years and 8 months to 11 years after operation and have no knowledge of evidence of recurrence of pseudomyxoma peritonæi. In one case of the series the condition was unusual in that there was extension of the gelatinous material into the thigh.

Prognosis in pseudomyxoma peritonæi of appendiceal origin seems to be better than in that of ovarian origin. The reaction of the peritoneum varies in different persons.

The treatment is surgical removal of the appendix and of the mucocoele together with as much of the gelatinous material as possible. Treatment by roentgen ray after operation may prove of

have just battled a pneumonia or whatever the exciting cause of their empyema may have been. In the border line cases it is confidently believed that the use of this technique will save many who would otherwise be lost.

A more dependable lung expansion, a minimum of scar tissue and a much shortened convalescence should be looked forward to.

CONCLUSIONS

The value of constant suction creating a small definite constant intrathoracic vacuum in treat-

ing empyema, seems based upon sound reasoning. When such a vacuum can be created and maintained so easily, by such a method as has been herein described, its use should become more general.

If the end results of treatment leave a patient with a chronic pleural cavity or dense adhesions extending from the outer chest wall to the lung root, a good functional aeration of that lung may not result.

A simple practical means seems now available for the treatment of double empyema.

lung toward the hilus is present. General, and at times great, thickening of the pleura of the affected side is seen. These abnormal states cause limitation of expansion of the affected lung, even diaphragmatic excursion may be limited. Such adhesions, if quite dense, may hold the lung as in a vise.

Comparison of cases treated by the usual open drainage method with cases treated by auto vacuum has, in the author's cases, reduced these abnormal results to the minimum. Where cases of double empyema are encountered, such a method as herein described, offers a happy way out of what would otherwise be a trying situation.

A Wilson's drainage tube (Fig. 1) is prepared in the following manner. Over its external face (the larger flange side, Fig. 2) is placed a sheet of rubber. Rubber dam material as used by dentists is excellent for this purpose. This small sheet of rubber is attached on one side only (Fig. 2 A). The method of attachment may be by a little rubber cement or by a safety pin. This simple procedure makes a one way valve trap, which, when placed in the chest wall will be found to offer no hindrance to the escape of pus and air from the empyemic cavity but will allow nothing to re enter it. The tube, prepared as above is now further prepared just before introduction into the chest wall by having its smaller flange side rolled up and held by a hæmostat (Fig. 3) to facilitate its easy introduction into a small chest wall opening.

The appropriate site for drainage is selected usually in the mid axillary line. The skin and deeper structures of the chest wall are infiltrated with a local anæsthetic. The rib is cut down upon through a small incision parallel to it and a small section removed. A sponge is held in the left hand, while with the right hand a blunt forceps is forced into the empyemic cavity. The jaws are now separated enough to make an opening of about $\frac{3}{4}$ inch. Instantly covering the wound with the gauze sponge held in the left hand to prevent immediate escape of the pus the free hand introduces the valve under the sponge, into the chest wall. When an empyema is entered in this manner much soiling of dressings and those about is avoided.

The operation of the valve may now be observed. The patient coughs slightly and as this

increases intrathoracic pressure quantities of pus and air rush out through the valve, then, as the thoracic wall relaxes there is produced an intrathoracic vacuum. The rubber tissue cover of the tube will then be observed covering the tube opening tightly through suction. An indentation over the valve hole can be seen. Although the amount of cough will be much less under these circumstances coughing will be frequent enough to maintain a constant intrathoracic vacuum.

Dressings may be applied over the device without fear of altering the mechanism the same may be said of their removal. It will be found that the flap will remain in place constantly, unless it is deliberately lifted from over the tube opening.

Instead of the patient having to depend upon adhesions to draw his collapsed lung back into its normal place against the chest wall, the constant vacuum described does it for him.

When an empyema develops on the opposite side or is already present, the other side may be operated upon in a similar manner within a few days. Collapse of both lungs and asphyxiation, which would necessarily happen if both sides are left open in the usual way need not be feared.

In the author's experience this device has never failed to keep up a constant vacuum as long as there is a cavity present. When it is found after a few weeks that the rubber cover is no longer being sucked against the tube, the cover may be lifted and the lung inspected through the tube opening. It is considered advisable to allow the tube to remain in place for at least 4 days after this point in the postoperative care has been reached. If such allowance is not made, and the tube is removed the patient may sneeze or cough suddenly which is likely to tear the lung away from the chest wall again and collapse it. If this very preventable condition should occur the replacement of the valve at once, will bring the lung back against the chest wall again within a few hours. Time may then be given for its firm attachment, before removal of the valve is again considered.

The postoperative shock and disturbance which at times is severe in these cases is thought to be due more to the augmented cough and distress incident to the sudden final collapse of the affected lung than to the operation itself. The use of the device and technique here described has seemed in the author's experience to produce a more rapid convalescence. It is thought much toxin laden lymph is extracted from the affected lung and pleura by the vacuum created.

Most of these cases are in a desperate weakened condition before they reach operation. They

If it is important that the size of the Wilson tube selected in each case shall be a longer and preferably some shorter than the total thickness of the chest wall at the site of operation. It has been found that the smallest size Wilson tube works very well on all children and the next size measuring $\frac{1}{2}$ inch is correct for practically all adult cases. The $\frac{1}{2}$ inch Wilson tube should be used only on the very thick walled, obese patients. Observation of these simple directions, together with care in not making the pleural opening wider than $\frac{1}{2}$ inch should insure a snug fit of the tube.

Fig 1 Tucker McLane forceps

colpurynter, especially when the membranes have ruptured early, is indicated. Rarely when progress has apparently ceased in spite of continued labor what remains of a soft readily dilatable cervix can be easily stretched by gentle manipulation. More rarely the rim of an incompletely dilated, rigid cervix must be incised and repaired after delivery. To attempt delivery through an imperfectly dilated os is to invite complications far worse than that which already exists.

Operative treatment is seldom indicated before the advent of the second stage, and even then is frequently unnecessary. The occiput rotating spontaneously in over 70 per cent of the cases. A simple prophylactic forceps operation with or without episiotomy, may then be considered optional.

Postural treatment (having the patient lie on the side toward which the fetal back is directed) for the correction of the faulty attitude and to bring about internal rotation, while a perfectly commendable procedure, is obviously difficult in a patient who is under the influence of anæsthesia, and who is therefore unable to co operate.

In about 5 per cent of the cases the head after complete dilatation, is found floating or is arrested high in the pelvis. For this small group version followed by breech extraction, particularly in the multipara is favored by most obstetricians, especially when intact membranes facilitate turning of the child.

In the 25 per cent remaining the head is found arrested at various levels within the pelvis the occiput still occupying its relation to the posterior quadrant. For the treatment of this group, a number of methods have been suggested. All of them in competent hands are productive of good results. The principal aim of each of them is directed toward the same end, namely, rotation of an occiput posterior to an occiput anterior while the means by which rotation is accomplished is either the hand of the accoucheur or the obstetrical forceps.

Fig 2 A The wrong way. Twisting the instruments around the axis of the handles causes the tips of the blades to describe an arc within the pelvis thus tearing the bladder and vagina loose from their attachments. B The correct way. Rotation of the handles through an arc causes the blades to revolve about their own axes. Thus the integrity of the maternal soft parts is preserved.

While it may be true that the best method is that one to which the operator has best trained himself, it is no less true that manual correction usually calls for the insertion of the whole hand into the vagina with displacement of the head upward and out of the pelvis to secure the degree of internal rotation necessary. This procedure however increases the danger of infection and invites the possibility of prolapse of the cord. Even after rotation has been accomplished in this manner backward rotation of the occiput, after the hand is withdrawn from the head and before the blades of the forceps can be applied, is an exasperating and frequent occurrence. DeLee recommends here the use of an Allis clamp or of a double volsellum forceps, by which the scalp, after rotation is firmly grasped and steadied by an assistant until the forceps can be applied.

The Pomeroy maneuver, recently described by Aranow, is manual rotation whereby the body of the baby is rotated on its own axis 180 degrees, thus bringing the sagittal suture back into the same oblique diameter of the pelvis. In this manner the right occipitoposterior position (occiput dextra posterior, 135 degrees) is converted into left occipitoanterior (occipito laevus 45 degrees) or left occipitoposterior (occiput laevus posterior 135 degrees) into right occipitoanterior (occiput dextra 45 degrees).

The method of Tarnier and that of Hodge, both aim at correction of the malposition by intravaginal manipulation and digital pressure, without displacement of the head. Both methods sometimes produce the desired result.

Until comparatively recent years rotation was not included among the 'properties' or 'functions' of the forceps. Smellie in 175-, was perhaps the first to perform instrumental rotation

THE MANAGEMENT OF THE OCCIPITOPOSTERIOR POSITION

WITH SPECIAL REFERENCE TO THE MODIFIED SCANZONI MANEUVER

RAYMOND J. PIERI, M.D., SYRACUSE, NEW YORK

DURING recent years much has been said and written concerning the proper management of those cases which come under the caption of this paper. In spite of excellent contributions to the literature on this important subject, to the physician who practices obstetrics today the occipitoposterior position remains still a bugbear.

The careful analysis of former labors in cases presenting the past history of stillborn children or of infants who succumbed shortly after instrumental delivery, often reveals the earmarks of faulty management of this common complication. Errors in the diagnosis and treatment of this position are observed so frequently that one wonders if the fault does not lie universally with the instruction of obstetrics, rather than with the instructor. DeLee justly ascribes to the improper conduct of these cases the appalling annual total in the United States alone of several thousand infant deaths and hundreds of maimed or invalided mothers.

Any condition which causes so much avoidable mortality and morbidity calls for an inventory of the various methods whereby these unhappy results can at least be reduced in number.

It has been estimated that 95 per cent of all cases are vertex presentations at the beginning of labor. In approximately one third of this number the occiput is directed posteriorly—right occipitoposterior (occiput dextra posterior, 135 degrees) or left occipitoposterior (occiput laevus posterior, 135 degrees). For the same reasons that explain the greater frequency of the left anterior position, left occiput anterior (occiput laevus 35 degrees) the occiput in most posterior positions is in the same oblique diameter, right occiput posterior (occiput dextra posterior 135 degrees).

The mechanism of labor in the posterior position presents one main difference from that in the anterior position—rotation in the former takes place through an arc of 135 degrees while in the anterior position the occiput describes an arc of 45 degrees.

Engagement of the head in occipitoposterior position occurs more slowly partly because of the promontory, and partly because an almost constant deflection or 'military' attitude of the presenting part brings a less favorable cephalic

diameter (the occipitofrontal instead of the suboccipitobregmatic) into the pelvic inlet. Because of the existence of these factors all of them unfavorable in tendency—internal rotation of the head in the posterior position, if it occurs at all, consumes more time.

Often the membranes rupture early, delaying the progress of labor and as the hours drag by increased risk to mother and babe is inevitable. Exhaustion, inertia and hemorrhage threaten the mother, while the prospect of a stillborn child becomes real in the neglected case. Lacerations here are more extensive than usual especially if the head rotates posteriorly to the hollow of the sacrum. It is not surprising therefore, that 'more children are lost from this complication than are lost from the effects of contracted pelvis' (DeLee).

To minimize these dangers by whatever means assure him of the best results, becomes the duty of every obstetrical attendant.

The proper management of a given case begins with the diagnosis of position. Failure to do this early or failure to do it at all is responsible for no small share of the misfortunes attributed to this position. The consequences of error are here so hazardous that every vertex labor which does not proceed smoothly should be carefully scrutinized for the possibility of a mistake in this direction.

Once the existence of posterior position has been established the prudent attendant fortifies his patience, adopts an attitude of watchful expectancy, and awaits some indication for interference.

The greatest danger during the period of dilatation in the average case is exhaustion of the mother. To offset this morphine and scopolamine, rectal anesthesia or analgesia and a labor room free from baneful external stimuli such as bright light, noise or conversation are the main stays during the first stage. All internal examinations are made through the rectum. Rupture of the membranes is to be prevented if possible until the cervix is completely dilated. Expulsive efforts on the part of the patient, while not to be encouraged during the first stage of any labor are here particularly to be condemned.

Usually the cervical canal if given time enough will spontaneously become completely effaced and the os fully dilated. At times, however, the

HOPKINS THURLOW 29

Fig 5 Rotation to right occiput transverse No traction

H H THURLOW 29

Fig 6 Rotation to right occiput anterior No traction The handles describe a wide arc

occipito-anterior (occiput laevus 45 degrees) the pelvic curve of the forceps in the initial application thus being directed toward the baby's fore head. An accurate cephalic application is essential to avoid slipping of the blades during rotation (Fig 3).

The forceps are now locked. To increase flexion and to free the head from the grasp of the soft parts the handles, gently compressed are carried to the patient's thigh toward which the baby's face is directed. In this movement the handles traverse a line parallel with that of the sagittal suture (Fig 4).

From this point rotation is accomplished with a gentle sweeping motion the handles describing a large arc, thus keeping the blades in approximately the same axis (Fig 2 B). The fingers of the free hand meanwhile, are touching the occiput to apprise the operator of the degree of anterior rotation. Rotation is continued until the occiput, passing through the transverse and the anterior positions, finally occupies the directly anterior or zero, position, and the handles of the forceps, inverted become directed toward the floor (Figs 5 and 7). No traction has been employed up to this point. The head has rotated in the same plane it occupied at the beginning of the maneuver, and

only the abnormality of position has been corrected. Excessive force to accomplish rotation is contra indicated.

To overcome backward rotation of the occiput slight traction toward the floor is now exerted upon the inverted handles. This fixes the head in its new position before the second application is made.

In the re application of the forceps, the posterior blade is inserted first. This aids in steadying the head and preventing its displacement during the application of the anterior blade.

The pelvic curve of the instruments now is directed toward the occiput.

The remainder of the delivery is completed exactly as that of any other occipito anterior position.

The use of the forceps to accomplish delivery in cases of posterior position has become increasingly popular. Special types of blades as the Kjelland forceps have been devised. Seides, emulating Bill introduced his 'two forceps maneuver,' while later DeLee described his 'key in lock' operation.

It may not be amiss here to add that not force, but art is the prerequisite to every obstetrical procedure. The untutored hand reflects its lack of skill in dead or mutilated children,

HOPKINS THURLOW-29

Fig. 3 The first application is the same as for the opposite anterior position

HOPKINS THURLOW 29

Fig. 4 Elevation of the handles to increase flexion and to free the head

In 1865 Scanzoni devised a method of delivery, whereby rotation and traction together were the principal features. It was after him that the original Scanzoni maneuver for the treatment of occipitoposterior positions derived its name. But rotation in these instances was doubtless imparted to the head by twisting of the handles of the forceps (Fig. 2A) for it was not until later (1881) that Tarnier brought forth the idea of sweeping the handles through a large circle to effect rotation of the head within the pelvis.

Needless to say, traction with rotation in the form of a spiral twist was not long popular, and as a consequence of many serious injuries to the pelvic floor attributed to this operation, the Scanzoni procedure fell into disrepute.

It remained for Bill, of Cleveland, by the "modified Scanzoni maneuver to prove unmistakably that the forceps can properly and safely be used as a rotator and that in this respect it is often superior to the hand in that the blades do not displace the head as does the hand. Indeed, to the accoucheur the forceps is but an extension of the hand and should be used as such in the performance of his art—much as the surgeon uses his knife or as one uses a pen with which to write. The instrument is but the agent through which the hand operates.

The technique of this operation is neither difficult nor dangerous. Properly executed it provides not only a beautiful obstetrical maneuver, but also a means by which may be avoided many of the unhappy results accredited to this position of the head.

It is necessary first that the attendant be familiar with the use of instruments and that all of the conditions governing the use of forceps be present. After the bladder is emptied the maternal soft parts are carefully prepared by the liberal use of a neutral liquid soap which not only assists in ironing out the pelvic passageway, but acts as an ideal lubricant for the passenger as well. The exact position of the head is then carefully determined, the posterior ear being located if necessary.

The choice of forceps depends upon the operator. Those commonly preferred are the Tucker-McLane variety (Fig. 1) solid blades with a long shank. The reason for this preference lies in the ease of their introduction, rotation and with drawal which renders their selection ideal for this operation.

The first application is made exactly as for the opposite anterior position. For right occipitoposterior (occiput dextra posterior 135 degrees) the first application then would be as for left

AN ORIGINAL METHOD OF CLOSURE OF A PARTIALLY APERITONEAL OR SHORT INTESTINAL END

GOLDER LEWIS McWHORTER Ph D M D, F A C S CHICAGO
 Assistant Clinical Professor of Surgery Rush Medical College of the University of Chicago

THERE is at present no thoroughly satisfactory method for closure of a short or partially aperitoneal intestinal end or one which has been cut short. As a result, leakage frequently occurs.

It is necessary to have a wide approximation of aperitoneal intestinal surfaces, which do not adhere so firmly as when covered with peritoneum, and to use preferably non absorbable suture material.

After resection of the duodenum and the ascending or the descending colon, there is usually a portion of the circumference not covered with peritoneum and there is frequently a short stump.

In an effort to avoid leakage from the lumen of the colon it is customary to use a side to side instead of an end to end anastomosis when the segment is not completely covered with peritoneum. Frequently a proximal colostomy is also done to safeguard closure of the ends of the colon.

After invagination, a partially aperitoneal or short intestinal end is usually covered with omentum and sutured to the peritoneal surface of an adjacent viscus or to the abdominal wall near the incision. A small drain may be inserted so that a possible leakage will find its way externally.

An original method of firmly invaginating short or partially aperitoneal intestinal ends has been used satisfactorily. This method is adapted particularly to closure of very short duodenal stumps, which, necessarily, may be cut close to the lesser pancreatic duct and to important blood vessels.

TECHNIQUE OF INVAGINATION

The intestine is cut off, preferably beyond a clamp applied so that the middle of the aperitoneal portion or short side forms one corner or angle (Fig 1, A). If possible the stump is invaginated without opening the lumen. This may be done by inserting a Cushing running suture from side to side over a crushing clamp, traction is made on the two ends of the suture after the clamp is removed.

When the intestinal end is cut very short, it is frequently impossible to use a clamp. The running invagination suture should then be started from the middle of the aperitoneal surface—the critical corner.

A fixation suture further to invaginate this corner is passed from it (Fig 1, A) to the intestinal wall some distance downward and as nearly opposite to it as to produce the desired invagination. If the intestinal stump is fairly long the

Fig 1 The critical corner A should be located in the middle of the aperitoneal portion of the intestinal end on the short side or next to a vital structure. A suture passed from this corner 1 to the opposite wall B assists in the invagination.

Fig 2 If possible closure of the intestinal lumen is done without opening it by suturing over a clamp. Several rows of sutures firmly fix the invagination of the end.

Fig 3 The desired maximum of invagination of the intestinal end is illustrated. There is no disturbance of the blood supply.

Fig 7 Rotation to the zero completed. Traction at this point to fix the head before the re application

and in extensive damage to the birth canal. The excellent survey of Douglas Miller reveals 2 cases of fracture of the parietal bone and 7 dead children after forceps rotation and delivery in 35 cases! To employ such force as is required to fracture an infant's skull is reprehensible to say the least. Since failure of the head in the posterior position to descend spontaneously is usually due to the

faulty position, forcible traction upon such a head, to bring it to a lower pelvic plane before rotation, is also reprehensible.

CONCLUSIONS

- 1 The diagnosis of position is essential to the proper management of any labor.
- 2 Occipitoposterior positions if neglected cause increased fetal mortality and maternal morbidity.
- 3 Usually during the first stage of labor in these cases, interference is not indicated except for conservative treatment for the support of the patient.
- 4 In the second stage rotation of the occiput manually or by means of forceps is often necessary to complete the delivery.
- 5 The modified Scanzoni maneuver, if more thoroughly understood, offers here certain advantages over other methods of delivery.

THE AMERICAN HOSPITAL

THE American hospital, like most American institutions, was modeled on the English plan, but in some very important respects the relations of the hospital to the public have been changed for the better. Whereas in England the fine public hospitals, well equipped and staffed with the best men that England affords, retain their primitive characteristics of caring only for the charity patient, in America generally speaking, there has grown gradually the plan that was adopted in 1889 when St. Mary's Hospital in Rochester was opened, of caring for all classes of people in the same hospital. It is becoming generally recognized that sickness is no respecter of persons and that the sick man regardless of race, creed, social or financial condition, is entitled to proper care, and that those at the upper end and middle of the financial scale should receive the same care as those at the lower end.

In one important respect however, the American hospital maintains something of the fundamental characteristics of those earliest institutions from which sprang the modern

hospital. Public hospitals in England were built to take care of those persons who had no other place to go, and they, therefore, were in every respect charitable organizations. They were not supported by public taxation, but by appealing to the generous minded for aid, and comparatively few of these splendid English institutions have endowments which are anything like adequate for their purposes.

The remarkable change in medicine which was brought forward by the discoveries of Pasteur and their application by Lister, changed the entire conception of hospitalization. From being a possible source of contagion and infection to all within its walls, the hospital, with the disappearance of such malign influences, became the safest retreat for the sick, and as we look at the hospital today, for those who are seriously ill and especially those requiring surgical operation, it has become the haven of refuge.

Unfortunately, in this more modern understanding of the hospital, the public has retained the attitude that the hospital must be supported, at least as far as the charity cases are concerned, by an appeal to charity, or to put it more frankly, the hospital is left to shift for itself as nobody's business.

The services of the medical profession for the poor are the one thing that all hospitals give away freely. I am proud to belong to a profession so truly humanitarian. The expenses of the hospital other than for medical services must be paid, however, and while it occasionally is the good fortune of an institution to have endowments or support from generous minded citizens, the large majority of hospitals have no such resources and either

suture may be introduced into the opposite wall, proximal to the end (Fig 1, *B*) by about the width of the lumen

Intermediate sutures of chromic catgut and a final row of intestinal approximation sutures, preferably of a fine, non absorbable material are inserted (Fig 2)

If the invagination of the critical corner (Fig 3) is carried beyond the line dividing the aperitoneal from the peritoneal surfaces, it will anchor them more firmly

If a very short intestinal end occurs and invagination is thus limited, an inversion and fixa-

tion suture may be passed from the critical corner to some point in the side of the intestinal wall along a line from *A* to *B* in Figure 1. This step will produce a maximum of invagination

The technique described may be used in the closure of any short intestinal end and will secure the maximum invagination of the corner which is nearest to the blood supply or to other important structures. Occasionally it may be desirable to secure both of the corners and anchor them in this manner

The method does not interfere with the blood supply

on the part of the public that it is their duty to care for the sick unable to pay, a duty which they recognize in the care of the insane and criminal

W J MAYO

SOME FACTORS INFLUENCING PERMANENT HEALING OF MALIGNANT TUMORS

RADIUM is not as much used in the treatment of malignant tumors as it should be—of that there can be little doubt. Reports from many expert workers in the field of radiation indicate an encouraging number of permanent healings in cases otherwise hopeless, yet many surgeons of wide experience will tell you that they have never seen a cure resulting from radium treatment. Several reasons have contributed to the skepticism of so large a number of the profession. Perhaps the most important is the almost prohibitive cost of radium, making it difficult to secure an amount adequate for effective use, but there are others, such as its application as a last resort in hopelessly advanced cases, the unwise selection of cases for its use, and above all lack of experience in its use in the earlier years following its introduction.

Forssell¹ has given a most complete and careful monograph on this subject. His report is based on a study of 1,448 patients treated at Radiumhemmet, a hospital for the treatment of cancer established in 1910 by the Stockholm Cancer Society and now receiving support from the Swedish Government. The results of the treatment have been followed at intervals for as long as 15 years in some cases. This is made possible by the fact that the Swedish Parliament voted to defray the traveling expenses of all patients too poor to bear the expense themselves.

During the first years of the institution only such tumors as were inoperable were treated

Later with improved technique and a larger supply of radium, border line cases were treated, and of late years certain operable cases have been also treated in which the results seem to indicate that radiotherapy gives better results than surgery alone or surgery combined with radiotherapy. In addition to its curative value, experience also indicates that in many hopeless cases radium offers a means of materially delaying the progress of the disease and alleviating symptoms, in certain instances giving a degree of relief which makes it possible for the patient to return to his usual vocation for a considerable length of time.

The insufficient amount of radium generally available for treatment is repeatedly emphasized in Forssell's paper. While there is no such thing as a fixed "cancer dose," a certain minimum amount is necessary. This makes it possible to apply the radium for the shortest time, by preference in a single sitting. Repeated treatments are advised only in cases in which the situation of the growth suggests the danger of too great reaction or damage to surrounding tissues, making it impossible to apply the dose at one treatment. In certain groups of cases, for example cancer of the uterus, radium is used almost exclusively, with exact local distribution at two, or at the most three treatments, over a short time usually from 3 to 4 weeks. On the other hand sarcomata are frequently treated by X ray alone or by a combination of radium and X ray therapy.

A factor of equal, or perhaps greater importance than inadequate amount of radium has proved to be the inexperience of the operator. During the early years of its use, from 1910 to 1913, the treatment was to a considerable extent experimental in an effort to elaborate a satisfactory technique. Early in 1914, when the technique had been fairly well established on a basis of a considerable experience the

must fail in their full duty to the patient or make an increased charge to the sick within the hospital who do pay, sufficient to cover the cost of maintaining care for the large number of patients who are unable to pay.

The injustice of this disregard for the sick man, already crippled in his resources by his own misfortunes in being obliged to bear taxes imposed on him for the care of others who are unable to pay, is manifest, and the financial burden lies not alone in the cost of room and board and in the cost of nursing, but in addition in a series of charges for the use of the operating room laboratories, X ray medicines, dressings, and other details of hospital care, which are as unexpected to the patient as they are embarrassing. *Altogether a financial burden so great is imposed that the common man hesitates to enter a hospital even when it is obviously for his own best interest. It is true that in the large cities, charity hospitals are maintained by the public but the self respecting American citizen of small means has pride, he has no desire for either himself or his family to accept charity and yet his only recourse is either to swallow his pride or strain his financial resources to the utmost.*

The community hospital must and does accept whatever sickness is brought to its doors. *The automobile wreck, for example, throwing the burden of a number of persons seriously injured on the hospital, has become a financial menace to these hospitals. Many small community hospitals throughout the country have been financially ruined by automobile accidents. The hospitals are not responsible for the wrecks, but they cannot refuse to care for the injured.*

The costs of such care should not be thrown on the hospitals but on the public. In large cities, most general hospitals no longer maintain an ambulance service but leave that

service in the hands of the public hospital in order to avoid financial embarrassment. The manifest duty of the governing bodies, municipal, county, or township, is to place this burden on the public where it belongs. Why should it make any difference where the patient is situated if he is a proper object of public support and is cared for well and economically? The medical care costs nothing in either case. In the large majority of instances governing bodies pay nothing, in others some conception of duty will be found but as a rule the amount they pay is less than the actual cost of care for the patients.

The high cost of hospitalization is a matter of concern to all good citizens. The sick man is a liability to his community, but he may be converted into an asset if he is made well as quickly as possible. Let us not forget that the hospital is a community necessity and not a profitable business.

The trained nurse has been accused, in the main unjustly, of contributing to the high cost of sickness. We must consider that the nurse has put in three years of twelve months each in her training and that her responsibilities are great and her hours are long. Few nurses after many years of conscientious labor have sufficient savings to be independent in their old age. It is equally true that the superior position which the nurse should occupy by reason of her training is not attained, and that much of the work that she does could and should be done by a hospital maid under her direction with a great reduction of the cost to the patient.

In the new hospitals that are to be built I look forward to seeing far reaching changes in planning construction and business management which will give sick people in moderate circumstances privacy and good care within a price that they can afford. And above all I look forward to a realization

percentage of absolute healing rose rapidly for example, in cancer of the uterus the percentage improved from 26.9 per cent in 1914 to 32.5 per cent in 1915. The treatment was then placed in the hands of another physician, lacking experience, and the figures for permanent healing sank to 8.5 per cent and later to 14.3 per cent respectively for the 2 years 1916 and 1917. When the new physician had gained sufficient personal experience the figures rose to the old level for the years 1918 to 1921.

This seems to show most strikingly the importance of establishing clinics in larger centers where patients apparently suited to this form of treatment can be received and carefully studied as to the best form of treatment, whether by surgery alone, by surgery and radiotherapy combined, or by radium alone. Forssell's careful follow up over such a long period of time gives convincing evidence

of the permanence of cure in a large number of cases. It is manifestly impossible for the vast majority of individual workers and for most small communities to support a radium clinic where a really sufficient amount of this expensive element can be obtained and held available for use. There are a few such clinics in our country, but unquestionably there is great need for the establishment of a much larger number of such centers of treatment for otherwise hopeless cases. The results also conclusively show the value of co-operative effort of large groups of medical men in referring patients and in follow up of results, thorough study of technique and its adaptation to the individual case, ample supplies of radium and apparatus. These with the experience of the operator and his adaptability to the work are certain to have a highly important influence upon future treatment of malignant tumors.

MARTIN B. TINKER, M.D.

MASTER SURGEONS OF AMERICA

MARCUS WHITMAN

THE first surgical operation performed by an American physician west of the Rocky Mountains was performed by a young doctor from New York state, Marcus Whitman, M D , in the latter part of August, 1835 The place was the annual rendezvous of fur traders and Indians on Green River, Wyoming, and the patient was the famous scout, Captain Jim Bridger The surgeon removed an iron arrow head, three inches long, from the patient's back where it had been embedded for three years The arrow head was crooked at the point and a cartilaginous substance had grown around it, rendering the operation difficult for that day and place, but it was completely successful and the reputation of the physician was established Similar operations were followed by an urgent demand for his medical and surgical services, while his kindness and firm, upright character won for him for the rest of his life the title "The Good Doctor" Dr Whitman was a man of remarkable physique, about five feet ten inches high, deep chested, and with a large head set close upon broad shoulders His endurance and physical strength were remarkable He had the body and the mind of the explorer, the adventurer, and the scientist

The young surgeon, thirty three years of age, had crossed the continent with a companion, Rev Samuel Parker of Middlefield, Massachusetts, to explore the Pacific Northwest as representatives of the American Board of Commissioners for Foreign Missions, and to report to the Board concerning the feasibility of establishing a mission among the Indians Romantic rumor had reached the East a year or two earlier that the Indians of Oregon Territory were asking for the gospel and the result was the sending of this investigating committee, consisting of a doctor and a minister, to determine the question

The number of Indians at the rendezvous in 1835 was so great and the information derived from them and from the trappers was so impressive that Dr Whitman returned East for reinforcements to establish at once a mission among the Indians The following summer he returned to Oregon with his bride, Narcissa Prentiss Whitman, Rev Henry Harmon Spalding and his bride, and a young man, William H Gray, who came as general factotum, and was later to become the first historian of Oregon

Dr Whitman and his wife were both of New England stock, their ancestors having settled in Massachusetts from England before 1635 They were well

MARCUS WHITMAN
180- 1847

mission of Mr and Mrs Spalding at Lapwai, 120 miles to the east, to Tshimakain, 150 miles to the north, where, in 1838, a new mission of the American Board had been begun by Rev Cushing Eells, Rev Elkanah Walker, and their wives, and even down to Vancouver, 300 miles westward, where the great post of the Hudson's Bay Fur Company was located. It was a record of service rarely equaled in the missionary annals of the world.

But Dr Whitman was fated to play a more important part than that of pioneer physician and surgeon in the Pacific Northwest. In those days the ownership of the Northwest was in doubt. The land was held under a treaty of joint occupancy between England and the United States, with the understanding that eventually the country which had the greater number of settlers in the field would become its owner. But the people of the United States were ignorant of its value, while the British Hudson's Bay Company was actively at work, deriving a rich annual revenue from trade with the Indians. Dr Whitman learned the fertility of the soil, the vastness of the river system, the extent of its forests, and its mineral resources. He became profoundly convinced of the value of the country to the United States.

In September, 1842, a little party of travelers from the East brought word that a new treaty was about to be negotiated between England and the United States, which, it was believed, would settle the Northwest boundary line. In the absence of reliable information concerning the value of the country it was likely that the United States would amiably allow Great Britain what she desired in the Northwest, in return for concessions elsewhere. Dr Whitman resolved to inform his government concerning the great value of the land of his adoption. To the remonstrances of his fellow missionaries he said, "Gentlemen, though I am a missionary I am not expatriated. To Washington I will go."

On October 3, 1842, he started to cross the continent with one white companion Lovejoy, who had just brought from the East the news of the impending treaty. Dr Whitman had other business than interviewing the government at Washington, for his fellow missionaries had entrusted him with important correspondence addressed to the American Board at Boston, but his primary object was political, and he went first to Washington by the most expeditious route.

His winter ride from Walla Walla to Washington was full of romantic and terrible adventures. It has been called "the greatest ride in history." Blocked by Indians on the warpath, and snows in the northern mountains, he turned south through Utah and made his way to Bent's Fort on the Arkansas River. Thence he hastened to Washington, his face and hands and feet frozen by exposure. Lovejoy remained in the Mississippi Valley to arouse interest in Oregon and urge people to join the wagon train which, it was hoped, would cross the continent that summer.

educated for their day, and came from comfortable homes of godly and hard working parents who lived thriftily on the frontier of western New York. Dr Whitman had been educated at Plainfield, Massachusetts, where he studied Latin under Rev. Moses Hallock. Then his family moved to Rushville, New York, and he studied medicine under Dr. Ira Bryant of that place. He had received his diploma at Fairfield in 1824, and had practiced medicine for four years in Canada and afterward in western New York. He had also gained a valuable business experience by a partnership with his brother in the management of a saw mill near Potter Center. His active mind, physical vigor, and adventurous disposition had made him eager for a larger field, and he had offered himself to the American Board "as physician, teacher, or agriculturist."

Mrs. Whitman was twenty-eight years of age, tall and noble looking, with golden hair, a gracious manner, and a lovely voice. An experienced teacher, she gave herself, heart and soul, to her husband's work. Her coming and that of Mrs. Spalding marked the true beginning of American civilization on the Pacific Coast. Until woman comes the home is lacking.

Dr. and Mrs. Whitman settled at Waulatpu, six miles west of the present town of Walla Walla, Washington, and began their life work for the Indians. The doctor installed his bride in a log cabin made from trees which he cut in the Blue Mountains, twenty miles away. The floor was hard trodden clay, and across the openings in the rough walls skins and blankets were hung to keep out the cold night air and the prowling savage. Here Mrs. Whitman established the first American home on the Pacific Coast, and here, on March 14, 1837, the first white child of American parents was born, Alice Clarissa Whitman.

When an American traveler, T. J. Farnum, visited the Whitman mission in 1839, he found that the young doctor and his wife had accomplished great things in a short time. In his diary for September 23 he wrote: "The old mission house stands on the northwest bank of the river, about four rods from the water side at the southeast corner of an enclosure containing about two hundred and fifty acres, two hundred of which are under good cultivation. The products are wheat, Indian corn, beans, pumpkins, Irish potatoes, etc., in the fields, and beets, carrots, onions, turnips, rutabagas, water, musk and nutmeg melons, squashes, asparagus, tomatoes, cucumbers, peas, etc., in the garden—all of good quality and abundant crops." A large mission house, 100 feet by 40 feet for the use of travelers and future immigrants, was in process of construction. A grist mill, the first in the Inland Empire, was in operation.

During these years of active work as pioneer and farmer, Dr. Whitman had learned the Indian language, had helped his wife with her teaching of the Indian boys and girls who crowded to the first school east of the Cascade Mountains, had ministered to the physical and spiritual needs of the Indians, and had acted as physician and surgeon for distant regions going when needed to the

Measles broke out among the Indians near the mission in the fall of 1847 Dr Whitman treated the patients among the Indians and among the visiting white immigrants with the same remedies, but many of the Indian patients died Taking his remedies, they followed also the Indian custom of a sweat bath In a low lodge of closely woven boughs by the bank of the river, water was poured on heated stones to make steam in which the sick were laid, emerging at last, dripping with sweat, they leaped into the ice cold stream When many of them died under this treatment it was whispered that Dr Whitman had poisoned them An Indian custom dictated revenge

On November 29, the discontent and hate which had gathered like a storm suddenly broke Dr and Mrs Whitman were killed and scalped All the boys and men in the mission were also killed, while the women and children, some forty in number, were held by the Indians for their own purposes and for ransom In the lust for blood and destruction the mission buildings were burned down the orchard was hacked to pieces, and scarcely a vestige left of the mission station in which the good doctor and his wife had spent their lives for those who slew them

The closing scene in the life of Dr Whitman saw him in the rôle of physician ministering to the sick Three Indians, wrapped in blankets, had come to the door of the mission and asked for medicine As he bent over his medicine chest to select the proper remedy for the sick Indian, one of the others slipped behind him and, raising his tomahawk, struck a glancing blow on the back of his head The doctor leaped for the throat of the other Indian but as he struggled the deadly tomahawk rose and fell striking the doctor on the top of the head penetrating the skull a fatal wound He died as the physician would like to die in the act of service Of him too, it might be said that "he came, not to be ministered unto, but to minister, and to give his life a ransom for many"

The one hundredth anniversary of the founding of the Whitman mission and the beginning of American civilization on the Pacific Coast will be celebrated in 1936 by the people of Walla Walla and the state of Washington in co-operation with Whitman College his living memorial

STEPHEN B L. PENROSE

Dr Whitman reached Washington on the third of March, 1843, and Congress adjourned the next day. He could make no impression on Daniel Webster, then Secretary of State, but was more successful with President Tyler. He obtained from the latter virtual agreement that no settlement of the Northwest boundary line would be made until the chance had been given to demonstrate that Oregon could be reached by wagons, and hence was accessible for settlement by the United States. Seven years before Dr Whitman had taken across the mountains the first wagon to the Pacific Northwest.

Horace Greeley wrote in the New York *Tribune* about Dr Whitman as he hurried from Washington, through New York, to Boston. He transacted his business with the American Board and reported that he was received coolly for abandoning his post. Then he turned westward and, after a brief visit in western New York state to see his family and the family of Mrs Whitman, he overtook the wagon train which had already started from the Missouri River, and was speedily elected its guide. Two hundred wagons, eight hundred or more American settlers, and two thousand horses and oxen composed the great wagon train of '43 which moved slowly westward across the prairies, through the Rocky Mountains, past the post of the protesting Hudson's Bay Company at Fort Hall, over the Blue Mountains to Wailatpu, and down to the Willamette Valley. That wagon train blazed a trail so broad and clear across the continent that at once settlers poured westward in an unending stream. Soon the Americans vastly outnumbered the English and when by treaty, June 17, 1846, the Northwest boundary line was settled, it was drawn at the 49th parallel, instead of the mouth of the Columbia, or perhaps even the 42nd parallel the northern boundary of California. A vast region of immense natural resources had been saved to the United States by the wagon train of '43 and by the doctor who rode at its head, who had been prophet enough to foresee the value of the country and hero enough to risk his life to save it. Has any member of the medical profession rendered a greater service to his country?

After the great wagon train had left the mission station at Wailatpu, where it had rested and supplied itself with provisions, it traveled down the Columbia and out of the life of Dr and Mrs Whitman. This faithful couple, true to their original intention, settled down as missionaries to the Indians striving to do what they could for them intellectually, physically and morally. They quietly took up again their missionary work, healing the sick, teaching the young, advising and inspiring the tribes.

But it was evident that the coming of so great a tide of white settlers would disturb and terrify the Indians. They felt that they would be driven from their homes and they blamed Dr Whitman for his part in hastening the tide. The signing of the treaty and occupation of the country by the United States meant practically the signing of the death warrant of Dr Whitman and his wife.

OLD MASTERPIECES IN SURGERY

ALFRED BROWN M D F A C S OMAHA NEBRASKA

THE CLINICAL CASES OF AMATUS LUSITANUS

THE country of the ancient Lusitanians which comprised the modern Portugal and a part of Western Spain had been battered about and subject to various countries up to the middle of the twelfth century. It had passed through the stages of being a colony of Greece and later of Rome then coming under the Moorish domination until finally under Alfonso I it became a kingdom in 1139. It then flourished as an independent kingdom until 1580 when it lost its autonomy and became subject to Spain. During its early period it borrowed its medicine and its medical ideas from the country to which it was subject, becoming in turn medically Greek, then medically Roman and finally during the period of Arabian domination Arabian in its medical thought. When it became a self ruling kingdom under Alfonso I it turned a little attention to medicine and founded two medical universities the first in Lisbon in 1290 and the second at Coimbra in 1307. These flourished up to the period of the Renaissance but produced practically no great men. Inheriting as it did the Jewish tradition in science and art many of Portugal's men of prominence in these fields were Jews and were driven out rather rapidly as soon as they obtained any prominence. Consequently they are found in other countries rather than in their native land.

It is rather interesting to note that these men dropped their own names and took either a part of their own name or an entirely new name and added to it the name of the ancient country Lusitania. So we find that one of the most prominent Portuguese of the sixteenth century called himself Amatus Lusitanus—Amatus of Lusitania. His real name was Juan Rodrigues de Castel Branco. He was born in the province of Beira in 1511 and was descended from a Jewish family which in order to be safe had through the force of public opinion embraced Christianity and followed that faith at least openly. Amatus did not follow his medical studies in Portugal either at the University of Lisbon or Coimbra but went to Spain and took his medical education in Salamanca where he studied under Alderate and attended the University at the same time as the famous Spanish physician Andres Laguna. He appeared to be particularly interested in surgery as he took a surgical service in two hospitals and then finding apparently that there was not sufficient opportunity for advancement in

Portugal left the country and went first to Antwerp and later to Ferrara. In the latter place he had the opportunity to follow out his anatomical studies through dissection both of human and animal bodies and says that he personally dissected more than twelve.

In 1549 he left Ferrara and went to the province of Ancona which had been annexed by the papal states in 1532 and there started to practice. In a short time he attained a very large following and a great reputation in surgery. However tragedy as it so commonly did in the sixteenth century stalked on the footsteps of success for in 1554 he was suspected by the Inquisition of following his former faith of Judaism. When this occurred there was only one thing for him to do and that was to leave Ancona and go to some country where he would be safe. In the meanwhile all of the wealth which he had gained during his residence in Ancona was seized by the Inquisition and a poor man he went to Pesaro where he was protected for a time by the Duke of Urbino. In spite of the fact that he was asked to go to Poland by the King he decided to go to Thessalonica now known as Salonica where Jews were free to worship in their own way and he then openly returned to the faith of his fathers.

Among his principal works of clinical interest is a series of case histories so to speak which he published in sections of 100 cases each. The first of these appeared in Florence published in 1554 the second in Venice in 1552. He then published a series of 400 cases at Basle in 1556 the fifth hundred at Pesaro in 1556 the sixth at the same place in 1558 and the seventh at Thessalonica in 1561. A completed collection appeared in Venice in 1557 before the publication of the sixth and seventh centuries as individual parts.

The general arrangement of this book is quite interesting. It consists of 400 clinical histories which are cited very carefully giving the symptoms, physical signs and results of what had been done in the various cases. To the important ones there is appended what is called a Scholia. In this Amatus goes over the general principles of the disease under consideration discusses the various points and cites the opinions of other authors concerning it. It is noteworthy that Amatus although interested in surgery as a young man and evidently practicing it at the time this book was written did not himself practice surgery as in several places he advises sending for a surgeon.

REVIEWS OF NEW BOOKS

THE second edition of *Science and Practice of Surgery* by Romanis and Mitchner¹ is now available. This is an English work depicting English methods and ideas. An apology should be offered for this statement since in reality there should be no English or German or American school of surgery. Close contact through rapid transportation and constant interchange of thought and ideas is rapidly producing a school of surgery which is international. It is only in a detail here an improvement there an advancement of a physiological or pathological concept here today and its clinical application in a distant land tomorrow that afford any geographic distinction. Truly individual lands have an opportunity in that various diseases may be confined to a considerable extent to climatic or geographic locations as bilharziosis to Egypt yet the greater part of all surgical afflictions are world widespread.

This the second edition is a distinct improvement over the first and much of the material has been altered and brought up to date. In the description of massive collapse of the lung it is stated that an X-ray shows the diaphragm to be depressed and Treatment consists in applying a blister to the neck to counter irritate the phrenic nerve and giving an expectorant mixture. I fear these statements would not be accepted by the junior quiz masters in American medical schools.

In the discussion on thyroid surgery the preparation of the toxic cases should be more fully described. Every surgeon recognizes that this part of the treatment is most important in fact often the most vital one. No reference is made to the postoperative administration of iodine. Many statements in the division on gall bladder surgery are open to serious question. These few comments are intended as a constructive criticism as in general all surgical topics are exceedingly well covered. Special note should be made of the chapter on diseases of the joints the authors deserve much credit for the clarity and completeness of their presentation.

This work of two volumes is a complete of necessity at times brief survey of general and special surgery and offers the student with stated exceptions an excellent and complete text for the study of surgery. An added convenience is a complete index to the whole work at the end of each volume.

JOHN A. WOLFER

THE second edition of *The Principles of Electrotherapy and Their Practical Application*² is one of the best available books on electrotherapy. An excellent history of electrotherapy is given in the

THE SCIENCE AND PRACTICE OF SURGERY By W. H. C. ROMANIS, M.A., M.B., M.Ch. (Cantab.) F.R.C.S. (Edin.) and P. H. MITCHNER, M.D., M.S. (Lond.) F.R.C.S. (Eng.) 2nd ed. 2 vols. New York: William Wood and Company 1929.

THE PRINCIPLES OF ELECTROTHERAPY AND THEIR PRACTICAL APPLICATION By W. J. T. STELL, M.A., D.M., B.Ch. (Oxon.) D.M. R. & L. (Cantab.) 2nd ed. New York: Oxford University Press 1929.

first part and in the second part are described the therapeutic actions of the various electrical currents. The chapter on the constant or galvanic current gives in detail the various experiments to show the lack of value as well as the value of this current. Details of interest are given as direct proof against the practicability of deep ionic medication.

In the chapter on the action of interrupted currents of low frequency the author likewise tries to judge scientifically the value of these currents. For instance, he says that although many special forms of current at varying rates of interruption have been designed and recommended by electrotherapists for exciting contraction in the involuntary muscles of the intestines the fact nevertheless remains that the involuntary muscles of the stomach and bowels are incapable of excitation by any of the currents employed in electrotherapy, and he explains the reason for this. But then he says that it is possible to treat indirectly certain forms of chronic constipation by stimulating the abdominal muscles.

There are also chapters on the therapeutic action of the high frequency and static currents. In the third part the action of radiant energy is considered. Electrical accidents are discussed in Part IV and electrodiagnosis in Part V. The last part of the book covers the application of electricity in certain disease conditions and tries to evaluate the application of these forms of treatment to various pathological conditions.

J. S. COULTER

THE fifth edition of the monograph on *Artificial Sunlight and its Therapeutic Uses*³ is beautifully printed and well illustrated. Unfortunately the author is inclined to overemphasize the use of artificial radiation to the disadvantage of long established methods as is shown in the statement. It is doubtful if any therapeutic measure effects as much good as ultraviolet therapy in diseases of the liver.

The book is of greatest value to the specialist in this form of therapy.

J. S. COULTER

THE second edition of Fisher's book on *Treatment by Manipulation*⁴ has been thoroughly revised and rewritten. Certain chapters have been enlarged especially those on osteopathy, tennis elbow, chronic arthritis and lesions of the sacro iliac joint. The author points out the danger of manipulation in improperly selected cases or when performed by inexperienced operators. He is very forceful in his condemnation of the unqualified practice of the bone setter and the osteopath. He divided into four main groups those cases which can be cured or benefited.

ARTIFICIAL SUNLIGHT AND ITS THERAPEUTIC USES By FRANCIS H. W. d. HUMPHREYS, M.D. (Brux.) F.R.C.P. (Edin.), M.R.C. (E.G.) L.R.C.P. (Lond.) L.M. (R. Dubl.) D.M. & A. (Cantab.) New York: Oxford University Press 1929.

TREATMENT BY MANIPULATION A PRACTICAL HANDBOOK FOR THE PRACTITIONER AND STUDENT By A. G. TIMBRELL FISHER, M.C. F.R.C.S. (E.G.) 2nd ed. rev. New York: The Macmillan Company 1929.

PRELIMINARY CLINICAL PROGRAM FOR PHILADELPHIA CONGRESS

A PRELIMINARY program of clinics and demonstrations to be given in the hospitals and medical schools of Philadelphia during the twentieth annual Clinical Congress of the American College of Surgeons to be held in that city October 13-17 appears in the following pages. It will be noted that clinics are scheduled for Monday afternoon and for the mornings and afternoons of the following four days. The hospital schedules are to be revised and amplified during the weeks preceding the Congress to present a more complete outline of the clinical work that will be demonstrated. The surgeons of Philadelphia are keenly interested to provide a complete showing of the clinical surgical activities of that great medical center.

A series of fracture clinics will form an important feature of this year's Clinical Congress. At many of the hospitals plans are being made for a complete showing of modern methods in the treatment of fractures with end results.

Programs for a series of five evening meetings are being prepared. On Monday evening at the presidential meeting the president elect Dr. C. Jeff Miller of New Orleans will be inaugurated and deliver the annual address. The annual Murphy oration in surgery will be another feature of that meeting. Distinguished surgeons of the United States and Canada and eminent surgeons from abroad have been invited to present papers dealing with surgical subjects of present day importance at scientific meetings on Tuesday, Wed-

nesday and Thursday evenings. On Friday evening at the annual convocation of the College, the 1930 class of candidates for fellowship in the College will be received.

An interesting program of papers, round table conferences and practical demonstrations dealing with the problems related to the hospital standardization program of the College and hospital efficiency in general is being prepared for the annual hospital conference which opens at 10 o'clock on Monday in the grand ballroom of the Bellevue Stratford Hotel. The conference will continue on Tuesday and Wednesday.

General headquarters for the Clinical Congress will be established at the Bellevue Stratford Hotel where all of the rooms on the second floor, including the grand ballroom, have been reserved for scientific meetings, conferences, film exhibitions, registration and ticket bureaus, bulletin boards, executive offices, technical exhibition, etc.

Attendance at the Philadelphia session will be limited to a number that can be comfortably accommodated at the clinics, under which plan it will be necessary for those who wish to attend to register in advance paying the registration fee of \$5.00. Attendance at the clinics will be controlled by means of special clinic tickets, which plan provides an efficient means for the distribution of visiting surgeons among the several clinics and insures against overcrowding the number of tickets issued for any clinic being limited to the capacity of the room in which that clinic will be given.

by manipulation. They are cases with adhesions functional or hysterical cases unreduced dislocations or subluxations, and a miscellaneous group. He outlines, under diagnosis, the various symptoms of adhesions as follows: limitation of movement, pain, weakness, tenderness, and recurrent effusion. He discusses manipulative procedures of hip, knee, ankle and foot, shoulder, elbow, wrist, hand and spine.

The author's qualifications are excellent. His material is well chosen and presented. The discussion on osteopathy and chiropractic should be read generally by the profession. This small book should be of value to every orthopedic, industrial, or traumatic surgeon.

PHILIP LEWIN M.D.

CHANDLER and **Burton Wood** have written a monograph on lipiodol in the diagnosis of thoracic disease,¹ which might well be used as an example

¹LIPIODOL IN THE DIAGNOSIS OF THORACIC DISEASE. By F. G. Chandler M.A. M.D. (Cantab.), F.R.C.P. (Lond.) and W. Burton Wood, M.A. M.D. (Cantab.) M.R.C.P. (Lond.). New York and London: Oxford University Press, 1928.

for other monographs. In a few pages they have presented the history of lipiodol, the technique of giving it, and a few words about the indications and contra-indications, while the remaining 100 pages of the book are taken up with about 50 excellent radiograms showing various intrathoracic conditions. By means of these radiograms, by means of the short notes under each one, they describe graphically the appearances found in bronchiectasis, lung abscess, emphysema, etc.

That they prefer to give iodine by means of cricothyroid puncture and not as so many of us do in this country by means of some sort of aspiration method or some method of instilling the lipiodol into the trachea through the mouth cannot be offered in criticism of the book, because in spite of their preference they describe these methods even showing roentgenograms in which several of these methods have been used and in which they have obtained the same excellency in their plates as they have with the cricothyroid puncture.

EDWARD F CORON Bone syphilis and other allied surgical conditions
C C NIERI Vaginitis clinic

EVANS DENTAL INSTITUTE

Tuesday

- ROBERT H IVY—9 Fracture of the jaw

Wednesday

- LAWRENCE CURTIS—9 Oral surgical clinic

Thursday

- ROBERT H IVY and LAWRENCE CURTIS—9 Oral surgical clinic

BABIS HOSPITAL

Tuesday

- JOHN SINCLAIR and WILLIAM BATES—2 30 Presentation of follow up cases of intussusception and congenital hypertrophic stenosis

Thursday

- JOHN SINCLAIR and I BENDER—2 30 Conservative treatment of cervical adenitis.

HAHNEMANN HOSPITAL

Monday

- H P LEOPOLD—2 Hernia clinic
D B JAMES and staff—2 Operative gynecology

Tuesday

- D B WEBSTER—9 Fracture clinic.
JOHN E JAMES and staff—2 Obstetrics
L T ASHCRAFT and staff—2 Genito urinary surgery

Wednesday

- L T ASHCRAFT and FRANK BENSON—9 Neoplasms of the genito urinary tract
H L NORTHPROP—2 General surgical clinic

Thursday

- J DEAN ELLIOTT—9 General surgical clinic
D B JAMES and staff—9 Operative gynecology
JOHN A BROOKE and staff—2 Dry clinic orthopedic surgery

Friday

- H L NORTHPROP and staff—9 General surgical clinic
FRANK BENSON—9 Indications for radium treatment

STETSON HOSPITAL

Monday

- CARL F KOENIG—1 30 X ray demonstration

Tuesday

- WILLIAM T ELLIS and JOHN A BOGER—12 General surgery

Wednesday

- STEPHEN E TRACY—8 30 Gynecology
CARL F KOENIG—1 30 X ray demonstration

Friday

- STEPHEN E TRACY—8 30 Gynecology
CARL F KOENIG—1 30 X ray demonstration

JFANES HOSPITAL

Wednesday

- R W TRAHAN—2 Carcinoma of breast
C A WHITCOMB—2 Lung tumors
E E DOWNS—2 The saturation method of X ray treatment
W S HASTINGS—2 Exhibition of interesting pathological specimens

Thursday

- R W TRAHAN—2 Carcinoma of skin.
C A WHITCOMB—2 Mediastinal masses
E E DOWNS—2 Exhibition of interesting X ray films
W S HASTINGS—2 Exhibition of interesting pathological specimens.

U S NAVAL HOSPITAL

Tuesday

- Staff—9 Surgical operations

Wednesday

- Staff—9 Surgical operations.

Thursday

- Staff—9 Surgical operations

Friday

- Staff—2 Discussion of surgical cases or surgical topics

SURGERY OF THE EYE, EAR, NOSE AND THROAT

JEFFERSON HOSPITAL

Tuesday

LOUIS H. CLERF and staff—9 Bronchoscopy
F. O. LEWIS and staff—9 Nose and throat operations

Wednesday

F. O. LEWIS and staff—10 Carcinoma of larynx
LOUIS H. CLERF and staff—11 Bronchoscopy

Thursday

LOUIS H. CLERF and staff—9 Bronchoscopy
F. O. LEWIS and staff—9 Nose and throat operations

Friday

C. F. G. SHANNON and staff—3 Ophthalmology

MT SINAI HOSPITAL

Monday

C. W. LEFEVER—3 30 Eye clinic operations and demonstration of cases

Tuesday

LEWIS FISHER—1 Ear nose and throat clinic, operation and demonstration of cases

Wednesday

DAVID HUSK—2 30 Ear nose and throat clinic
GABRIEL TUCKER—4 Bronchoscopy

Thursday

MORRIS WEINSTEIN—2 Ear nose and throat clinic operations and demonstration of cases

Friday

MATTHEW ERSNER—1 Ear nose and throat clinic operations and demonstration of cases

ST JOSEPH'S HOSPITAL

Tuesday

GEORGE MORLEY MARSHALL—9 The Marshall operation for nasal deformity with end results
A. J. KEENE—3 Otolaryngological operations

Wednesday

ARTHUR WIGLEY—9 Otolaryngological operations

Thursday

GEORGE MORLEY MARSHALL—9 The radical mastoid with end results
C. T. MCCARTHY—2 Otolaryngological operations

Friday

FRANCIS GOWEN—9 Otolaryngological operations

UNIVERSITY HOSPITAL

Wednesday

GEORGE FETTEROLF and staff—2 Otolaryngological clinic operations and demonstration of cases

Friday

GEORGE FETTEROLF and staff—2 Otolaryngological clinic operations and demonstration of cases
T. B. HOLLOWAY—4 Ophthalmological clinic

SAMARITAN HOSPITAL

Monday

MATTHEW ERSNER—3 Operative otology

Tuesday

CHEVALIER JACKSON and associate—8 30 Bronchoscopic clinic

ROBERT RIDPATH—2 Laryngological clinic

LUTHER C. PETER—3 Operative ophthalmology

Wednesday

CHEVALIER JACKSON and associates—8 30 Bronchoscopic clinic

Thursday

CHEVALIER JACKSON and associates—8 30 Bronchoscopic clinic

ROBERT RIDPATH—2 Operative laryngology

LUTHER C. PETER—4 Ophthalmological surgery

Friday

CHEVALIER JACKSON—8 30 Bronchoscopic clinic

MATTHEW ERSNER—4 Otological clinic

EPISCOPAL HOSPITAL

Monday

FREDERICK KRAUS—2 Eye clinic

W. R. WATSON—2 Ear nose and throat clinic

Tuesday

HAROLD VON GOLDBERG— Eye clinic

Wednesday

W. R. WATSON—1 30 Ear nose and throat clinic

A. C. FEWELL—3 Eye clinic

Thursday

C. C. BIEDERT—1 30 Ear nose and throat clinic

FREDERICK KRAUS—1 30 Eye clinic

Friday

C. C. BIEDERT—1 30 Ear nose and throat clinic

HAROLD VON GOLDBERG—1 30 Eye clinic

JEWISH HOSPITAL

Wednesday

J. C. KNIFE—3 Ophthalmological operations

Thursday

A. S. KAUFMAN and R. F. RIDPATH—2 Otolaryngological operations

SUBJECT INDEX TO VOLUME L

- ABDOMEN** Implantation malignancy of abdominal wall 907
- Abnormalities** Micromelia in child irradiated in utero 79
- Sacrocoxygeal teratomata** with malignant degeneration in childhood 85
- Value of indwelling urethral catheters in urinary surgery** 441
- Postirradiation pregnancy report of a case** 492
- Annular pancreas** 533.
- Bifid os calcis** 1012
- Abortion** Postirradiation pregnancy 492
- Theory and practice of intra uterine charcoal treatment in gynecology and midwifery** 873
- Acetylene Anaesthesia** ed 117
- Alcohol injections for postoperative pain in thoracic surgery** 74
- Alvarez** Speculations on control of intestinal function ed 643
- Amenorrhoea** Postirradiation pregnancy report of a case 492
- American College of Surgeons—**
Address of Retiring President Franklin H. Martin 285
Address of Welcome Herman L. Kretschmer 284
Board on Medical Motion Picture Films 357
Board on Traumatic Surgery 310-349 331 332 348 355
- Candidates** Presentation of for fellowship 495
- Clinical Congress** Nineteenth Annual Chicago October 14-18 1929 ed 279
- Scientific programs** ed 280
- Hospital and surgical practice** ed 281
- Clinics of ed** 281 in Philadelphia 930 927 1051
- Committee on Arrangements** Chicago 359
- Committee on Treatment of Fractures** 353
- Committee on Treatment of Malignant Diseases** 351
- Convocation** Seventeenth ed 282
- Department of Clinical Research** 350
- Fellowship address—The medical revolution a study in the humanization of science** Glenn Frank 302
- Gavel** 285
- Greetings from College of Surgeons of Australia** 359
- Hospital Standardization Conference** 360-384
- Inaugural Address—Surgery in the Medical Department of the United States Army** Merritt W. Ireland 289
- Library and Literary Research Department** 358
- Mace** The Great 288
- John B. Murphy Oration—Some principles in abdominal surgery** D. P. D. Wilkie 129
- Oration on Fractures (first address)** Charles L. Scudder 193
- Peace Jubilee** 288
- President's address—The Medical Department of the United States Army** 296
- Feet try of Bone Sarcoma** 354
- State and Provincial Sectional Meetings** 356
- Anæmia** Treatment of pernicious by liver feeding 244
- Blood regeneration in severe** 244
- Observations on treatment of** 246
- Physiological of pregnancy study of one thousand patients** 954
- Anæsthesia** ed 117
- Premedication for local with intravenous barbituric compounds** 494
- Luminal and the newer concept of (semi) Anæsthesia** ed 775
- Local in abdominal surgery** 879
- Anæsthetics** Experience with sodium amytal as an intravenous 828
- Clinical experience with new local anæsthetic drugs** 907
- Ankle** Bifid os calcis 1012
- Anthropology of the Negro** its bearing on the mortality in head injuries a review of six hundred cases 499
- Appendicitis** Bacteriology and pathogenesis of 562
- Observations upon the extenized appendix of the dog** 572
- Appendix** Duodenal and gastric ulcer cholecystitis and appendicitis a consideration of their pathological relations 59
- Some principles in abdominal surgery** 129
- Abdominal technique system of operative exposures** 455
- Observations upon extenized appendix of dog** 572
- Pseudomyxoma peritonæi originating from mucocele of appendix** 1023
- Arm** Arthrodesis of shoulder by means of osteopenosteal grafts 468
- Arteries** Mechanism controlling migration of omentum 541
- Arthritis** Surgical indications for sympathetic ganglionectomy and trunk resection in treatment of chronic arthritis 204
- Arthrodesis of shoulder by means of osteopenosteal grafts** 468
- Asphyxia** Traumatic with report of five additional cases 578
- Atelectasis** Postoperative pulmonary report of unusual case 45
- Mechanism of obstructive pulmonary** 385
- Postoperative pulmonary complications and bronchial obstruction postoperative bronchitis atelectasis (apneumatosi) and pneumonitis considered as phases of same syndrome** 795
- BACILLI** tubercle Culture of from urine report of one thousand two hundred cultures 985
- Bacteriology and pathogenesis of appendicitis** 562
- Barbituric acid compounds** Premedication for local anesthesia with intravenous barbituric compounds 494
- Bifurcation operation** indications technique and results 90
- Bile ducts** Effect of cholecystenterostomy on biliary tract 40
- Reflex of pancreatic and duodenal secretions through a drainage tube in the common** 627
- Local anesthesia in abdominal surgery** 879
- Bladder** Technique of the Voelcker extrapentonealization of urinary with illustrative cases 69
- Ruptured urethra operation** 105
- Radiology as a complete or partial substitute for surgery in treatment of cancer of female pelvic organs** 173
- Value of indwelling urethral catheters in urinary surgery** 441
- Abdominal technique system of operative exposures** 455
- Solitary tuberculoma of bladder** 1015
- Blastomycosis** Localized infection caused by yeast like fungi with special reference to spinal involvement 972
- Blood** Treatment of pernicious anæmia by liver feeding 234
- regeneration in severe anæmia** 244
- Observations on treatment of** 246
- Sedimentation test in pregnancy and in puerperium study of five hundred forty patients** 429
- Hemolytic icterus and technique of splenectomy** 606
- Physiological anæmia in pregnancy**

- study of one thousand cases 954 Total gastrectomy with report of successful case 1008
- Blood sugar Use of intravenous glucose in diabetic patients 769
- Blood vessels Injection treatment of varicose veins 545 Solitary cysts of the kidney report of seven cases and observations on pathogenesis of these cysts 668 Circulatory complications of prostatectomy 864
- Boils Relation between acute infections of the upper respiratory tract and infections of the kidney ed 503
- Bone Chondrosarcoma of 216 changes in hyperparathyroidism 783
- Brain Anthropology of Negro its bearing on mortality in head injuries review of six hundred cases 499 Three score and ten ed 774
- Breast Liposarcoma of mammary gland 81 Standardization of electrosurgery radical operation for cancer of the breast taken as an example in general surgery 261
- Bronchi Mechanism of obstructive pulmonary atelectasis 385 Postoperative pulmonary complications and bronchial obstruction postoperative bronchitis atelectasis (apneumotosis) and pneumonitis considered as phases of the same syndrome 795
- Burns Implantation method of skin grafting 634
- CÆCOSTOMY** Left partial colectomy 65
- Cesarean section Present day treatment of placenta prævia 113 General consideration of cor 512
- Cancer Incidence of among Indians in Southwest 196 Recognition of early cervical 200 An inquiry into the basic cause and nature of cervical pathology of cervicitis (erosion of the cervix) and relation between cervicitis and cervical cancer 513 688
- Carbon dioxide Anesthesia ed 117
- Carbuncles Relation between acute infections of upper respiratory tract and infections of kidney ed 503
- Catgut How can we insure sterility of 271
- Catheters Value of indwelling ureteral in urinary surgery 441
- Cell growth Laws of 163
- Central America Conference on Traumatic Surgery 329
- Cervicitis Inquiry into basic cause and nature of cervical cancer pathology of cervicitis (erosion of cervix) and relation between cervicitis and cervical cancer 513 688
- Charcoal therapy Theory and practice of intra uterine in gynecology and midwifery 873
- Chloroform Anesthesia ed 117
- Cholecystenterostomy Effect of on biliary tract 40
- Cholecystgastrostomy Effect of on biliary tract 40
- Cholecystitis a bacteriological and experimental study of three hundred surgically resected gall bladders 655 Relation of hepatitis to chronic 959
- Cholelithiasis in Korean 51
- Chordoblastoma Four rare rectal tumors—intrarectal solid teratoma fibroleiomyoma parafinoma and 762
- Circulatory disease Per arterial sympathectomy in of extremities report of cases 426
- Cocaine poisoning Premedication for local anesthesia with intravenous barbituric compounds 494
- Colitis Regional migratory chronic ulcerative 964
- Colon Left partial colectomy 65 Resection and obstruction of (obstructive resection) 504 Diverticulitis of 836 Simple, non specific ulcer of 870 Median colotomy 903 Regional migratory chronic ulcerative colitis 964
- Colostomy Median 903
- Cranium Anthropology of the Negro its bearing on mortality in head injuries review of six hundred cases 499
- Cyanosis Traumatic asphyxia with report of five additional cases 578
- Cystadenoma Pseudomucinous analysis of thirty cases in which the cysts were not ruptured before operation 752
- DIABETES** Use of intravenous glucose in diabetic patients 769
- Diaphragm Redistribution of respiration following paralysis of hemidiaphragm 929
- Diseases of childhood Sacrococcygeal teratomata with malignant degeneration 85
- Disease cardiovascular Method of reducing the incidence of fatal postoperative pulmonary embolism results of its use in four thousand five hundred surgical cases 154 Raynaud's Surgical indications for sympathetic ganglionectomy and trunk resection in treatment of chronic arthritis 204 Raynaud's Speculations on control of intestinal function ed 643
- Doctor Medical revolution study in humanization of science 302
- Drugs, Clinical experience with new local drugs 997
- Duodenum Formes frustes type of perforated peptic ulcer 10 Duodenal and gastric ulcer cholecystitis and appendicitis a consideration of their pathological relations 59 Some principles in abdominal surgery 129 Anatomical consideration of the ulcer bearing area (lesser curvature of the stomach pylorus and first part of duodenum) 416 Reflux of pancreatic and duodenal secretions through a drainage tube in the common bile duct 627 Chronic duodenal ulcer 745 Total gastrectomy with report of successful case 1008
- EAR** Reconstruction of external 601
- Electrosurgery Standardization of radical operation for cancer of breast taken as example in general surgery 261
- Embolism Method of reducing incidence of fatal postoperative pulmonary embolism results of its use in four thousand five hundred surgical cases 154 Operative treatment of of lungs 891
- Embryology Annular pancreas 533
- Empyema Constant vacuum aspiration treatment of simple device in creating vacuum 1029
- Endometrium Morphological similarity of certain luteal cysts and endometriosis of ovary 1
- Epididymis Operation for tuberculosis of 624
- Ether Anesthesia ed 117
- Ethylene Anesthesia ed 117
- Extrapentonealization of bladder Technique of Voelcker with illustrative cases 69
- Extremities Per arterial sympathectomy in circulatory disorders of 426
- FALLOPIAN** tubes Pseudotuberculous salpingitis 663
- Femur Bifurcation operation indications technique and results 90 Congenital dislocation of hip diagnosis and new method of treatment in infancy 757 Operative treatment of ununited fracture of neck of 835
- Fetus Postconception pelvic irradiation of Albino rat (mus Norvegicus) its effect upon the offspring 861
- Fibroleiomyoma Four rare rectal tumors intrarectal solid teratoma parafinoma and chordoblastoma 762
- Fingers Rupture of tendons of hand with study of extensor tendon insertions in fingers 611
- Foot Bifid os calcis 1012 Spontaneous fracture of os calcis bilateral osteo arthropathies in tabetic patient 1014

- Forssell Some factors influencing permanent healing of malignant tumors ed 204
 Fractures Oration on 193 Spontaneous of os calcis bilateral osteoarthropathies in tabetic patient 104
 Fungi yeast like Localized infection caused by with special reference to spinal involvement 972

GALLBLADDER Effect of cholecystenterostomy on biliary tract 40 Cholelithiasis in Korean 51 Duodenal and gastric ulcer cholecystitis and appendicitis a consideration of their pathological relations 59 Cholecystitis a bacteriologic and experimental study of three hundred surgically resected 655 Local anasthesia in abdominal surgery 879 Relation of hepatitis to chronic cholecystitis 959

The Gynecology of Mercatus 924

The Clinical Cases of Amatus Lusitanus 1048

Omentum Mechanism controlling migration of 321

Absorption and transference of particulate material by great 851

Prolapse of intestine through preformed opening in great 899

Operating room equipment How can we determine efficiency of surgical mask 266

How can we insure sterility of catgut 271

Operations—

Albee Operative treatment of ununited fracture of neck of femur 885

Lorenz Bifurcation operation indications technique and results 90

Polya Operation for carcinoma of sigmoid 733

Trendelenburg Operative treatment of embolism of lungs 891

Voelcker Technique of Voelcker extrapontonealization of the urinary bladder with illustrative cases 69

Os calcis Bifid 1012

Spontaneous fracture of bilateral osteo-arthritis in diabetic patient 1014

Osmosis and permeability Absorption and transference of particulate material by great omentum 851

Ovary Morphological similarity of certain luteal cysts and endometriosis of 1

Radiology as complete or partial substitute for surgery in treatment of cancer of female pelvic organs 173

Preconception ovarian irradiation its influence upon descendants of Albino rat (mus Norvegicus) 588

Pseudomucinous cystadenoma analysis of thirty cases in which cysts were not ruptured before operation 752

Postconception pelvic irradiation of Albino rat (mus Norvegicus) effect upon offspring 891

Implantation malignancy of abdominal wall 907

PAIN Alcohol injections for postoperative in thoracic surgery 74

Surgical treatment of acute intestinal obstruction 184

Palsy Flexor plasty of thumb in thenar palsy 1005

Pancoast Joseph 921

Pancreas Annular 533

Pancreatic secretion Reflux of and duodenal secretions through a drainage tube in common bile duct 627

Paraffinoma Four rare rectal tumors intrarectal solid teratoma fibroleiomyoma and chordoblastoma 765

- Parathyroid gland Bone changes in hyperparathyroidism, 783
- Pelvic floor, Warren apron in repair of high laceration of rectum associated with third degree laceration of, 747
- Periodic heal examination Conference on Traumatic Surgery, 316
- Pentoneum Pseudomyxoma peritonei originating from mucocoele of appendix 1023
- Pipendino (pipendino-alkyl benzoates) Clinical experience with new local anesthetic drugs 997
- Pipendyl (pipendyl benzoates) Clinical experience with new local anesthetic drugs 997
- Placenta praevia Present day treatment of 113
- Pneumonia Postoperative pulmonary complications and bronchial obstruction postoperative bronchitis atelectasis (pneumatoxis) and pneumonitis considered as phases of same syndrome 795
- Pneumoperitoneum Formes frustes type of perforated peptic ulcer 10
- Pregnancy Micromelia in child irradiated in utero 79 Present day treatment of placenta praevia 113 Sedimentation test in pregnancy and in puerperium study of five hundred forty patients 429 Effect of serum from pregnant women on estrual cycle of guinea pig preliminary report upon possibility of its use as test for pregnancy 435 Post radiation pregnancy report of case 492 Increased tolerance of pregnant rabbits for insulin 586 Preconception ovarian irradiation its influence upon descendants of Albino rat (mus Norvegicus) 588 Postconception pelvic irradiation of Albino rat (mus Norvegicus) its effect upon offspring 861 Physiological anemia of pregnancy study of one thousand patients 954
- Procaine Anesthesia ed 117
- Prostate Suprapubic prostatectomy with closure 251 Circulatory complications of prostatectomy 864
- Puerperium Sedimentation test in pregnancy and in puerperium study of five hundred forty patients 429
- RACE** Influence on infections Cholelithiasis in Korean 51
- Race and malignancy Incidence of cancer among Indians in Southwest 196
- Radiology as complete or partial substitute for surgery in treatment of cancer of female pelvic organs 173
- Radium therapy Micromelia in child irradiated in utero 79 in treatment of cancer of vulva 110 Preconception ovarian irradiation its influence upon descendants of Albino rat (mus Norvegicus) 588 Postconception pelvic irradiation of Albino rat (mus Norvegicus) its effect upon offspring 861 Some factors influencing permanent healing of malignant tumors ed 1041
- Ravenswood Hospital—staff conference demonstration 367
- Rectum Warren apron in repair of high laceration of associated with third degree laceration of pelvic floor 741 Four rare tumors of intrarectal solid teratoma fibrosarcoma parafibroma and chordoblastoma 702
- Rehabilitation Three score and ten ed 774
- Respiration Redistribution of following paralysis of hemidiaphragm 929
- Respiratory tract infections Relation between infections of upper and infections of kidney ed 503
- Reticulo-endothelial system Hemolytic icterus and technique of splenectomy, 606
- Rhinoplasty Reconstruction of external ear 601
- Roentgenography Use of iodized oil (lipiodol and iodipin) in diagnosis of joint lesions 888
- Roentgen ray therapy Micromelia in child irradiated in utero 79, Radium therapy in treatment of cancer of vulva 110 Postradiation pregnancy report of case 492, Preconception ovarian irradiation its influence upon descendants of Albino rat (mus Norvegicus) 588 Postconception pelvic irradiation of Albino rat (mus Norvegicus), effect on offspring 861 Some factors influencing permanent healing of malignant tumors ed 1041
- Royle Speculations on control of intestinal function ed 643
- SALPINGITIS** Pseudotuberculous 663
- Science Medical revolution study in humanization of 302
- Sedimentation test in pregnancy and in puerperium study of five hundred forty patients 429
- Sepsis Theory and practice of intra uterine charcoal treatment in gynecology and obstetrics 873
- Shippen William Jr 120
- Shoulder Arthrodesis of shoulder by means of osteopen osteal grafts 468
- Sick The American Hospital ed 1039
- Sigmoid Operation for carcinoma of 733
- Skin defects of Sieve graft for covering 1018
- Skin grafting Use of ultraviolet light in preparation of infected granulation tissue for value of very thick Thiersch grafts 478, Implantation method of 634
- Sodium amylal (sodium iso-amyl-ethyl barbiturate) Experiences with as intravenous anesthetic, 828
- Sodium iso-amyl-ethyl Anesthesia ed 117
- Spine An extension frame for reduction of fracture of vertebral body 101 Localized infection caused by yeast like fungi with special reference to spinal involvement 972
- Spleen Some principles in abdominal surgery 129 Hemolytic icterus and technique of splenectomy 606 Local anaesthesia in abdominal surgery 879
- Splenectomy Hemolytic icterus and technique of 606 Sterilization How can we insure sterility of catgut 271
- Stomach Formes frustes type of perforated peptic ulcer 10 Duodenal and gastric ulcer cholecystitis and appendicitis consideration of their pathological relations 59 Anomalous consideration of ulcer bearing area (lesser curvature of stomach pylorus and first part of duodenum) 416 Abdominal technique 595 Item of operative exposures 455 Chronic duodenal ulcer 745 Local anesthesia in abdominal surgery 879 Carcinoma of small bowel 939 Sarcoma of 948 Total gastrectomy with report of successful case 1008
- Sublingual gland Mixed tumors of tongue and 407
- Suprarenals Report of case of paroxysmal hypertension cured by removal of adrenal tumor 160
- Surgeon Industrial Conference on Traumatic Surgery 312 314 316 339
- Surgery Gynecology and Obstetrics 285
- Surgery in Medical Department of United States Army 289
- Surgery abdominal system of operative exposures 455 Local anesthesia in 879
- Surgery Industrial Conference on Traumatic Surgery 310-349
- Surgery plastic Reconstruction of external ear 601, Implantation method of skin grafting 634 Flexor plasty of thumb in thenar palsy 1005 Sieve graft stable transplant for covering large skin defects 1018
- Surgery Postoperative complications Reflux of pancreatic and duodenal secretions through drainage tube in common bile duct 627 pulmonary and bronchial obstruction, postoperative bronchitis atelectasis

- (apneumotosis) and pneumonitis considered as phases of same syndrome 795
 Surgery technique Some principles in abdominal 129
 Original method of closure of partially apertoneal or short intestinal end 1037
 Surgery Traumatic Conference on 310-349
 Surgery urinary Value of indwelling ureteral catheters in 441
 Surgical practice Hospital and surgical practice ed 281
 Sympathectomy Surgical indications for sympathetic ganglionectomy and trunk resection in treatment of chronic arthritis 204 Peri arterial in circulatory disorders of extremities report of cases 426

TABES Spontaneous fractures of os calcis bilateral osteo arthropathies in tabetic patient 1014

Tait Lawson ed 914

Tendon Hamangioma of and tendon sheath 397 Rupture of hand with study of extensor insertions in fingers 611

Tendon sheath Hamangioma of 397

Tenoplasty Rupture of tendons of hand with study of extensor tendon insertions in fingers 611

Tenosynovitis Rupture of tendons of hand with study of extensor tendon insertions in fingers 611

Teratoma Four rare rectal tumors—intra-rectal solid fibroliomyoma paraffinoma and chordoblastoma 762

Test Effect of serum from pregnant women on oestral cycle of guinea pig preliminary report upon possibility of its use for test for pregnancy 435

Thiersch grafts Use of ultraviolet light in preparation of infected granulation tissue for skin grafting value of very thick 478

Thorax Alcohol injections for postoperative pain in surgery of 74 Dangers involved in operation of thoracoplasty for pulmonary tuberculosis 146

Three Score and ten ed 774

Thumb Flexor plasty of in the nary paby 1005

Thyroid gland Undiagnosed hyperthyroidism ed 118
 Hyperthyroidism associated with cardiac disorders 139 Laws of cell growth 163 Technique for subtotal thyroidectomy in exophthalmic goiter 1001

Thrombophlebitis Injection treatment of varicose veins 545

Thyroidectomy Technique of subtotal in exophthalmic goiter 1001

Tongue Mixed tumors of and sublingual gland 407

Tonsils and some experience of their surgical treatment 167

Toxemia of pregnancy Increased tolerance of pregnant rabbits for insulin 585

Transportation of injured Conference on Traumatic surgery 322

Traumatism Conference on Traumatic Surgery 329

Tuberculosis Right paraduodenal hernia and isolated hyperplastic tuberculous obstruction comment and report of case affecting jejunum and ileum operation and recovery 29 Dangers involved in operation of thoracoplasty for pulmonary 146 of kidney Value of

indwelling ureteral catheters in urinary surgery 441
 Operation for of epididymus 624 pulmonary Redistribution of respiration following paralysis of hemi diaphragm 929, Localized infection caused by yeast like fungi with special reference to spinal involvement 972 Culture of tubercle bacilli from urine report of one thousand two hundred cultures 933

Tumor Liposarcoma of mammary gland 81 Sacrococcygeal teratomata with malignant degeneration in childhood 83 Chondrosarcoma of bone 216 Hamangioma of tendon and tendon sheath 397 Mixed of tongue and sublingual gland 407 dermoid Implantation malignancy of abdominal wall 907 Hamangioma of uterus 990 tuberculoma Solitary of bladder 1015 Pseudomyoma peritoneal originating from mucocoele of appendix 1023 malignant Some factors influencing permanent healing of ed 1041

ULCEr Formes frustes type of perforated peptic 10
 Anatomical consideration of ulcer bearing area (lesser curvature of stomach pylorus and first part of duodenum) 416 Implantation method of skin grafting 634

Ultraviolet light Use of in preparation of infected granulation tissue for skin grafting value of very thick Thiersch grafts 478

Umbilicus Implantation malignancy of abdominal wall 907

Ureter Primary carcinoma of report of case and review of literature 17 Stone in 106 Value of indwelling ureteral catheters in urinary surgery 441 Heminephrectomy or resection of part of kidney report of four cases 473

Urethra Ruptured operation for 105 Rupture of report of twelve cases 639

Urine Culture of tubercle bacilli from report of one thousand two hundred cultures 935

Uterus Morphological similarity of certain luteal cysts and endometriosis of ovary 1 Radiology as complete or partial substitute for surgery in treatment of cancer of female pelvic organs 173 Recognition of early cervical cancer 200 Inquiry into basic cause and nature of cervical cancer pathology of cervix (erosion of cervix) and relation between cervicitis and cervical cancer 513 688 Technique of ventrofixation of 599 Total versus subtotal abdominal hysterectomy ed 644 Hamangioma of 990

VAGINA Radiology as complete or partial substitute for surgery in treatment of cancer of female pelvic organs 173

Varicose veins Injection treatment of 545

Veronal Luminal and new concept of anesthesia ed 775

Vulva Radium therapy in treatment of cancer of 110

WARREN apron in repair of high laceration of rectum associated with third degree laceration of pelvic floor 741
